This paper attempts to provide analytical tools to facilitate the analysis and design of a class of radial flux PM synchronous machines (fig. 1). The developed model gives exact field distribution due to permanent magnet source in the slots region (radial slots), the airgap region and the PM's region. The developed model embraces both internal and external rotor topologies (figure 1). Most of developed models do not take into account slotting in an explicit manner [1], [2]. In [3], authors presented an exact analytical description of magnetic field in idealized surface mounted permanent magnet structures which does take into account stator slotting. However, the developed model was limited to machines with integer number of slots per pole per phase. The proposed model, in this paper, is more general and can be used for machines with fractional numbers of slots per pole per phase. In [4], authors presented a model which does take into account stator slotting for an axial flux synchronous machine.

II. MAGNETIC FIELD CREATED BY PERMANENT MAGNETS

Figure 2 shows different regions (slots (I), airgap (II), permanent magnets (III), region under magnets (IV)) where the exact analytical solution is established. Region IV is only considered in case of a non-magnetic permanent magnets supporting armature. Permeability of all ferromagnetic parts is assumed to be infinite. The permeability of permanent magnets is assumed to be equal to that of air.

The governing field equations, in terms of the Coulomb gauge, $\nabla \times \mathbf{A} = 0$, are:

$$\begin{cases} \nabla^2 \mathbf{A} = 0, & \text{in regions I, II and IV} \\ \nabla^2 \mathbf{A} = -\mu_0 \nabla \times \mathbf{M}, & \text{in region III} \end{cases} \quad (1)$$

\mathbf{A} only has A_z component which is independent of z (infinitely long machine in axial direction). \mathbf{M} is the magnetization.

Combining equations (1) with boundary conditions, and using separation of variables method, help establish a set of linear equations ($N_H \times N_H$) (where N_H is the number of considered harmonics), where coefficients of magnetic vector potential solution in region III are the unknown. Solving these linear equations and using interface conditions give coefficients of magnetic vector potential in other regions.

Fig. 1. Radial-field PM machines topologies: internal rotor (a) and external rotor (b).

Fig. 2. Polar coordinates system (quasi-Halbach magnets distribution).

Obtained linear equations are solved using Gaussian elimination method. The developed model takes into account rotor movement helping the authors to calculate global quantities such as electromotive force and cogging torque.

III. COMPARISON WITH FINITE ELEMENT ANALYSIS

Figure 3 shows comparisons of flux density components space distribution in the different regions. Table I gives some characteristics of the machine to which both methods (analytical technique and finite element) have been applied. Finite element method has been applied to real geometry of the machine with a relative permeability of $1e6$ for stator core. As seen, the predictions from analytical model are in good agreement with finite element calculations.

Oscillations in the analytical prediction in figure 3.c (radial component B_r) are due to the finite number of terms in the Fourier series ($N_H = 40$). Numerical problems occur in estimation of analytical solution for a number of harmonics $N_H > 40$.

TABLE I – MACHINE'S PARAMETERS

Pole number	6
Slot number	18
Magnets distribution	Quasi-Halbach
R_0, R_1, R_2 and R_3 (mm)	50, 58, 60 and 84
w (rad)	$\pi / 18$

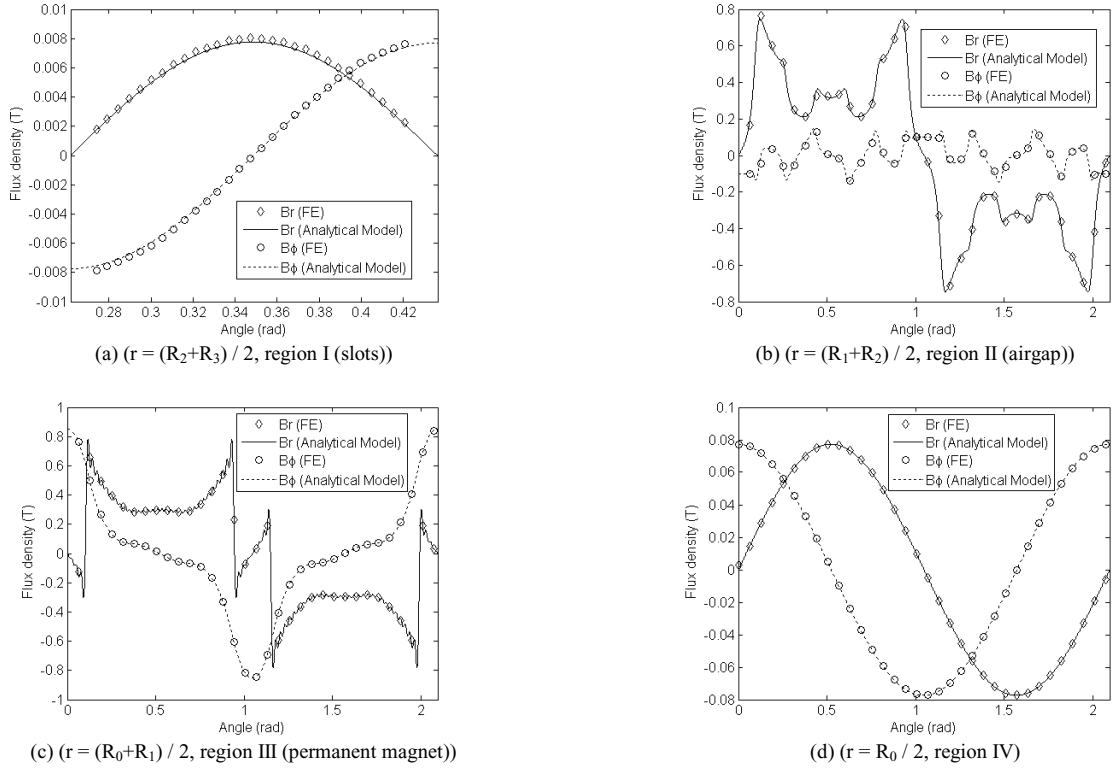

Fig. 3. Comparison of field distribution by both finite element and analytical model (machine with quasi-Halbach magnets distribution and a non-magnetic PM supporting armature).

Indeed, analytical solutions agree extremely well with the finite element results. The analytical model can then be used to estimate and analyze open circuit performance (cogging torque, induced back electromotive force, airgap radial forces distribution) of surface mounted permanent magnet synchronous machines. Cogging torque is estimated using Maxwell stress tensor and E.M.F. is calculated by differentiating magnetic flux passing through a given phase. Induced back electromotive force can be estimated for numerous types of windings distributions (integer or fractional slot number per pole per phase, overlapping or non overlapping windings distributions). Figure 4 compares cogging torque waveforms obtained by both finite elements and analytical model. Cogging torque is computed using Maxwell stress tensor on the PM's surface.

In the full paper, analytical solutions for other machine topologies (magnetic rotor yoke, external rotor topologies) will be compared to corresponding finite element calculations.

IV. CONCLUSION

This paper presents a general analytical model for the analysis and design of a class of surface mounted permanent magnet synchronous machines. The model is developed in the slots, the airgap and the PM's region and its accuracy has been validated by finite element analyses.

In the full paper, the mathematical approach leading to the exact solutions of Maxwell's equations in the different regions will be detailed. Results from other machine topologies will be compared to corresponding finite element calculations.

The developed model will be used to estimate and analyze open circuit performance (cogging torque, induced

Quasistatic Electromagnetic Field Computation by Conformal Mapping in Permanent Magnet Synchronous Machines

Martin Hafner, David Franck and Kay Hameyer
Institute of Electrical Machines – RWTH Aachen University
Schinkelstraße 4, D-52062 Aachen, Germany

E-mail: Martin.Hafner@IEM.RWTH-Aachen.de, David.Franck@IEM.RWTH-Aachen.de

Abstract—In the design of modern servo drives or electrical drives for positioning, torque pulsation, tangential forces and ripple torque are highly undesirable effects. These quantities are directly linked with the occurring harmonic air gap flux density waves. This paper presents a time-effective method to compute the radial and tangential field components in load and no-load condition by conformal mapping in frequency domain. The proposed method is applied to a surface permanent magnet synchronous machine, and compared to numeric results obtained by nonlinear FEA. The analytical results are in good agreement to the finite element simulations.

I. INTRODUCTION

Nowadays the design of electric machines is accomplished by virtual prototyping to short time-to-market. Since finite element analysis (FEA) is time consuming and requires a high computational effort, analytic models are applied that are focused on an estimation of the fundamental air gap flux density. Consequently, the effect of air gap field harmonics on the main machine characteristics, like EMF, cogging-torque and load-torque, as well as the impact of geometry variations on those quantities are neglected. In this paper, an analytic conformal mapping method in frequency domain for permanent magnet synchronous machines (PMSM) is applied to consider the occurring air gap field harmonics for torque and EMF computation. Even if that approach attributes infinite permeability characteristics, a comparison with standard nonlinear FEA shows that it nevertheless gives a good approximation of the air gap flux density spectrum and all derived quantities.

II. COMPUTATIONAL FRAMEWORK

A. Rotor Field Distribution in the Slotless Stator

The analytical technique for computing the 2D magnetic no-load field distribution in the air gap of radial-magnetized permanent magnet rotors has been published by [1]. The derived parametric field solution is applicable for internal and external rotors. In further researches the approach has been generalized to radial and parallel magnetizations, [2]. Recently, [3] published a further extension to radial sine and sinusoidal direction magnetizations. In case of a slotless stator, the radial flux density $B_r(\Theta)$ and the tangential flux density $B_\varphi(\Theta)$ are given by

$$B_r(\Theta) + jB_\varphi(\Theta) = \sum_{n=0}^{\infty} (B_{r,n} + jB_{\varphi,n}) e^{jnp\Theta} \quad (1)$$

where n is the frequency order, p the number of pole pairs, Θ the mechanical angle. The Fourier coefficients $B_{r,n}$ and $B_{\varphi,n}$ represent the solution of the linear Laplace problem with magnets and a slotless stator.

B. Rotor Field Distribution in the Slotted Stator

Stator slotting significantly influences the magnetic field distribution:

- 1) Different radial magnetic permeances of teeth and slot affects the local distribution of the flux in the air gap, so that a flux concentration beneath the stator teeth can be observed.
- 2) In case of slotting, a characteristic peak of the flux density can be observed over the PM vertices in the air gap.
- 3) Slotting mixes up radial and tangential components, as shown by $B_\varphi\lambda_\varphi$ and $B_r\lambda_\varphi$ in (2).

A common method for modeling these effects on the magnetic field distribution are known as "permeance functions" in literature. In a former research, [4] models the impact of effect 1) on the radial flux density component only. The recent publication [5] derives by four complex conformal mappings, including a Schwarz-Christoffel transformation, a permeance function which takes the effects 1) - 3) into account. Assuming a infinite permeable stator core, this ansatz has shown to yield identical flux density results in comparison to FE simulation applying Neumann boundary conditions.

For that approach, the conformal transformations are used to transform slotted stator geometry into a slottless stator, where the Laplace equation for the air gap field can be solved analytically. By this, the impact of slotting on the field distribution keeps considered. Correlating the field distribution with slotting sB to the field without slotting (1) yields the complex permeance $\underline{\lambda}$,

$${}^sB(\Theta) = (B_r + jB_\varphi)\underline{\lambda}^* \quad (2)$$

which describes the individual characteristic of the slotting on the field.

Even if the Laplace equation can be solved analytically, the combined governing equations can not be solved directly. Therefore the local-dependent complex permeance number is evaluated numerically in a nonlinear iterative solution. At each point of an equidistant sampled arc in the air gap with the length of one slot pitch, the complex permeance number, that fulfills (2), is evaluated

$$\underline{\lambda} = \lambda_r + j\lambda_\varphi \quad (3)$$

where λ_r and λ_φ represent the permeance variations in radial and tangential direction. The sampling points of the slot pitch can be expressed by a Fourier-Series and extended to the whole

air gap, yielding,

$$\underline{\lambda}(\Theta) = \sum_0^{N_\lambda} \lambda_{r,n} \cos(nN_s\Theta) + j \sum_1^{N_\lambda} \lambda_{\varphi,n} \sin(nN_s\Theta) \quad (4)$$

where N_s is the number of stator teeth and N_λ the sampling rate depending maximal occurring frequency.

C. Armature winding field

The magnetic field distribution of a current in a single slot, assuming a infinite slot depth and a infinite permeability in a slotless stator, can be obtained by three conformal mappings [6]. Since coils occupy two slots with opposite directed currents, a flux density distribution ${}^c B$ for the whole air gap per coil can be assembled in functions of the coil current I_c and the number coil turns N by

$${}^c B(\Theta, N, I_c) = NI_c \sum_1^{N_a} ({}^c B_{r,n} + j {}^c B_{\varphi,n}) e^{jn\Theta} \quad (5)$$

where N_a denotes the maximal frequency order and the radial and tangential quantities ${}^c B_{r,n}$ and ${}^c B_{\varphi,n}$ the Fourier coefficients of the coil computed for one ampere. According to the winding schema of the PMSM a flux distribution ${}^p B$ for all phases can be found by adding shifted terms of (5). In case of a symmetric current load (UVW) I , the allover armature field ${}^a B$ is given by

$${}^a B(\Theta, I) = ({}^p B_U, {}^p B_V, {}^p B_W) \cdot \left(e^{j\phi_q}, e^{j(\phi_q+120^\circ)}, e^{j(\phi_q+240^\circ)} \right)^T \quad (6)$$

where the angle ϕ_q defines the relative phase orientation to the quadrature axis of the machine.

D. Field Distribution in the Slotted Air Gap

The magnetic air gap field in case of stator slotting can be assumed as a superposition of the field component fields due to permanent magnet and stator excitation.

Introducing a time-discretization Δ_{FE} and a corresponding time-stepping n_{FE} , the rotor flux distribution gives,

$${}^s B^t(f) = {}^s \underline{B}(\Theta) e^{j\omega \cdot \frac{n \cdot n_{FE}}{N_{el} \cdot p}} \quad (7)$$

where n is the rotor speed and N_{el} the number of computation steps per electric period. The corresponding time-depend armature field is frequency-shifted by the stator frequency f_1 , yielding

$${}^a B^t(f, I) = {}^a \underline{B}(\Theta, I) e^{j2\pi f_1 t} e^{j\omega n_{FE} \cdot \frac{n \cdot n_{FE}}{N_{el} \cdot p}} \quad (8)$$

For a given time step t (7) and (8) represent the allover load and no-load flux density distribution in the slotted air gap.

III. APPLICATION

To demonstrate the proposed method, a PMSM, designed by in-house sizing software is investigated. Its cross-section together with the field distribution in rated operation is given in fig. 2(a). The FEA flux density is sampled in the air gap for each time step individually. The spectrum for a certain time instance obtained numerically and by (7), (8) is shown in Fig. 1(b); the corresponding local flux distribution for a pole pitch is given in 1(a). The resulting torque according to Maxwell stress tensor for both magnetic fields are given in fig. 2(b).

(a) Local field distribution of PMSM (b) Flux density amplitude for different order.

(a) Six pole PMSM with field lines in rated operation. (b) Torque characteristic over electric period.

Fig. 2. PMSM cross section and torque characteristic over an electric period by FEA and conf. mapping in rated operation.

IV. CONCLUSION

Electromagnetic field computations are ubiquitous in the design of electrical machines. Even if established finite-element methods yield very accurate result, their high computational effort inhibits an application in early design stages or multi-object optimizations of electrical drives. In that case, it is worth to seek for approximative and time-saving representations. In this paper, the air gap field of a PMSM under load and no-load is computed by conformal mapping in frequency domain. A first demonstration on a PMSM shows, that the obtained occurring harmonic air gap flux waves under load condition are in good agreement to nonlinear FEA results. A detailed comparison in different load conditions between the proposed method and standard simulation will be presented in the full paper submission.

Abstract— This paper presents an accurate method to calculate the main inductances associated to InterCell Transformers (ICTs) in order to facilitate the transformer design. In this application the leakage inductance is a key parameter which theoretically requires 3D Finite Element simulation. We show in this paper that a very good estimation can be found using only two 2D FEM simulations: one related to the field contained inside the core window and the other related to the field outside. In the final paper, results obtained for various sizes and shapes of ICTs will be compared to the values measured on actual devices.

I. INTRODUCTION

One of the main goals in power electronics is the increase of power density in converters. The use of interleaved converters is especially interesting since they increase the apparent frequency of the voltage applied across the filters. They also improve the dynamic behavior of the converter. A traditional interleaved converter consists of several identical commutation cells with the outputs interconnected through separate inductors as shown in Fig. 1.

Fig. 1. Traditional interleaved converter

The association of these inductors may result in large ripple in the current flowing in each cell [1]. This leads to high conduction losses in the switches and high copper losses in the inductors. In order to reduce these problems, coupling the inductors allows obtaining the same relative current ripple in the commutation cells and at the output. This is obtained by the use of intercell transformers [2-4]. In such devices, the ripple of the output current i_o is a function of the leakage inductance. For this reason, predicting the current ripple, the AC losses, the voltage ripple, the saturation current and many other crucial parameters requires an accurate prediction of the leakage inductance. An analytic formulation of the field distribution inside the window is easily obtained under the assumption that the window is rectangular and its depth is infinite. However, practical components are far from this assumption, and the field outside the window (which cannot be easily modeled) has a very significant contribution to the overall leakage inductance.

II. MAGNETIC MODEL OF SIMPLE INTERCELL TRANSFORMERS

Let's analyze the operation of intercell transformers by taking as an example the transformer on Fig. 2. In this transformer, each winding is connected to a commutation cell in such a way that the fluxes from both legs (Φ_1 and Φ_2) are obliged to pass by the air (leakage flux).

Fig. 2. Physical aspect of a simple intercell transformer

If we use the transformer of Fig. 2 in an interleaved converter composed of 2 commutation cells, and supposing that output voltage is filtered (which is usually the case), we can note that the voltage across each winding is rectangular. Consequently, a triangular flux is imposed in each leg of the transformer. We may calculate the reluctance of the core (R_{mag}) of this simple transformer by using the average magnetic path length of the core, its cross-section and the average permeability of the magnetic path (calculated for gapped and ungapped cores).

A. Low Permeability Cores Used in Intercell Transformers

Usually high permeability cores are used in the construction of intercell transformers in order to minimize magnetizing current. However, in certain applications it is preferable to use low permeability cores if we take into account cost, size and loss density when designing the transformer.

In an intercell transformer, if a low permeability core is used, the core reluctance is comparable to the leakage reluctance. In this case, the current in each cell will be the sum of the magnetizing current (of which fundamental frequency is equal to the switching frequency) and the "coupled" ripple (of which fundamental frequency is equal to the double of the switching frequency).

III. FEM SIMULATION TO FIND LEAKAGE RELUCTANCE

In order to determine the current in each cell, the leakage reluctances must be found. It may be done analytically [5-7] or by the use of finite-elements methods. Although analytical methods allow speeding up the optimization process of transformer design, they are restricted to particular geometries.

The use of 3D FEM simulation may result in accurate calculation of the leakage inductance, but it is very time

consuming. 2D FEM simulation can be considered [8] if the procedure used in the simulation takes into account 3D effects.

This work presents a simple procedure that allows the calculation of the leakage inductance and reluctance of intercell transformers, based on 2D FEM simulations.

This procedure relies on the calculation of 2 linear inductances (inductance per unit of length): one related to the part of the winding inside the core window and the other one to the outside. For a better understanding of this model, let's consider the transformer of Fig. 2. First, we simulate a frontal cut of this transformer only with the conductors inside the core window, as shown in Fig. 3a. Like this, we can calculate the linear inductance (L_{leakin} , H/m) related to the volume inside the core window. Then, a second simulation is needed. We simulate a frontal cut of this transformer only with the conductors outside the core window, as shown in Fig. 3b. Thus we can calculate the linear inductance ($L_{leakout}$, H/m) related to the volume outside the core window.

To calculate the total leakage inductance, we use the following equation:

$$L_{leak} = L_{leakin}d_{in} + L_{leakout}d_{out} \quad (2)$$

where d_{in} is the average turn length inside the core window and d_{out} is the average turn length outside the core window.

The calculation of the leakage reluctance is simply:

$$R_{leak} = N^2 / L_{leak} \quad (3)$$

where N is the number of turns in each winding.

a) intercell transformer with the conductors inside the core window

b) intercell transformer with the conductors outside the core window

Fig. 2. FEMM simulation of intercell transformer (magnetic field intensity)

IV. EXPERIMENTAL RESULTS

A middle power inductor was used to verify the accuracy of the simulation. This inductor has 14 turns in each leg and it is suitable to be used as an intercell transformer. It is made using a Mega Flux magnetic alloy powder core with a relative permeability equal to 40.

Simulations were made using FEMM software, version 4.2. Simulation output graphs are shown in Fig. 3. Results found are shown in Table I. Measurements were made at 15kHz and low flux density.

TABLE I
SIMULATION AND EXPERIMENTAL RESULTS

	Simulation	Measure
$L_{leakout} * d_{out}$ (μH)	55	
$L_{leakin} * d_{in}$ (μH)	3.5	
L_{leak} (μH)	58.5	61.1
L_{mag} (μH)	69	62

Note that there is only 2.6% of difference between the leakage inductance simulated and measured. The magnetizing inductance was also analytically calculated and its value was the same as that found in the simulation.

The procedure shown in section III was also verified in other transformers tested in the laboratory.

V. CONCLUSION

Intercell transformers are used in interleaved converters in order to reduce current ripple in each commutation cell. Low permeability cores may be used in intercell transformers but magnetizing and leakage inductances must be found with the purpose of estimating current ripple. A simple procedure, based on only two 2D FEM simulations, allows the calculation of the leakage inductance and the accuracy in the design of intercell transformers. Experimental results confirm the accuracy of this method for calculating the leakage inductance.

Abstract — We are studying a new analysis method to calculate the shape of ferrofluid spikes. The shape of a ferrofluid is influenced by the magnetic force, surface force, and gravity. Therefore, the electromagnetic field equation is coupled with Navier-Stokes equation employing the MPS and FEM. This paper describes the analysis algorithm of coupled method, and the way to convert particles data for MPS method to elements data for FEM.

I. INTRODUCTION

Recently, a ferrofluid [1] which consist of nano-size magnetic particles and organic solvents is a topic of great interest because of its characteristics [2]. The shape of a ferrofluid is intricately influenced by the magnetic force, surface force, and gravity, and the effective analysis methods to calculate a shape of a ferrofluid have not been proposed.

Under the circumstances, we are studying a new analysis method to calculate the deformation of ferrofluid spikes. In this method, Navier-Stokes equation is solved by the MPS method and magnetic field equation is solved by FEM. Because of the difference between the MPS method data (a group of particles) and FEM data (a group of elements), data conversion is required to couple the MPS method and FEM.

This paper describes the analysis algorithm of coupled method, and the way to convert particles data for MPS method to elements data for FEM.

II. ANALYSIS METHOD

The shape of a ferrofluid is influenced by the magnetic force, surface force, and gravity. Therefore, to analyze the phenomenon, the electromagnetic field Equations (1) is coupled with Navier-Stokes equation (3) as follows. The magnetic force is calculated by Maxwell's stress tensor (2).

$$\text{rot } H = J \quad (1)$$

$$\text{div } B = 0$$

$$T = T_{ij} = \frac{1}{\mu_0} B_i B_j - \frac{1}{2} \delta_{ij} (\mu_0 B^2) \quad (2)$$

H is the magnetic field, J is the current, B is the magnetic flux density, T is Maxwell's stress tensor, μ_0 is the permeability of vacuum.

$$\frac{\partial \psi}{\partial t} = -\frac{1}{\rho} \nabla P + \nu \nabla^2 \psi + f \quad (3)$$

ψ is the flow velocity, ρ is the density, P is the pressure, ν is the kinematic viscosity, f is the external force (gravity, surface tension and magnetic force).

Fig. 1 shows the flowchart of analysis method. Deformation of a ferrofluid is difficult to analyze by conventional fluid

analysis methods such as CDF, FEM and so on. In this method, Navier-Stokes equation is solved by the MPS [3] method

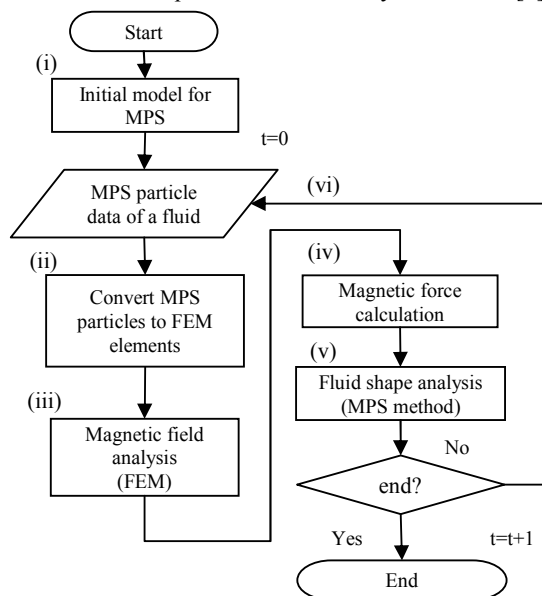

Fig. 1. Flowchart of coupled method

because it is useful to apply large deformed fluid model. On the other hand, magnetic field equation is solved by FEM [4] because it can save CPU time as compared with MPS method. Because of the difference between the MPS method data (a group of particles) and FEM data (a group of elements), data conversion is required to couple the MPS method and FEM.

- (i) Make initial MPS particle data (position, velocity, and pressure of each particle) from shape of a fluid.
- (ii) Convert MPS particles to FEM elements to calculate magnetic field around a fluid (Fig. 2).
- (iii) Calculate magnetic field by FEM.
- (iv) Calculate magnetic force on a particle.
- (v) Calculate shape of a fluid by MPS method.
- (vi) Renew MPS particle data.

The data conversion (Fig. 1 (ii)) is carried out in each analysis step. To calculate motion of a ferrofluid, the data conversion has to be done automatically. This data conversion method adopts the Delaunay partition [5] and Marching Cubes [6].

Fig. 2 shows the flowchart of detail data conversion.

- (i) Create of point data for MPS method.
- (ii) Make boundary faces between a fluid and air region using Marching Cubes.
- (iii) Execute Delaunay partition.
- (iv) Add material conditions.
- (v) Add boundary conditions
- (vi) Produce element data for FEM.

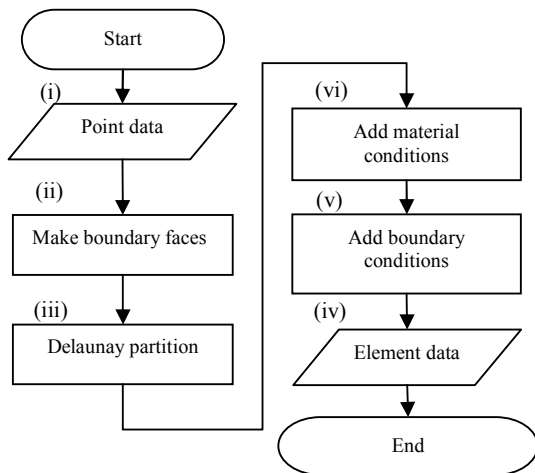

Fig. 2. Flowchart for data conversion of MPS to FEM.

III. ANALYZED MODEL AND DATA CONVERSION RESULTS

Fig. 3 shows the analyzed model of a ferrofluid. It mainly consists of a ferrofluid in a dish and a magnet. A ferrofluid is deformed by magnetic field.

Fig. 4 shows the initial MPS model before deformation. A ferrofluid in a dish is converted into a group of particle. A magnet is omitted to save CPU time. Fig. 5 shows the FEM model converted from MPS model. Table 1 shows the calculated conditions of particle-element conversion.

IV. CONCLUSION

In this paper, the numerical method to calculate the shape of a ferrofluid was proposed by coupling the MPS method with FEM. In the final paper, the effectiveness of this method will be shown through the comparison with the measurement.

Abstract—Isogeometric Analysis (IGA) is a novel discretization method, introduced in [1], which is based on non-uniform rational B-splines (NURBS). Among other features, IGA uses directly the geometry description coming from computer aided desing (CAD) software without approximation, and the analysis is performed using shape functions of variable (possibly high) regularity. In this work we propose a new discretization scheme based on continuous B-splines, adapting the ideas of [1] to the solution of Maxwell's equations. We present extensive numerical results to show that our scheme is free of spurious modes, and that it approximates singular solutions in non-convex domains.

I. INTRODUCTION

In this work we focus on Maxwell's eigenvalue problem: Find $\omega \in \mathbb{R}$ and $\mathbf{u} \in \mathbf{H}_0(\mathbf{curl})$, $\mathbf{u} \neq \mathbf{0}$, satisfying

$$(\mathbf{curl}\mathbf{u}, \mathbf{curl}\mathbf{v}) = \omega^2(\mathbf{u}, \mathbf{v}) \quad \forall \mathbf{v} \in \mathbf{H}_0(\mathbf{curl}), \quad (1)$$

where $\mathbf{H}_0(\mathbf{curl})$ is the space of square integrable functions such that their curl is also square integrable, and their tangential component is zero on the boundary.

It is known that the solution of (1) with nodal finite elements produces an approximation with spurious modes in non-convex geometries. Instead, edge elements provide a solution which is free of spurious modes and that approximates singular solutions in non-convex geometries. However, the electromagnetic fields computed with edge elements are discontinuous, and in recent years some methods have been introduced in order to discretize the equations with continuous finite elements (see, e.g. [2]-[4]).

In [1] the concept of Isogeometric Analysis (IGA) was introduced with the aim of bridging the gap between computer aided design (CAD) and the finite element method. Loosely speaking, in IGA the space of non-uniform rational B-Splines (NURBS) describing the geometry is also used as the space of trial and test functions in the discrete variational formulation: i.e., an isoparametric concept is adopted. The main advantage of this approach is that *the geometry is exactly described at the coarsest level*, and mesh refinement is done without affecting the geometry. Moreover, NURBS basis functions have higher continuity than usual finite elements. Following the ideas of [1], in this work we present a new numerical technique, based on (non-rational) B-splines, for the numerical solution of problem (1) with continuous functions.

II. B-SPLINES SPACES

In one dimension, B-splines basis functions of order m are constructed from an open knot vector

$$\Xi = \{0 = \xi_1 \leq \xi_2 \leq \dots \leq \xi_{n+m} = 1\}, \quad (2)$$

where the *open* nomenclature means that the first and last knots are repeated m times. Using the iterative procedure described in [1], from the knot vector we can construct n B-splines of degree $p = m - 1$. These B-splines are positive piecewise polynomials which form a partition of unity. If a knot appears only once, the B-splines have $p - 1$ continuous derivatives in that knot. The number of continuous derivatives is reduced by one each time we repeat the knot.

In two dimensions the definition of B-splines is easily generalized by tensor products. We consider two knot vectors Ξ_1 and Ξ_2 , that define a mesh in the parametric domain $\Omega_0 = [0, 1] \times [0, 1]$. The B-splines basis functions are then defined as $B_{ij}(x, y) := B_i(x)B_j(y)$, where B_i is constructed from the knot vector Ξ_1 and B_j from Ξ_2 . These B-splines essentially satisfy the same properties we have seen in one dimension. Associating to each of the B-spline basis functions a positive weight we define the NURBS basis functions N_{ij} as in [1]. Then, requiring a control point $\mathbf{C}_{ij} \in \mathbb{R}^2$ for each function we describe our physical domain Ω by a parametrization of the form

$$\begin{aligned} \mathbf{F} : \Omega_0 &\longrightarrow \Omega \\ \mathbf{x} &\longmapsto \mathbf{F}(\mathbf{x}) := \sum_{i,j} N_{ij}(\mathbf{x})\mathbf{C}_{ij}. \end{aligned} \quad (3)$$

This parametrization also maps the mesh in the patch Ω_0 to a mesh in the physical domain Ω . The refinement of the mesh is done as in [1]: new knots are inserted in the knot vectors, but the parametrization (3) remains unchanged. Moreover, our technique can also be extended to the cases where the geometry is more complicated and described by several patches, analogously as it is explained in [1].

III. DISCRETIZATION TECHNIQUE BASED ON B-SPLINES

We now introduce a discretization scheme for problem (1) such that it satisfies de De Rham diagram. Denoting by $S^{p,q}$ the space of B-splines of degree p in the x -direction, and degree q in the y -direction, we will seek our solutions in the space $S^{p-1,p} \times S^{p,p-1}$. We can prove that with this choice the diagram

$$S^{p,p} \xrightarrow{\mathbf{grad}} S^{p-1,p} \times S^{p,p-1} \xrightarrow{\mathbf{curl}} S^{p-1,p-1} \quad (4)$$

9. Numerical Techniques

is satisfied: i.e., $\ker(\text{curl}) = \text{grad}(S^{p,p})$.

In fact, our discretization technique can be understood as a generalization of edge finite elements. As it is well known, edge elements, combined with an adequate choice of nodal finite elements, satisfy a diagram analogous to (4). Moreover, if the knots of the knot vector (2) are repeated exactly p times, our discretization technique in the parametric domain Ω_0 coincides exactly with an approximation by edge elements. The main advantage of our technique respect to edge elements is that it provides smoother solutions, and in particular the electromagnetic fields can be approximated with continuous functions.

IV. NUMERICAL RESULTS

The error analysis of the numerical technique we presented is still being developed. So far, the convergence of the method has been only proved for regular solutions. However, the method has been used to solve several numerical tests and it performed well in all the cases.

A. Test 1: Maxwell eigenvalues in the square

As the first test case we have solved problem (1) in the square. The problem has been solved considering different degrees and continuities for the space of solutions. In every case our solution is free of spurious modes. Note that degree elevation provides better and better convergence rate (see Fig.1) at the price of very few additional degrees of freedom. For instance, passing from $p = 2$ to $p = 3$ we add only $4(N + 2)$ shape functions, where N is the number of subdivisions of the interval $[0, 1]$, while for standard edge elements the increase would be equal to $8N^2 + 4N$. Moreover, our method provides a solution for which the divergence is well defined, and in this test case it tends to zero with good convergence rates.

Figure 1. Convergence rates in the square domain, where h is the mesh size.

B. Test 2: Maxwell eigenvalues in an L-shaped domain

The second test we present concerns the computation of Maxwell eigenvalues in a non-convex geometry, in particular an L-shaped domain. The geometry is described with a single C^1 mapping \mathbf{F} from the square Ω_0 (see Fig. 2). It is known that the first eigenfunction is singular (see [5]), and nodal finite elements fail to approximate it. Instead, our method approximates this eigenfunction correctly, as it is seen in Fig. 3.

Figure 2. L-shaped domain. Coarsest mesh for computations.

Figure 3. L-shaped domain. Approximation of the first eigenfunction.

V. CONCLUSION

We have presented the first numerical results for the isogeometric generalization of edge elements. In particular, our technique: *i*) is adequate for the optimal treatment of complex geometries, *ii*) produces regular fields preserving the optimal convergence rates also towards singular solutions. Finally, the main drawback of this technique is the patchwise tensor product structure. We emphasize that local refinement and non structured meshes can be obtained by adapting the theory of T-splines [6] to IGA. This goes beyond electromagnetic applications and it is object of intense studies.

Abstract—Diffuse Optical Tomography (DOT) has been intensively developed over recent years. It is an imaging technique which aims to recover the optical properties of biological tissue. The image reconstruction problem in DOT is a non-linear ill-posed problem which requires feasible forward model that describe light propagation within the medium accurately. The forward problem in DOT can be modelled in a frequency domain as a diffusion equation with Robin boundary conditions. In case of multilayered geometries the forward problem can be treated as a set of coupled equations. In this paper we present the solution for diffuse light propagation in a four layer concentric spherical model using overlapping or nonoverlapping domain decomposition methods and the Boundary Element Method.

Index Terms—Diffuse Optical Tomography, Domain Decomposition Methods, Boundary Element Method.

I. INTRODUCTION

Diffuse Optical Tomography in medicine aims to recover the optical properties of biological tissue from measurement of the transmitted light made at multiple points on the surface of the body. This boundary data measurements can be used to recover a spatial distribution of internal absorption and scattering coefficients.

The main topic within this field is the development of an efficient and accurate method for calculating the intensity of light transmitted or reflected from the object under experimental investigation. In case of sufficiently high scattering the diffusion equation with Robin boundary conditions [3] is an acceptable model of light propagation. A method we use to solve this problem includes analytical expression based on Green functions [2], and numerical methods based on Finite Difference Method (FDM) or Finite Element Methods (FEM).

In this paper it is assumed that the object being studied is considered as a set of disjoint simply connected regions with constant optical coefficients within each region, but that may differ between regions. In this case the diffusion equation can be replaced by a set of Helmholtz equations for each domain, together with interface conditions. For this problem, analytical solution isn't easily available. Although volume based PDE solvers such as FDM or FEM can be applied to this problem, there are often practical difficulties in constructing meshes for general geometries that respect the interfaces accurately. In contrast, the use of boundary integral methods (e.g. BEM) involve only representation of the surface meshes and can be much easier to implement.

II. FORMULATION OF THE PROBLEM

The problem of Optical Tomography in a highly diffusive body Ω with boundary Γ can be modelled by the use of the diffusion equation in the frequency domain form:

$$-\nabla \cdot \kappa(\mathbf{r}) \nabla \Phi(\mathbf{r}; \omega) + \mu_a(\mathbf{r}) \Phi(\mathbf{r}; \omega) + \frac{(i\omega)}{c} \Phi(\mathbf{r}, \omega) = q(\mathbf{r}; \omega) \quad (1)$$

with Robin boundary conditions:

$$\Phi(\mathbf{m}; \omega) + 2\alpha\kappa(\mathbf{m}) \frac{\partial \Phi(\mathbf{m}; \omega)}{\partial \nu} = h^-(\mathbf{m}; \omega), \quad \mathbf{m} \text{ on } \Gamma \quad (2)$$

where $\omega \in \mathbf{R}^+$ is the frequency modulation, Φ is the radiance c is the velocity of light, q is an internal source of light in medium, h^- is an incoming flux, α is a boundary term which incorporates the refractive index mismatch at the tissue-air boundary, ν is the outward normal at the boundary Γ , κ and μ_a are the diffusion and absorption coefficients, respectively. We define, $\kappa = \frac{1}{3(\mu_a + \mu'_s)}$, where μ'_s is the reduced scattering coefficient [1], [2]. We use the notation \mathbf{r} for a position vector in Ω and \mathbf{m} for a position vector restricted to a surface.

III. INTEGRAL FORMULATION AND NUMERICAL IMPLEMENTATION

The boundary integral formulation makes use of Green's function of the Helmholtz equation, which in the absence of boundary conditions is also referred to as the fundamental solution. We define a Green's function of Eq. (1) in each sub-domain Ω_l as solution of the equations

$$\nabla^2 G_l(\mathbf{r}, \mathbf{r}'; \omega) - \omega_l^2 G_l(\mathbf{r}, \mathbf{r}'; \omega) = -\delta(\mathbf{r} - \mathbf{r}') \quad (3)$$

with the asymptotic $G_l(\mathbf{r}, \mathbf{r}'; \omega)|_{r \rightarrow \infty} = 0$ where $G_l(\mathbf{r}, \mathbf{r}'; \omega)$ is the response of the infinite media to a single source $q_l = \delta$ at position $\mathbf{r} = \mathbf{r}'$. From equations (3) and (1), by multiplying (3) with $\Phi_l(\mathbf{r}; \omega)$ and (1) with $G_l(\mathbf{r}, \mathbf{r}'; \omega)$, and subtracting we get:

$$\begin{aligned} &\Phi_l(\mathbf{r}; \omega) \nabla^2 G_l(\mathbf{r}, \mathbf{r}'; \omega) - G_l(\mathbf{r}, \mathbf{r}'; \omega) \nabla^2 \Phi_l(\mathbf{r}; \omega) = \\ &-\delta(\mathbf{r} - \mathbf{r}') \Phi_l(\mathbf{r}; \omega) + \frac{q_l(\mathbf{r}; \omega)}{\kappa_l} G_l(\mathbf{r}, \mathbf{r}'; \omega) \end{aligned} \quad (4)$$

As far as numerical implementation is considered the surface interfaces Γ_l are discretised in P_l surface elements $\tau_{l,k}; k = 1, \dots, P_l$ with N_l vertices $N_{l,k}; k = 1, \dots, N_l$

after which we can approximate the functions U_l and V_l by the use of nodal basis functions ϕ_k , restricted to Γ_l .

$$\begin{aligned} U_l(\mathbf{m}; \omega) &\simeq \sum_{k'=1}^{N_l} U_{l,k'}(\omega) \phi_{l,k'}(\mathbf{m}), \\ V_l(\mathbf{m}; \omega) &\simeq \sum_{k'=1}^{N_l} V_{l,k'}(\omega) \phi_{l,k'}(\mathbf{m}) \end{aligned} \quad (5)$$

Representation above expresses both U_l and V_l in terms of the complex coefficients $U_{l,k'}$, $V_{l,k'}$ interpolated by the nodal basis functions and thus enforces V_l to be at least C^0 continuous.

The integrals occurring in the Boundary Integral equations take the form:

$$u_l(\mathbf{m}; \omega) = \sum_{k'=1}^{N_l} U_{l,k'}(\omega) \int_{\Gamma_l} \partial_l G_l(\mathbf{m}, \mathbf{m}'; \omega) \phi_{l,k'}(\mathbf{m}') dS(\mathbf{m}') \quad (6)$$

$$v_l(\mathbf{m}; \omega) = \sum_{k'=1}^{N_l} V_{l,k'}(\omega) \int_{\Gamma_l} \partial_l G_l(\mathbf{m}, \mathbf{m}'; \omega) \phi_{l,k'}(\mathbf{m}') dS(\mathbf{m}') \quad (7)$$

Function $v_l(\mathbf{m}; \omega)$, which is obtained by convolution with a Green's function, is known as a *single layer potential*, and function $u_l(\mathbf{m}; \omega)$, which is obtained by convolution with the normal derivative of a Green's function, is known as a *double layer potential*.

IV. THE FOUR LAYER SPHERICAL MODEL

In our research we have taken into consideration a four layer concentric spherical model. The Generalised Minimum Residuals Method (GMRES) was used to solve the linear matrix equation $\mathbf{K}\mathbf{f} = \mathbf{b}$ obtained from BEM. Here, \mathbf{f} is the discrete version of $\{f\}$ and contains approximations in (5), \mathbf{K} is the system matrix, and \mathbf{b} the vector of known coefficients calculated from the light sources in the problem. \mathbf{K} is a block-bounded asymmetric matrix. In order to solve equation of 20000 unknowns it takes up to 50 hours to a 64-bit Athlon processor. Taking advantage of domain decomposition methods [4] as well as BEM we are able to decrease computation time to minutes. BEM is preferable to other methods because it provides in each node not only the value of the state function but its normal derivative as well. In the Fig. 1 we can see the solution of the state function in concentric spherical model.

Fig. 1. The logarithm of amplitude of photon density. The outer surface of the object (left) and its cross-section (right).

Generally, there are two kinds of approaches depending on whether the subdomains overlap (Schwarz methods) or are separated (Schur Complement methods)[5]. The latter are

called substructuring methods and are based on nonoverlapping decompositions of the region into a set of subdomains. The number of equations needed to solve this smaller problem is minor, compared to the whole system. Thus the amount of memory required for allocating the equations is smaller too. In the Fig. 2 a scheme of the Dirichlet-Neumann substructuring algorithm is presented.

Fig. 2. Boundary condition transmission in the Dirichlet-Neumann algorithm.

The results presented in the Fig. 3 are taken from the nodes located on the circumference of adjacent spheres (cross-section with the largest radius). The chart on the bottom right corner shows results with a relative error less than two percent when compared to the solution without use of any decomposition method.

Fig. 3. Results from the Dirichlet-Neumann substructuring algorithm.

In case of overlapping subdomains the decomposition algorithm reduces the number of sequential steps in contrast to the previous one. It is an advantage from standpoint of ill-posed problems which may converge very slow. The main drawback of this approach is the use of greater memory resources as one iteration refers to two regions simultaneously.

Galerkin Projection Method for Sliding Interfaces in Finite Element Analysis of Electrical Machines

Enno Lange, François Henrotte and Kay Hameyer
 Institute of Electrical Machines – RWTH Aachen University
 Schinkelstraße 4, D-52056 Aachen, Germany
 E-mail: Enno.Lange@IEM.RWTH-Aachen.de

Abstract— This paper proposes the application of the Galerkin projection method to implement the relative motion of stator and rotor in the FE simulations of electrical machines. The non-conforming representation of stator and rotor regions impose no restriction on time or space discretization. The symmetry and sparsity of the system of FE equations are preserved. The method is applied to the 2D simulation of the cogging torque of a synchronous machine and the results are compared with a conforming moving band approach with remeshing of the air gap at each time step.

I. INTRODUCTION

SEVERAL approaches to simulate the movement within a Finite Element analysis (FEA) of electrical machines have been developed. Static and transient analysis of the machines require a flexible variation of the rotor position. An obvious and early adopted approach is the moving band (MB) technique [4] whose principle is to re-generate at each time step a single layer of conforming finite elements in a thin annulus-shaped region of the air gap. However, in practical the automatic remeshing of the air gap is only tractable for 2D rotating machines. For linear motion in 2D and motion in 3D models, air gap remeshing would imply invoking a full-fledged automatic mesh generator at each time step, which is impractical. The mortar element method (MEM) was proposed in [8] and applied to a 2D machine problem in [1]. The Lagrange multiplier (LM) method has been extensively investigated in [2]. Both MEM and LM can be extended to 3D problems, but the MEM requires an additional integration mesh [9], and for the LM the conditioning worsens significantly [6].

The non-conforming approach proposed in this paper is based on a mesh-to-mesh Galerkin projection method (GPM) which has been introduced in [5]. While applications described in [7] project a known field from a source to a target mesh, in this paper the GPM is implemented in a standard FE assembly process.

II. PROJECTION METHOD AND FORMULATION

Let $L^2(\Omega)$ be the space of square integrable functions on $\Omega \subset \mathbb{R}^n$, $n = 1, 2, 3$. The scalar product relative to the L^2 -norm of F and G is defined as

$$(F, G)_\Omega = \int_\Omega F(x) \cdot G(x) dx. \quad (1)$$

A field $F^\Omega \in L^2(\Omega)$ can be interpolated in a discrete domain as:

$$F^\Omega = \sum_{i=1}^n f_i \alpha_i^\Omega \quad (2)$$

where α_i^Ω is the shape function associated to the node or edge i and f_i is the corresponding coefficient.

The sliding boundaries of the rotor (master) and the stator (slave) domain are denoted Γ_N and Γ_M respectively. Note that the choice of the master boundary is based on the discretization: The boundary with the largest number of unknowns is chosen as the master boundary. Let $p : \Gamma_N \mapsto \Gamma_M$ be a bijective mapping. Consider the two magnetic vector potential fields $F^N \in L^2(\Gamma_N)$ and $G^M \in L^2(\Gamma_M)$. One wishes to have $\gamma(F^N \circ p^{-1}) = G^M$ on Γ_M and $F^N = \gamma(G^M \circ p)$ on Γ_N with $\gamma = \pm 1$ according to whether the identification between Γ_N and Γ_M is a symmetry (or an identity) or an antisymmetry. This writes in weak form:

$$\int_{\Gamma_M} (\gamma(F^N \circ p^{-1}) - G^M) \alpha_k^M d\Gamma_M = 0, \quad \forall k = 1 \dots m \quad (3)$$

$$\int_{\Gamma_N} (F^N - \gamma(G^M \circ p)) \alpha_k^N d\Gamma_N = 0, \quad \forall k = 1 \dots n \quad (4)$$

It can be shown that (3) and (4) loose their symmetry on the discrete level. Thus, the idea is to use only the projection p and avoid its inverse p^{-1} by applying p to (3) which leads to the following formulation:

$$\int_{\Gamma_N} (\gamma F^N - (G^M \circ p)) (\alpha_k^M \circ p) d\Gamma_N = 0, \quad (5)$$

$$\int_{\Gamma_N} (F^N - \gamma(G^M \circ p)) \alpha_k^N d\Gamma_N = 0. \quad (6)$$

If, after discretization, F^N and G^M are expressed by (2), (5) and (6) can be written in matrix form

$$\begin{bmatrix} \mathbf{A} & -\gamma\mathbf{B} \\ -\gamma\mathbf{C} & \mathbf{D} \end{bmatrix} \begin{bmatrix} \mathbf{g} \\ \mathbf{f} \end{bmatrix} = 0 \quad (7)$$

with the components of \mathbf{A} and \mathbf{D} being:

$$A_{mj} = \int_{\Gamma_N} (\alpha_m^M \circ p) (\alpha_j^M \circ p) d\Gamma_N, \quad (8)$$

$$D_{ni} = \int_{\Gamma_N} \alpha_n^N \alpha_i^N d\Gamma_N. \quad (9)$$

And the components of \mathbf{B} and \mathbf{C} expand to:

$$B_{mi} = \int_{\Gamma_N} \alpha_m^N (\alpha_i^M \circ p) \, d\Gamma_N, \quad (10)$$

$$C_{nj} = \int_{\Gamma_N} (\alpha_n^M \circ p) \alpha_j^N \, d\Gamma_N. \quad (11)$$

Obviously $B_{mi} = C_{jn}$ and the resulting system (7) is symmetric. The GPM can be incorporated into the equation system of any standard Galerkin FE formulation. Furthermore, no restriction regarding the degree or the type of the degrees of freedom are imposed.

III. APPLICATION: COGGING TORQUE

The GPM has been implemented in the *iMOOSE*-package [10]. The cogging torque of a permanent magnet synchronous machine with surface mounted magnets has been studied. The torque is calculated according to Arkkio's method [3]. The numeric field solution is obtained by means of a standard magnetic vector potential FE formulation combined with either the GPM or the MB technique. Despite its non-conformity, the mesh density for GPM, as shown in Fig. 1, is identical to the one for MB. The mapping $p = f(\varphi)$ is the rotation about the center of the rotor by the angle φ . The simulated cogging torques, normalized to the nominal torque T_0 , are compared in Fig 2. Additionally, the relative difference between the GPM and the MB is shown. The GPM has as well been applied to meshes with slightly differing numbers of unknowns n in Γ_N and m in Γ_M ($0.75 < n/m < 1.25$). The results are similar to the ones shown in Fig. 2.

IV. DISCUSSION

Numerical results show a good agreement between the non-conforming GPM and the conforming MB. In general it can be stated, that the torque calculated by the GPM follows a smoother waveform compared to the one of the MB. The higher harmonics in the MB waveform are suspected to stem from the remeshing process. The differences between the GPM and the MB do not follow a certain pattern. Larger differences occur around the maximum as well as around the zero crossing of the torque waveform.

Fig. 2. Cogging torque vs. rotation angle by means of GPM and MB

V. CONCLUSION

This abstract presents a non-conforming method to model the sliding interfaces in electrical machines for FEA. The method is applied to the simulation of the cogging torque of a permanent magnet machine and the results are compared to a classical MB technique. The first results and the straightforward implementation of the GPM compared to MEM or LM approaches for 3D problems promise a flexible and versatile approach to deal with sliding conditions in electrical machines. The application to 3D problems as well as further investigations regarding energy conservation, error estimations, numerical integration and a comparison to measurements will be presented in the full paper.

Abstract— This paper proposes a novel method for the improvement of the convergence to a steady state in time-periodic transient eddy-current analyses with nonlinear magnetic materials. The proposed method, which is based on the time-periodic finite-element method and the singularity decomposition-explicit error correction method, can extract poorly converged error components corresponding to large time constants of an analyzed system. The correction of the extracted error components accelerates the convergence to a steady state efficiently. Some numerical results verify the effectiveness of the proposed method.

I. INTRODUCTION

For the further speed-up of the electromagnetic field computations by the finite-element method (FEM), a fast iterative linear solver for large-scale sparse system of equations such as a multigrid method [1] and a method to stably accelerate the convergence of the Newton-Raphson (NR) method such as a line search technique [2] have been investigated intensively.

On the other hand, to carry out transient eddy-current analyses taking account of nonlinear magnetic properties, a step-by-step calculation is necessary by using time integration methods such as the backward Euler method. As is the often case with finite-element analyses coupled to electric circuit, an extremely large number of time steps are required to attain steady state solutions in the case that the time constant of the analyzed problem is large. The time-periodic FEM (TPFEM) [3] has an advantage that the steady state solution can be obtained directly without transient calculation. However, we have to treat a large-scale nonsymmetric coefficient matrix, which results in the huge computational costs. Therefore, it is indispensable to improve the convergence characteristic of transient calculation as well as that of linear iterative solvers and the NR method for the further reduction of computational costs required for the analysis of practical problems.

As a solution to the above difficulty, we propose a novel method for the improvement of the convergence characteristic of step-by-step time integrations in nonlinear transient eddy-current analyses. The proposed method, which is based on the TPFEM and the singularity decomposition-explicit error correction (SD-EEC) method [4]-[6], can extract poorly converged error components which correspond to large time constants of an analyzed system. The correction of the

extracted error components accelerates the convergence of transient calculation efficiently. The formulations based on the ordinary or half time-periodic boundary condition are presented. Finally, the effectiveness of the proposed method is examined in the finite-element analysis coupled to electric circuit.

II. METHOD OF ANALYSIS

A. Time-periodic finite-element method

A nonlinear system of equations, for example, derived from the $A\text{-}\phi$ formulation in quasi-static field coupled to electric circuit equations, is expressed as follows:

$$S(\mathbf{x}) + C \frac{\partial}{\partial t} \mathbf{x} = \mathbf{f} \quad (1)$$

where \mathbf{x} is the unknown vector, and \mathbf{f} is the right-hand-side vector. The number of unknowns is m . The matrix S is generally nonlinear because of magnetic properties of magnetic materials and the coefficient matrix C is constant.

When one or half period is divided into n time steps and the θ method is adopted for the time integration scheme, the linearized equations of the TPFEM under the ordinary or half time-periodic boundary condition are given by

$$\begin{bmatrix} \tilde{C}_0 + \tilde{S}_1 & O & \cdots & O & \mp \tilde{C}_n \\ -\tilde{C}_1 & \tilde{C}_1 + \tilde{S}_2 & \cdots & O & O \\ O & -\tilde{C}_2 & \ddots & \ddots & \vdots \\ \vdots & \vdots & \ddots & \ddots & O \\ O & O & \cdots & -\tilde{C}_{n-1} & \tilde{C}_{n-1} + \tilde{S}_n \end{bmatrix} \begin{Bmatrix} \Delta \mathbf{x}_1 \\ \vdots \\ \Delta \mathbf{x}_n \end{Bmatrix} = \begin{Bmatrix} -\mathbf{G}_1 \\ \vdots \\ -\mathbf{G}_n \end{Bmatrix}$$

$$\tilde{C}_i = \frac{C}{\Delta t} - (1-\theta)S_i, \tilde{S}_i = (1-\theta)S_{i-1} + \theta S_i, S_i = \frac{\partial S}{\partial \mathbf{x}}(\mathbf{x}_i). \quad (2)$$

Here, the subscripts indicate the time step, $\Delta \mathbf{x}_i$ is the increment of \mathbf{x}_i , \mathbf{G}_i is the residual, the signs $-$ and $+$ of \tilde{C}_n correspond to the ordinary and half time-periodic boundary conditions $\mathbf{x}(t+T) = \pm \mathbf{x}(t)$, respectively, and T is the period.

The solutions obtained from step-by-step calculations of (1) starting with \mathbf{x}_0 as initial value are equivalent to those obtained from (2) by using forward block Gauss-Seidel (GS) method [3]. It's noted that low frequency error components converge slowly in the GS method. Therefore, in the case that the time constant of (1) is significantly large, a large number of time steps are necessary to obtain steady state solutions.

B. Improvement of convergence characteristic of transient calculation based on the SD-EEC method

The following nonlinear system of equations is considered

$$A(\mathbf{x}) = \mathbf{b}, \quad (3)$$

where $A(\mathbf{x})$ is a nonlinear matrix with respect to \mathbf{x} and \mathbf{b} is the right-hand-side vector. The procedure of the SD-EEC method taking into account the nonlinearity of A is as follows:

- (i) Update the approximate solution $\tilde{\mathbf{x}}$ by iterative methods.
- (ii) Compute $\mathbf{r} = B^T(\mathbf{b} - A(\tilde{\mathbf{x}}))$ by using auxiliary matrix B .

Obtain correction vector \mathbf{p} by solving $B^T \frac{\partial A(\tilde{\mathbf{x}})}{\partial \mathbf{x}} B \mathbf{p} = \mathbf{r}$.

- (iii) Update the approximate solution by $\tilde{\mathbf{x}} \leftarrow \tilde{\mathbf{x}} + B\mathbf{p}$

where the superscript T means transpose.

In order to accelerate the convergence of transient calculation, we apply the SD-EEC procedure to (2). The auxiliary matrix B is constructed so as to approximate the dc error component, which corresponds to large time constants and is poorly converged, in a transient calculation as follows:

$$B = [I \quad \dots \quad I \quad \dots \quad I]^T \quad (4)$$

where I is a $m \times m$ identity matrix and B is a $nm \times m$ matrix. The correction vector \mathbf{p} can be obtained by solving the following equation

$$\left(\sum_{i=1}^n \tilde{S}_i + \tilde{C}_0 \mp \tilde{C}_n \right) \mathbf{p} = -\tilde{C}_0(\mathbf{x}_0) \pm \tilde{C}_n(\mathbf{x}_n). \quad (5)$$

The step-by-step calculation is restarted by adopting the corrected solution $\mathbf{x}_n + \mathbf{p}$ as the initial value \mathbf{x}_0 for the next one or half period. Although the procedure of solving (5) is added to the ordinary transient calculation once per one or half period, the additional computational costs are fairly small compared with the total computational costs required for normal step-by-step calculation.

III. NUMERICAL EXAMPLES

The effectiveness of the proposed method is investigated in a nonlinear eddy-current analysis of the iron core model shown in Fig. 1. The exciting coil is wound around the core and excited by a sinusoidal voltage of 100 Hz. The coil turns is 3000, the resistance of the coil is 45.79 Ω , the conductivity of the core is 7.505×10^6 S/m, and the nonlinear magnetic property is the same as mentioned in [7]. Because of the symmetry, one-eighth part of the whole model is analyzed. The number of elements and unknowns are 29250 and 88081, respectively. One period is divided into 20 time steps.

Fig. 2(a) shows the time variation of the coil current in the case that the applied voltage is $1000 \sin(2\pi f t)$ V. In this problem, we can use the correction method based on the half time-periodic boundary condition. Whereas the steady state solution cannot be obtained from the step-by-step calculation in 5 periods, the proposed method accomplishes the convergence of the transient calculation after only two corrections, which results in the drastic reduction of the computational time. Fig. 2(b) shows the time variation of the coil current in the case that the applied voltage is $1000(1 - \cos(2\pi f t))$ V. The correction method based on the ordinary time-periodic boundary condition is applied to this problem. The steady state solution is attained in two periods.

From the above results, the effectiveness of the proposed method can be confirmed. The detailed discussion about the formulation of the proposed method and more numerical results will be included in the full paper.

Abstract — A novel precondition method for edge-based full-wave electromagnetic finite element method is presented. The method utilizes the symmetric block Gauss-Seidel iteration based on an extension of the node patch edges. Numerical results demonstrate an excellent performance for our proposed preconditioner.

I. INTRODUCTION

Edge-based finite element approach to the simulation of arbitrarily shaped 3D complex structures is an efficient and versatile technique for passive electromagnetic analysis. In edge-element analyses, however, the large null space of the coefficient matrices causes difficulties in convergence when iterative solution techniques are applied. Several approaches have been reported to improve this slow convergence performance by preconditioning the original finite element matrix[1][2]. One of the effective approaches exploits the block Jacobi or block Gauss-Seidel iterations as preconditioning with the blocks composed of the edges around every node[3][4]. Our approach extends this ‘node patch’ to a long stencil whose corresponding block becomes a narrow band matrix. The stencil which consists of the long strip of node patches not only contributes to preserve a divergence free nature of the Maxwell’s equations but also improves global convergence, resulting in an excellent convergence property. Numerical experiments support the effectiveness of our approach.

II. FORMULATION

A. Edge-Based Finite Element Formulation

A time harmonic boundary value problem for the vector wave equation is expressed by the electric field vector as follows:

$$\nabla \times \frac{1}{\mu_r} \nabla \times \mathbf{E} + j\omega\mu_0\sigma\mathbf{E} - \omega^2\mu_0\varepsilon_0\varepsilon_r\mathbf{E} = -j\omega\mu_0\mathbf{J}_v \text{ in } \Omega \quad (1)$$

$$\mathbf{E} \times \mathbf{n} = 0 \text{ on } \Gamma_D \quad (2)$$

where Ω is a finite three dimensional domain with a Dirichlet-type boundary Γ_D and outward normal vector \mathbf{n} . $\mu_0, \mu_r, \varepsilon_0, \varepsilon_r, \sigma, \omega$ and \mathbf{J}_v are the magnetic permeability of free space, the relative magnetic permeability, the electric permittivity of free space, the relative electric permittivity, the conductivity, the angle frequency and the impressed volume electric current density, respectively. Using a Galerkin’s testing procedure leads to the following finite element system:

$$\mathbf{M}_{ee} \mathbf{x}_e = -j\omega \mathbf{f}_e \quad (3)$$

where \mathbf{M}_{ee} is the finite element matrix, \mathbf{x}_e denotes the vector of the unknown expansion coefficients of \mathbf{E} and \mathbf{f}_e is the approximation of the source term associated with the impressed current \mathbf{J}_v [5].

B. Symmetric Block Gauss-Seidel Preconditioning

Preconditioning is a means of transforming the original linear system into well-conditioned one with the same solution, but that is likely to be easier to solve with an iterative algorithm. The popular incomplete Cholesky preconditioner, however, normally results in low-order convergence due to the large null space of an edge-based coefficient matrix. High-order convergence may be achieved by a ‘node patch’ defined by edges around a node shown in Fig.1. A symmetric block Gauss-Seidel preconditioning is used in units of the node patch edges defined at every node.

Fig.1 Node-Patch Edges for n1(Dashed Lines)

Symmetric Gauss-Seidel Iteration is given by

```

Input: r; Output: z = M-1r
z=0
for i=1,2,...,p,p-1,...,2,1
  z = z + RiTAi-1Ri(r-Az)
end for
  
```

where \mathbf{M} stands for a precondition matrix and \mathbf{A}_i is a sub-matrix whose elements are chosen according to the edges in the i -th node patch.

III. BLOCK GAUSS-SEIDEL PRECONDITIONER BASED ON A LONG STENCIL OF NODE PATCHES

A. Extended Node Patch for Unstructured Mesh

We extend the definition of the node patch to a long strip stencil depicted in Fig.2, where the extended node patch consists of edges around the nodes $n1, n2, n3$ and $n4$.

Fig.2 Extended Node Patch Edges for n1, n2, n3 and n4 (Dashed Lines)

B. Extended Node Patch for Structured Mesh

As for a structured mesh, the extended node patch can be easily defined similarly. In an analytical space with hexahedral blocks, for example, one of the practical extended node patch definitions is obtained as the set of edges like:

$$\begin{aligned} Xpatch_{ijk} &= \{e \mid e \text{ is originating from } n_{ijk}, i=0, \dots, n_x\}, \\ Ypatch_{ijk} &= \{e \mid e \text{ is originating from } n_{ijk}, j=0, \dots, n_y\} \text{ and} \\ Zpatch_{ijk} &= \{e \mid e \text{ is originating from } n_{ijk}, k=0, \dots, n_z\}, \end{aligned}$$

where e is an edge, n_{ijk} is a node at (i,j,k) , n_x , n_y and n_z are the number of nodes in X, Y and Z direction, respectively. With this definition, the resultant block matrix becomes a narrow block band matrix, which can be quickly factored and solved numerically.

IV. NUMERICAL RESULTS

A. Convergence Behaviors

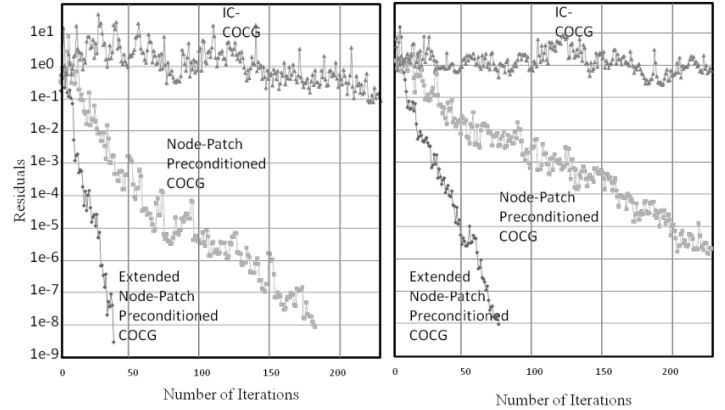

We applied the proposed preconditioning method to the large electromagnetic scattering field depicted in Fig.3. The analysis space is divided into $24 \times 24 \times 24$ cubic elements enclosed by 4-layer perfectly matched layers. Total 92256 unknowns are to be solved in a large, sparse matrix equation preconditioned by the X, Y and Z patches in Fig.3 (b). Current sources as an excitation are located in the center of the space. The convergence profiles in 74MHz and in 148MHz cases are shown in Fig.4. Comparison with the conventional IC-COCC method shows that the excellent convergence property of a normal and an extended node-patch stencil preconditionings.

(a) Analysis Model (b) Extended Node Patches
Fig.3 Overview of the Analysis Model and Stencils

The numerical convergence is measured by the relative

residual defined by $\|\text{current residual}\|/\|\text{initial residual}\|$, in which $\|\bullet\|$ denotes the L2-norm. The iteration process is terminated when it becomes below $10e-8$.

(a) 74MHz (b) 148MHz
Fig.4 Comparisons of the Convergence Behaviors

B. Memory Requirements

The preconditioning method using a normal or extended node patch block iterations requires many number of small size matrix calculations including factorizations and backward and forward substitutions. A normal node patch, for example, requires a 6×6 matrix for each node. The extended node-patches based on our stencil require a long but narrow band matrix, which can be easily factored and solved with the small number of fill-ins. With hexahedral element modeling, the bandwidth is less than that of the original matrix, that means that the method is a very memory-effective preconditioner.

V. CONCLUSION

An efficient and reliable preconditioning method for the edge-based finite element method has been derived, and numerically evaluated. The new preconditioner is based on an extended node-patch symmetric block Gauss-Seidel iteration. The effectiveness in performance and required memory resource has been demonstrated as a preconditioner for the COCC method for a large space electromagnetic scattering problem. The test results serve to validate the method and illustrate the valuable advantages associated with using the newly proposed extended node patch preconditioning procedure for practical 3D electromagnetic scattering analyses.

Abstract — The scattering analysis by method of moments may lead to integral equations with severe singularities in their kernels. In this work we demonstrate that when these singularities are removed by the extraction technique and enough basis functions are used to describe surface current behavior, the numerical solution converges with Z-matrix integrals numerically evaluated using 2-point Gaussian quadrature. The numerical convergence is investigated in the analysis of the electromagnetic scattering by conducting and dielectric spheres.

I. INTRODUCTION

In the analysis of electromagnetic scattering by homogeneous bodies, the numerical evaluation of surface integral equations by the method of moments (MoM) has proved its efficiency to treat surfaces with arbitrary shape. The choice of suitable basis functions to represent the surface currents, the numerical evaluation of singular integrals, and efficient algorithms for the matrix inversion are fundamental to obtain accuracy and convergence from the MoM analysis. However, the numerical evaluation of singularities arising in the integral kernels is not a simple task. In [1] a robust numerical technique (extraction technique) is presented to remove singularities arising in the scattering by conducting bodies of revolution (BOR's). In [2] the method is extended to handle triangular basis functions in a Galerkin scheme.

For homogeneous dielectric BOR's the accuracy of the MoM analysis deteriorates as the dielectric constant increases [3]. In [4] different integral equation formulations are used to overcome this problem, but still with relatively small accuracy. This drawback may be partially overcome by increasing the number of segments used to represent the BOR generatrix, which should be made proportional to the dielectric constant and, consequently, increases the Z-matrix size. In [5] triangular functions for both basis and testing functions were used, simply represented by a series of pulses. It was observed that, to attain certain accuracy, more pulses had to be used to represent the triangular functions as the dielectric constant of the BOR increased. In some sense this leads to the perception that accuracy increases with the number of quadrature points used to evaluate the integrals.

In this work we analyze the plane-wave scattering by conducting and dielectric spheres. We observe that when the extraction technique [2] is applied and a sufficient number of triangular basis functions (TBF's) is used to represent the surface geometry, numerical convergence is attained when 2-point Gaussian quadratures are applied to evaluate the

integrals of the MoM Z-matrix. The accuracy increases if more TBF's are used but does not change with the number of quadrature points.

II. INTEGRAL EQUATION EVALUATION

The MoM solution involving surface electric (EFIE) and magnetic (MFIE) field integral equations leads to many different formulations [3], [6]. The EFIE formulation is the choice for open conducting shells. For closed conducting surfaces the combined field integral equation (CFIE) avoids spurious resonances [6]. The CFIE is a linear combination of EFIE and MFIE. For dielectric bodies, EFIE and MFIE can be linearly combined in several forms [3]. One of the most adopted combination is the Müller formulation [3]. All these formulation, when applied to the analysis of the scattering by BOR's, lead to integrals of the form [2]:

$$I = \int_{\phi=0}^{2\pi} \int_{\alpha=-1}^1 \int_{\alpha'=-1}^1 \left(\frac{ab}{c} \right) F(\phi) \frac{e^{-jkR}}{R^d} d\alpha' d\alpha d\phi, \quad (1)$$

where $R=|\mathbf{r} - \mathbf{r}'|$ is the distance between source and observation points, a may be equal to 1, α' or α'^2 , b may be equal to 1, α or α^2 , c may be equal to 1, ρ , ρ' or $\rho\rho'$, and the exponent $d = 1$ or 3. The integral (1) has removable singularities whenever the observation point \mathbf{r} is very close to the source point \mathbf{r}' . The concept adopted in [2] to treat these singularities is to split the corresponding integrands into two: one that is regular and can be numerically evaluated by a Gaussian quadrature and another that contains a removable singularity and can be integrated analytically.

III. NUMERICAL RESULTS

To evaluate the numerical convergence we consider the CFIE and Müller formulation to the plane-wave scattering by perfect electric conductor (PEC) and dielectric spheres, respectively. The accuracy of the numerical results was verified against analytical solutions based on Mie series using the RMS error:

$$E_{\text{RMS}}(\%) = (E_{J_r} + E_{J_\phi} + E_{M_r} + E_{M_\phi})/4, \quad (2)$$

with E_x representing a RMS defined by

$$E_x(\%) = \sqrt{\frac{1}{N} \sum_{m=1}^N \left(|X_m^{\text{MoM}} - X_m^{\text{Mie}}| / |X_m^{\text{Mie}}| \right)^2}, \quad (3)$$

where X is any one of the electric (J_t or J_ϕ) or magnetic (M_t or M_ϕ) surface current components while X^{MoM} and X^{Mic} represent the corresponding numerical and analytical solutions, respectively.

The first case study is a PEC sphere, as illustrated in Fig. 1. The sphere radius is $1\lambda_0$ (the wavelength in vacuum). Different numbers of segments per λ_0 were used to represent the sphere generatrix. The TBF is defined over two consecutive segments [1]. Over each segment the regular integrals in α and α' of (1) were both evaluated using a NIP-point Gaussian quadrature, with NIP varied from 1 to 10. Singularities were removed by extraction technique [2]. Figure 2 shows the RMS error as function of NIP. Convergence is attained using NIP = 2, independently from the number of segments per λ_0 , which is determinant for the RMS error. When singularities are not removed the RMS error increases, as expected.

Fig. 1. Plane-wave scattering by homogeneous sphere

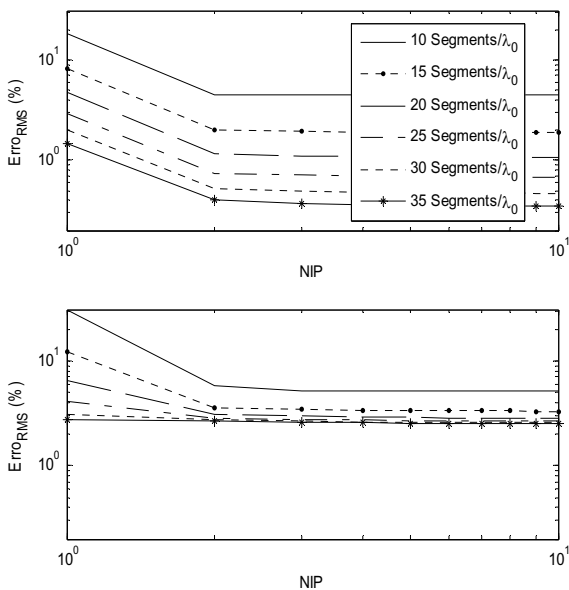

Fig. 2. Error for PEC sphere a) with singularities removal b) without singularities removal

The RMS error for dielectric spheres are illustrated in Fig. 4 for relative permittivity $\epsilon_r = 2$ and 20. Once more, when singularities are removed numerical convergence is attained for NIP = 2. The number of segments/ λ_0 influences the RMS error, which diminishes as more segments are used. When singularities are not removed, convergence is attained only for larger NIP values, especially for large values of ϵ_r .

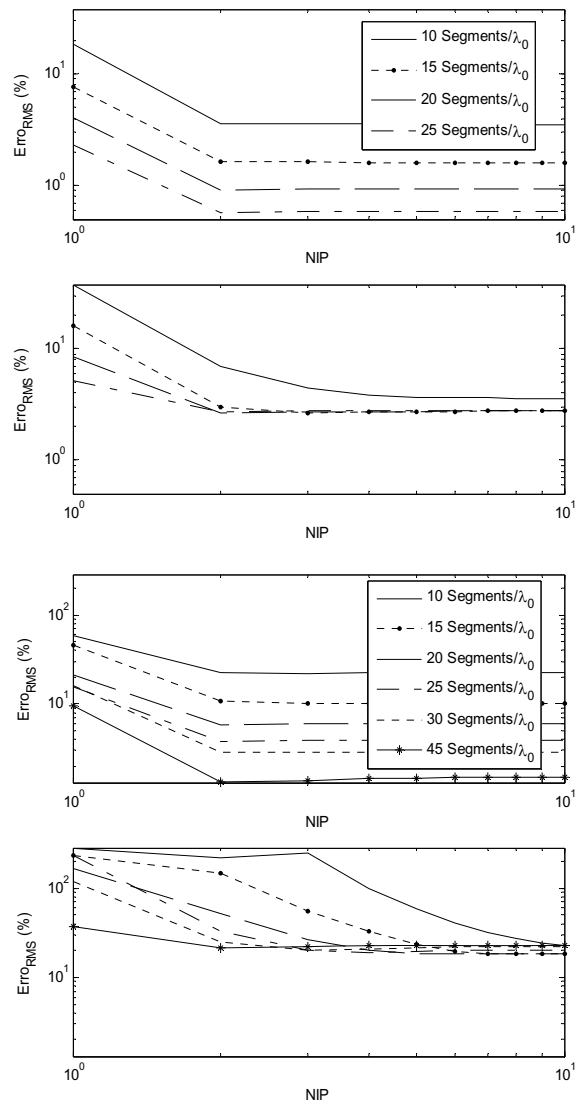

Fig. 3. Error for dielectric sphere a) $\epsilon_r=2$ with singularities removal b) $\epsilon_r=2$ without singularities removal c) $\epsilon_r=20$ with singularities removal d) $\epsilon_r=20$ without singularities removal

A 3-D FE Particle-in-Cell Parallel code with adaptive load balancing

S. Coco, A. Laudani, G. Pollicino, P. Tirrò
 University of Catania, DIEES
 V.le A. Doria 6, Catania, I-95125, Italy
 alaudani@diees.unict.it

Abstract — In this paper the authors present a Finite Element PIC Parallel approach, based on an appositely developed parallelization algorithm for the balancing of load among several processors. In particular the master processor establishes the number of slave processors, where the particle tracing procedures must be launched, according to the number of particles and to the simulation time resulting during the previous time step. The tests performed have shown a reduction of about 10-20% of the simulation time in comparison with analysis performed using a fixed processors loading scheme.

I. INTRODUCTION

Particle-in-Cell (PIC) codes are used for the electromagnetic analysis of electron devices in terms of particle trajectories. In fact, the interaction between the electromagnetic fields and the charged particles is described by the classical Maxwell's electrodynamics equations, coupled with the Newton-Lorentz's equations for the motion of particles. However in the evolution of the charged particles beam, the particles themselves are source of electromagnetic fields. Unluckily the analytic solution of the coupled equations system can be obtained only for domains of simple geometry. For realistic devices the domain has complicated boundaries (for example shadow and control grid in electron guns) and the numerical solution is a not trivial task, since it is necessary to manage and process an huge amount of data coming out from the required domain discretization and from the representation of particle distribution. Although the PIC methods are often and successfully used in device simulation for electron trajectories tracing, but these approaches have also a high computational cost.

In this paper the authors present a Finite Element Parallel PIC approach which uses appositely developed parallelization algorithms for the balancing of load among several processors, whose number is not previously fixed, but is modified during the simulation according to the amount of particles to manage. The tests performed have shown a reduction of about 10-20% of the simulation time in comparison with analysis performed using a fixed processors loading scheme.

II. 3-D FE PARTICLE IN CELL APPROACH

The dynamics of a set of charged particles subject to an electromagnetic field in collisionless conditions can be described by means of the Vlasov equation for the particle distribution function $f(t, \mathbf{x}, \mathbf{p})$, defined in the phase space $(\mathbf{x}, \mathbf{p}) \in \mathfrak{R}_x \times \mathfrak{R}_p$ and time t ,

$$\frac{\partial f}{\partial t} + \frac{\mathbf{p}}{m} \cdot \nabla_x f + q(\mathbf{E} + \frac{\mathbf{p}}{m} \times \mathbf{B}) \cdot \nabla_p f = 0 \quad (1)$$

where \mathbf{p} is the particle momentum, m and q are the particle mass and charge respectively. The electric field \mathbf{E} and magnetic field \mathbf{B} satisfy the Maxwell equations, for which the charge and current density

$$\rho(t, \mathbf{x}) = q \int_{R_p} f(t, \mathbf{x}, \mathbf{p}) d\mathbf{p} \quad (2)$$

$$\mathbf{J}(t, \mathbf{x}) = q \int_{R_p} \frac{\mathbf{p}}{m} f(t, \mathbf{x}, \mathbf{p}) d\mathbf{p} \quad (3)$$

are the source terms.

The Vlasov equation together with the Maxwell equations constitutes a system of coupled equations called Vlasov-Maxwell system [1]. An attractive computational tool for numerically solving this nonlinear Vlasov-Maxwell problem is the particle-in-cell (PIC) method, in which the particles' beam is represented by a reasonable number of dot-like macro-particles sources of electromagnetic field, subject to the dynamic equations. Each macro-particle represents an appropriate number of elementary particles of a specific type. A type of particles is characterized by its specific ratio between charge and mass. Since the movement of elementary particles is to be simulated, each macro-particle moves like an elementary particle of the proper type. However, when determining the fields it must be taken into account that each macro-particle consists of many elementary particles. In the solution process the interaction with the 'self-consistent fields' (those generated by the charge particles) and the applied external fields is obtained through an appropriate computational scheme, which schedules at each integration step of the trajectories:

- 1- the distribution of space charge and current density
- 2- the solution of the fields' equations.

To solve the evolution equation we used an FE approach, which is adequate to describe the complex three-dimensional geometries of electron devices by using irregular discretizations. Moreover, the finite element method gives the possibility of using a more accurate modeling of the most critical device regions (such as in proximity of the electrodes, where the gradient of the unknown function is higher), using an adaptive meshing without affecting the number of degrees of freedom.

Although solving the evolution equations of the fields is one of main components of a PIC code; however its execution time accounts for less than 10%–20% of the simulation's total

time. The remaining time is spent on tracing particles' trajectories and calculating the particle-field interactions, expressed computationally as local interpolation operations (in the case of FEM a very time consuming procedure is the individuation of the element containing the moving particle in the case of unstructured mesh). These operations are the major performance bottleneck of PIC codes. Strategies to optimize PIC performance have been studied and implemented extensively for codes running on large scale distributed memory architectures and grid computing environment [1].

III. PARALLELIZATION OF THE PIC ALGORITHM

When parallelizing an algorithm one problem concerns the assignment of the computational tasks to the various processes. In order to have a good load balancing for the trajectories tracing, it is possible to split the macro-particles integration task over processors, but even in this case an optimal parallel code is obtained only by following a dynamic load balancing. To fulfill the dynamic load balancing we define a master processor that at each time-step counts the particles and assigns the various tracing tasks to the slave processors; each slave processor integrates the dynamic equation of macro-particles assigned to it and computes the space charge distribution and current density using a copy of the FE mesh. Then it sends its results together with the copy of the charge and current density vectors ($[\rho]$ and $[J]$ respectively) to the master processor (see figg. 1 and 2 for flow charts of master and slave processors). This "reduces" the vectors $[\rho]$ and $[J]$ by adding the outputs of all the slave processor and solves the fields' equation. Thus, the main time consuming procedure, that is the particles tracing, is "equally" distributed among the processes. In literature [2-3] in order to evaluate the parallelization speedup the total simulation time is compared for simulations with and without load distribution among processors, respectively, and for a different number of particles. It is worth noticing that the speedup curve is very close to the ideal case only if few processes and a huge amount of particles are employed. In addition, it is very far from the optimal case, when the number of processes increases above a certain value. Consequently the number of parallel processes to get optimum speedup depends on the number of particles used in the simulation. In order to overcome this problem a heuristic adaptive algorithm has been developed to avoid excessive inter-process communication. In particular the master processor establishes the optimal number of slave processors, where the particle tracing procedures are launched according to the number of particles and to the simulation time resulting in the previous time step. It is worth noticing to emphasize that in the case of PIC time-dependent solution the total number of particles can vary during the simulation since the pushing of the particles inside the domain and the extraction procedure do not necessarily follow a deterministic law.

So during a run the processors used in the parallelization scheme are not fixed but can increase or decrease, from a time step-iteration to another. The FE PIC parallel code is written in C/MPI and has been developed in the LINUX OS environment. In order to carry out the dynamics load balancing

using a variable number of processors the processors are configured like master-slave structure. At each time step, the master processor establishes the number of the active slave processors, and takes care of the dynamic load balancing, while the slave processors trace the particles trajectories. The minimum number of particles above which the first split is performed is 500k and the maximum number of slave processors used was 8. The tests performed have shown that by using this adaptive load balancing the overall speedup is of about 10-20% with respect to a fixed number of processors. A more detailed description will be given in the full paper, together with application examples.

Abstract— In this paper, the outline of the parallel computing method of the magnetic field for rotating machines by using the 3-D finite element method with edge elements is developed. The performance of the method running on the Earth Simulator is quantitatively clarified.

I. INTRODUCTION

In fields such as structural mechanics and fluid dynamics, the large-scale parallel computing on a supercomputer has been already researched. However, for the practical numerical analysis of the magnetic field for rotating machines, the large-scale parallel computing is still in an early stage of investigation.

We have developed the parallel computing method of the magnetic field by using the three-dimensional Finite-Element Method (3-D FEM) with edge elements for rotating machines.

In this paper, we describe the outline of the developed method and an optimization of the method for the Earth Simulator, which is a vector type parallel supercomputer in Japan. Moreover, the performance of the proposed method running on the Earth Simulator is quantitatively clarified.

II. OUTLINE OF PARALLEL COMPUTING METHOD

A. Domain Decomposition Method

The Domain Decomposition Method (DDM) is adopted for the parallel computing [1]. Using the DDM, the analyzed domain is divided into multiple subdomains, and the subdomains are calculated in parallel while doing appropriate data communications between those subdomains.

Fig. 1 illustrates the DDM for FEM with edge elements. This figure shows that one domain is divided in two subdomains.

The number of edges in each subdomain is almost the same to split the CPU power into subdomains evenly. The divided domain has the overlap elements. By using the overlap elements, the data communication between subdomains becomes unnecessary when the element coefficient matrix is made.

B. Data Communication

The overlap element has two kinds of edges, one is called ‘boundary edges’ and another is called ‘external edges’. In Fig. 1 (b), the boundary edges are drawn as the bold line (edge 7 in *Subdomain I*, and edges 8 and 9 in *Subdomain II*), and the external edges are drawn as the dotted lines (edges 8 and 9 in *Subdomain I*, and edge 7 in *Subdomain II*). The boundary

edge in one subdomain is the external edge in another subdomain. By using this relationship, the data communication in the process of matrix solving is achieved properly. Fig. 2 shows the calculation of matrix-vector product divided into two subdomains. In order to calculate the *Subdomain I*, the values of potential of external edges 8 and 9 are obtained from those of the corresponding boundary edges 8 and 9 in *Subdomain II*. Similarly, in order to calculate the *Subdomain II*, the value of potential of external edge 7 is obtained from *Subdomain I*. This procedure is repeated in solving the matrix equation.

The code for the parallel computing is written using the Message Passing Interface (MPI) that allows many computers to communicate with one another.

Fig. 1. Domain decomposition method for finite-element method with edge elements

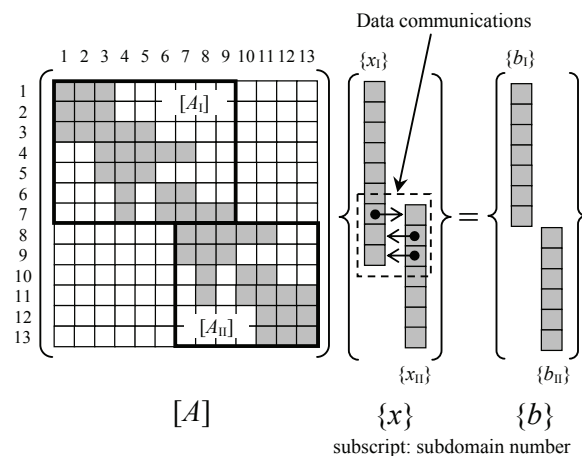

Fig. 2. Calculation of matrix-vector product divided into two subdomains

III. OPTIMIZATION FOR EARTH SIMULATOR

The Earth Simulator is a distributed-memory type parallel computer system, which consists of 640 processor nodes connected by the crossbar network. Each processor node has 8 vector processors. The whole system has 5120 processors with 10 TB of main memory and the peak performance of 40 Tflops.

In our parallel computing method, the Scaled Conjugate Gradient (SCG) method is used as the matrix-solving method because of its simplicity and efficiency.

On the vector processor, the vector efficiency affects computing speed. Therefore, the Descending-order Jagged Diagonal Storage (DJDS) [2] format in Fig. 3 (a) is adopted as the storage of sparse matrix format because it can attain longer vector length and thus lead to higher vector efficiency than the Compressed Row Storage (CRS) format in Fig. 3 (b). The DJDS format involves permuting rows in decreasing order of the number of non-zero elements in each row.

Fig. 3. Storage format of matrix

IV. NUMERICAL RESULTS AND DISCUSSION

A. Fundamental Equation of Magnetic Field

The fundamental equation of magnetic field is given by the magnetic vector potential A as follows:

$$\text{rot}(\nu \text{rot} A) = \nu_0 \text{rot} M + J_0 + J_e \quad (1)$$

where ν is the reluctivity, ν_0 is the reluctivity of the vacuum, M is the magnetization of permanent magnet, J_0 is the exciting current density, J_e is the eddy current density.

B. Analyzed Model

Fig. 4 shows the analyzed model of the IPM motor. In order to evaluate the parallel computing efficiency, we calculate the model using three kinds of meshes: coarse mesh, middle mesh, and fine mesh. The number of unknown variables of the coarse, middle and fine meshes is 328,298, 969,298 and 4,007,888, respectively. Fig. 5 shows the middle mesh that is divided into four subdomains.

C. Performance of Proposed Method

Fig. 6 shows the distribution of flux density vectors calculated in each subdomain.

Fig. 7 shows the speed-up obtained for three kinds of meshes. The speed-up is evaluated in one time step. The saturation of the speed-up for the larger number of CPUs is due to an increase in the ratio of communication cost to computing cost. For any given number of CPUs, the speed-up becomes larger as the number of unknown variables increase. This is because the ratio of the communication cost to the

computing cost decreases, and the average vector length becomes longer. In the fine mesh, the proposed method achieved over 60-fold speed-up by 128 CPUs.

V. CONCLUSION

We have developed a parallel computing method of the 3-D finite element method for rotating machines by the domain decomposition method. In this method, speed-up becomes larger as the number of unknown variables increases. Specifically, in the fine mesh that has 4,007,888 unknown variables, the proposed method achieved over 60-fold speed-up by 128 CPUs. Better speed-up is expected in a larger scale analysis.

Abstract — An iterative process based on the wave concept (WCIP) is formulated and applied. A recursive relationship between a wave source and reflected waves from a discontinuity plane is computed. In order to simplify calculations and accelerate the convergence with reduced central processing unit time, a two dimensional Fast Modal Transformation (FMT) algorithm using periodic walls is used with the 2D-FFT algorithm.

I. INTRODUCTION

Several analytical and numerical techniques are reported in the literature for the analysis of monolithic microwave integrated circuits (MMICs), among them: the method of moments [1], the finite elements method and the finite difference time domain method [2]. For the reduction of development times and costs of MMICs, it is of primary importance the use of fast and efficient software tools, which can accurately predict the electrical behavior of a device. The computational time of these numerical techniques is the limiting factor in the practical design of microwaves circuits. In this paper a tool that reduces the required computational effort is proposed. It employs the Wave Concept Iterative Procedure (WCIP), an integral based on generalized wave definitions. This method is not conditioned by the complexity of the circuit design and was proved to be particularly interesting for planar multi-layers circuits [3]-[4]. The WCIP approach consists in separating the structure under study into interfaces with upper and lower homogeneous media. The boundary conditions on the interface are represented by the diffraction operator, S , and in the homogeneous media by the reflection operator, Γ . They are respectively defined in spatial and modal domains. In this case, a formulation based on the periodic walls is applied.

In the work reported herein, the analysis and simulation of a rectangular waveguide including a microstrip open line and a microstrip patch antenna with periodic walls using a WCIP were carried out. Section 2 provides the theoretical formulation used in the development of the WCIP. Simulation results are presented in section 3. Finally, conclusions are included in section 4.

II. FORMULATION OF THE WCIP

The spatial and modal waves are directly deduced from each other with a Fast Modal Transformation (FMT) and its inverse transform (FMT^{-1}). As illustrated in Fig. 1, the FMT is comprised of the 2D-FFT algorithm and transformation from the spectral to the modal domain.

A Fast Modal Transform (FMT) and its inverse ensure conversions between the two domains.

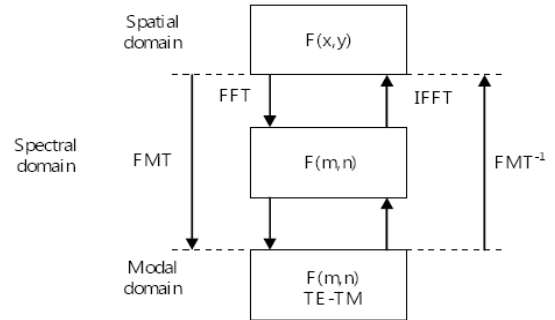

Fig. 1. Block diagram for the Fast Modal Transformation (FMT) algorithm

Let us consider a single, but general, interface problem with its waveguide transversal cut shown on Fig. 2. The Γ operator is described in the modal domain. The S operator expressed in the spatial domain assigns boundary conditions at the interface plan. The air-dielectric interface is divided into cells and includes three sub domains: dielectric, metal, source. The source generates two waves, one in each side of the interface.

Fig. 2. Iterative Process illustration for a microstrip line

The representation of electromagnetic fields using the Wave Concept is a well-established procedure [5]. This formulation concept is also used in the Transverse Line Matrix method (T.L.M.).

The incident (A) and reflected (B) waves and the electric field (E) and current density (J) can be related by:

$$A_i = \frac{1}{2\sqrt{Z_{0i}}} (E_i + Z_{0i} J_i) \quad (1)$$

$$B_i = \frac{1}{2\sqrt{Z_{0i}}} (E_i - Z_{0i} J_i) \quad (2)$$

Where, Z_{0i} is the characteristic impedance of medium i .

9. Numerical Techniques

The usually used WCIP scheme is very simple. It can be represented through two equations:

$$A = SB + A_0 \quad (3)$$

$$B = \Gamma A \quad (4)$$

Where, A_0 is the local source of the circuit.

Finally, it is possible to express the boundary conditions in terms of waves on each cell.

$$E_i = \sqrt{Z_{oi}} (A_i + B_i) \quad (5)$$

$$J_i = \frac{1}{\sqrt{Z_{oi}}} (A_i - B_i) \quad (6)$$

III. SIMULATIONS RESULTS

In order to present the performance of the proposed tool two case studies were conducted. The simulation results for two different structures are given in sections A and B.

A. Microstrip open line

A microstrip open line in a waveguide of dimension 32mm x 8mm with periodic walls was simulated with the Matlab software. The microstrip line lies on a substrate with $\epsilon_r = 2.2$ and height of 1mm.

The simulated source has dimensions of 2mm x 2mm, while the simulated microstrip line is 2mm wide, and 25 mm long.

Figure 3 shows the computed input impedance, Z_{in} ,

Fig. 3. Input impedance in Ohms as a function of frequency in Hz

The Z_{in} is in conformity with the theory [6]. The Z_{in} imaginary part is calculated by $-\cot(\beta l)$. As expected, the real part reaches a positive peak value at the line resonance frequency.

B. Microstrip patch antenna

A patch antenna with resonance frequency of 1.32 GHz as analyzed in [6], is now considered. Its physical construction guarantees a characteristic impedance of 50 Ohms.

Fig. 4. Absolute value of the input reflection coefficient, $|S_{11}|$ in dB as a function of frequency in Hz

As can be seen in Fig. 4 (blue curve), the resonance frequency simulated result is very close to the measured frequency (about 1.38 GHz). Also, this is in good agreement with the measured frequency presented in [7]. Therefore, it can be used to confirm that the method proposed herein gives rather satisfactory results, as they are closer to the measured ones than those of the simulations in [7], with a comparatively small computational effort.

IV. CONCLUSION

In this paper, an implementation of the WCIP using periodic walls is presented. A microstrip open line and a microstrip antenna patch have been analyzed and simulated. The obtained results show that the method herein formulated and implemented in software, is suitable to electromagnetic analysis of planar circuits. Very good agreement among simulated results, available theory, and physical implementation has been achieved.

Abstract — This work is devoted to the combined numerical technique which makes possible the effective simulation of very large electromagnetic models. The two principle constituents of the proposed combined approach are the curved finite elements and their realization on the basis of Message Passing Interface (MPI). The usage of the curved finite elements allows to minimize the error introduced by the indispensable spatial discretization, while employing the MPI programming technique makes it possible to significantly speed up the calculation process. In the paper it is demonstrated how the proposed numerical technique can be used to tackle large electromagnetic problems.

I. INTRODUCTION

Electromagnetic problems are formulated on the basis of Maxwell's equations and are completed by the corresponding material relations. The obtained vector valued equations can be solved exactly only for a limited number of problems with reasonable complexity. Problems of practical importance are usually solved only approximately on a discretized level. From the above reasoning it is of crucial importance to make the process of numerical solution robust and effective with respect to the calculation time and memory consumption.

II. FINITE ELEMENT METHOD

During the last decades various discretization techniques have been developed with individual advantages depending on the aspired application. In the current work the focus is put on the classical finite element method for the spatial discretization with vector valued basis functions on tetrahedral elements in a hierarchical setup [1]-[3]. In order to improve the accuracy of the spatial approximation in those cases where non-flat material interfaces are involved, the linear mapping of a unit tetrahedron to any element of the mesh is replaced by a nonlinear variant. For this purpose, the set of scalar basis functions of lowest order employed to set up a transformation that includes merely the corner points of the element is extended by higher order scalar basis functions. On the one hand, increasing the desired order for the interpolation leads to the more geometrically flexible transformation; on the other, it simultaneously increases the numerical efforts since more control points have to be involved into the calculation process.

Quadratic interpolation as the simplest complete nonlinear representative requires the knowledge of ten control points per tetrahedron, where four of them are typically allocated on the

corners of the element and the remaining six are usually placed in the center of the corresponding edges. Thus, each face of such an element can be represented by a function of second order behavior and can therefore smoothly conform to curvilinear interfaces. In case of hierarchical scalar basis functions, the control vectors are represented by difference vectors from the edge centers to the surface points instead of the surface vectors itself. In Fig. 1, two different approaches are visualized.

Fig. 1. Linear versus curvilinear transformation of a unit tetrahedron conforming to a sphere of radius 2 touching the element in three corner points

Assuming the notation $A = \{a_{ij}\}$ for the stiffness matrix and $B = \{b_{ij}\}$ for the mass matrix the following definitions

$$a_{ij} = \iiint_{\Omega} \text{curl } \vec{w}_i \cdot \text{curl } \vec{w}_j / \mu \, d\Omega$$

$$b_{ij} = \iiint_{\Omega} \vec{w}_i \cdot \vec{w}_j \, \varepsilon \, d\Omega$$
(1)

are employed. Here, vectors $\vec{w}_i, i = 1, \dots, N_{\text{DoFs}}$ refer to the vector valued basis functions and Ω denotes the entire computational domain. Material properties are given in term of the permeability μ and the permittivity ε .

Due to the compact support of the applied basis functions, the population of the matrices is very sparse. The integration in (1) is typically performed independently for each individual element and a subsequent summation of each contribution allows then to assemble the entire sparse matrix in an efficient parallel strategy. The individual contributions can be summarized to

$$\begin{aligned}
a_{ij}^e &= \iiint_{\Omega_0} \text{curl } \vec{w}'_i \cdot \text{curl } \vec{w}'_j / (\mu |J|) d\Omega \\
b_{ij}^e &= \iiint_{\Omega_0} \vec{w}'_i \cdot \vec{w}'_j \varepsilon |J| d\Omega
\end{aligned} \tag{2}$$

where $\vec{w}'_i = J^{-1} \vec{w}_i$, $\text{curl } \vec{w}'_i = J^T \text{curl } \vec{w}_i$ and matrix J denotes the Jacobian of the involved geometrical transformations. In (2), the integration is performed only on a unit tetrahedron Ω_0 and can be carried out analytically for linear geometry transformations. In contrast to this, in case of higher order spatial transformations with curvilinear elements, a numerical integration technique with sufficient accuracy to capture the variation of the integrand is employed. As soon as an element matrix is calculated, the assembling of the entire system of equations is proceeded step by step by means of inserting those local values into the global system.

III. IMPLEMENTATION

The geometric modeling of the structure is performed within the CST Studio Suite which is also used for the tetrahedral meshing [4]. The necessary information is passed to the FEM program by means of ASCII or binary file transfer. The entire FEM algorithm is implemented in C++ thus enabling high performance and clear arrangement of the whole program [5]. The external mesh information is used in a first step to set up a graph representing the population pattern of the sparse stiffness and mass matrices in a way that only the degrees of freedom (DoF) are considered. Constraints placed due to boundary conditions are incorporated in the matrix setup. The entire graph is initially arbitrarily distributed among all the contributing processes but has to be partitioned in proper clusters of contiguous elements to keep the communication overhead during the computations low. The final distribution of the various DoFs among the processors is determined with the help of the graph partitioning library ParMeTiS [6]. This knowledge is necessary to allocate the memory used to manage the matrices in an advantageous way. An efficient implementation can be found for example within the software package PETSc [7] which also provides proper linear solvers and various preconditioners.

Once the mesh and material information are properly distributed among all the processors, an efficient assembly of the global matrices can be performed. During this step, a distinction is made between elements based on linear geometric mapping and their nonlinear counterparts.

IV. CONVERGENCE ANALYSIS

In the following we refer to the solution of Maxwell's equations within closed perfect conductive structures. The continuous formulation is thus turned into the discrete generalized eigenvalue problem

$$A\vec{c} = \lambda B\vec{c} \tag{3}$$

with the eigenvector \vec{c} collecting all the individual weighting coefficients for the expansion $\vec{E} = \sum_i c_i \vec{w}_i$ of the electric

field intensity. In this setup, the eigenvalue $\lambda = \omega^2$ represents the squared value of the corresponding angular frequency.

For the problem of finding the resonant frequency of the fundamental mode within a hollow perfect conductive sphere, an analytical solution can be derived. Comparing the numerical solutions f obtained on different discretization levels with the analytical one denoted by f_0 enables to carry out a convergence analysis which is illustrated in Fig. 2 for a number of selected approximation schemes.

Fig. 2. Convergence analysis for the resonant frequency of the fundamental mode in a unit sphere with perfect conducting boundary conditions

From this graph one can clearly see that all methods enabling linear geometric modeling suffer from an inexact boundary geometry representation whereas the curvilinear geometric modeling overcomes this difficulty.

V. CONCLUSION

In this digest we report on the successive implementation of a parallel FEM kernel featuring curvilinear tetrahedra elements. In contrast to the results reported in the literature, the superior convergence of higher order approximations versus lower order variants can be preserved even on non-flat material interfaces with a usage of a moderate geometrical transformation order. In the full paper we extend the calculations to practically relevant structures.

Multicore Acceleration of CG Algorithms using Blocked-Pipeline-Matching Techniques

David M. Fernández, Dennis Giannacopoulos and Warren J. Gross
 Department of Electrical and Computer Engineering, McGill University
 3480 University Street, Montreal (QC), H3A 2A7, Canada

Abstract—To realize the acceleration potential of multicore computing environments computational electromagnetics researchers must address parallel programming paradigms early in application development. We present a new blocked-pipeline-matched sparse representation and show speedup results for the conjugate gradient method by parallelizing the sparse matrix-vector multiplication kernel on multicore systems for a set of finite element matrices to demonstrate the potential of this approach.

I. INTRODUCTION

Multicore processors represent one of the newest mainstream computing trends for enhancing the performance of scientific kernels, bringing about new opportunities and challenges to electromagnetic (EM) practitioners. Parallel programming challenges must now be confronted earlier in application development in order to exploit this new trend. Some EM computations are highly parallelizable, offering different opportunities for multicore acceleration (e.g. parallel mesh builders, parallel iterative solvers, etc). Of particular interest to this work is the solution of the large-sparse linear systems that arise when solving EM problems.

This work focuses on accelerating the *conjugate gradient* (CG) solver by parallelizing its dominant computing kernel, the sparse matrix-vector multiplication (SMVM) where a sparse matrix A multiplies a dense vector x . A new block-partitioned sparse format is presented to accelerate the SMVM kernel using both high-level parallelism, e.g., scheduling tasks across cores in multicore or clustered processors, and low-level parallelism within processor cores, such as vectorization, loop transformations and time skewing. First, we identify the key challenges confronted in parallelizing general sparse kernels and then describe the new sparse format and the algorithmic approach, showing performance results to validate it.

II. PREVIOUS WORK

Parallelizing and optimizing dense linear algebra kernels is a well understood task that has given rise to a variety of Basic Linear Algebra Subprograms (BLAS) libraries (e.g. LAPACK, ScaLAPAC) [1], [2]. Sparse kernels on the other hand represent a greater challenge. They enable larger problems, using less memory resources and computing on non-zero matrix entries only; however, drawbacks such as increased instructions overhead and irregular and indirect access to data significantly limit the use of hardware optimization techniques and BLAS operations. Support for parallel sparse kernels

on clustered systems is available in some newer packages (e.g. SPARSEKIT, NIST's Sparse BLAS, and PETSc) which operate on general sparse formats (e.g. compressed sparse row-CSR [3]), but are generally only optimized for dense kernels. Efficient multicore implementations and low-level parallelism on sparse kernels have yet to be thoroughly addressed.

Specialized formats have been used as means to regularize the computations and data layout of general sparse formats at the expense of processing some extra zeros, unveiling better opportunities for high and low-level parallelism. The Block-CSR (BCSR), Ellpack-ITpack and Jagged-diagonals formats are the three classic formats used for this purpose, however they each demand certain matrix properties to be efficient [3]. Recent work on specialized sparse matrix formats [4]–[6] has shown that further performance improvements are possible without such restrictions. In [6] we report up to 14 times speedup (SU) compared to a single core CSR SMVM implementation obtained by designing a specialized sparse format (called pipeline-matched sparse format-PMS).

III. NEW SPARSE FORMAT FOR PARALLEL PROCESSING

Based on the experience gained in [6] we introduce a blocked adaptation of PMS, that exploits both locality and vector units in modern processors, as opposed to other blocked formats that only aim at exploiting locality.

A. Blocked Pipeline-Matched Sparse Representation

The new format called *blocked pipeline-matched sparse* (BPMS) representation defines clear data boundaries for partitions (as PMS [6]), nonetheless it also offers better opportunities to exploit fine grained parallelism. In BPMS the matrix is stored in small dense matrix-blocks, which are enforced to be a multiple of the vector-registers size on the target architecture as in PMS; thus allowing to easily exploit vector or single-instruction multiple-data (SIMD) parallelism in multicore processors. Furthermore, when the size is a multiple greater than one, loop transformations can be implemented to enhance performance (not possible on PMS). BPMS stores the matrix data in four linear arrays as follows: (i) the nonzero elements of the matrix stored in dense square/rectangular blocks by rows (elements in blocks are stored row-wise), with zero padding to match the pipeline width of the target processor (as in PMS); (ii) the column indices of the first element in each block (as in BCSR); (iii) the row index of the first element

in a block that starts a new row (as in BCSR); and (iv) the number of dense blocks preceding the block pointed to by each of the row indices. The row indices can be used to determine high-level boundaries for data-partitions to spread across processing cores. The newly introduced fourth vector aids in load balancing by providing information on the amount of data to compute on for each coarse data-partition defined.

The main advantage of BPMS over other blocked formats such as BCSR, is that it takes advantage of vector units in modern processors. The pipeline-matching in BPMS blocks creates vector-data sets aligned to natural vector boundaries, that ease implementing vector operations. Traditional blocked formats only exploit data-locality by creating small blocks (also achieved by BPMS), but do not align data to vector boundaries nor do they assure data sizes to fit within vector-registers. In addition to this, BPMS includes a fourth vector that provides important information to load balance the matrix data when partitioning it across processors and provides useful information for low level loop optimizations. To further enhance locality and efficiently support building dense blocks minimizing padded-zeros, we apply a reordering technique (reverse Cuthill-McKee [7]) that reduces the matrix bandwidth before creating the BPMS representation. The insight provided by the reordering process can also be used to define coarse data-partition boundaries within the matrix (full details in long version). The two level partitioning used for the PMS format [6] is still used here to stream data across the cores of a multicore processor with user-managed cache (e.g. Cell BE processor) or FPGA based systems.

IV. RESULTS

The new BPMS representation was implemented in an Intel Core2 Quad 2.40GHz CPU, 4GB of global DRAM and 64-bit Linux system. Compilation was done using GCC 4.1.2 with different optimization flags (e.g. -O2, -O3), reporting the best results only. The matrix-blocks were configured as 2-by-2 elements to match the 4-element single-precision floating-points (SPFP) vectors in the Intel processor (common in other multicore chips). Time SU results for the SMVM kernel using CSR versus the new BPMS and PMS formats are shown in Fig. 1 for increasing matrix sizes on one CPU-core. CSR provides the base computing time since it contains no zero padding, whereas PMS and BPMS have extra computational overhead. The SU curve increases as the matrices grow and stabilizes around 1.5x SU, which shows that BPMS performs better than CSR as the cache misses in the CSR kernel become regular. BPMS also demonstrates good scaling for increasing matrix sizes, requiring less padded-zeros. This is true in general, but non-zero padding may slightly increase for very irregularly-structured matrices, e.g., the two matrices in the valley of Fig. 1. The BPMS-SMVM kernel was not vectorized for this test, so a maximum increase of 4X the reported SU can be expected when vectorizing for SPFP on modern processors.

A high-level parallelized version of the SMVM kernel was implemented across different numbers of cores using standard Pthreads and the new BPMS format (configured as before). We

Fig. 2. SU scaling for CG-BPMS using 1-4 cores.

TABLE I
BPMS-CG GFLOPS RESULTS FOR 1 AND 4 CORES.

Matrix Name(#)	fidapm37(1)	bcsstk32(2)	s3dkt3m2(3)	s3dkq4m2(4)
Non-zeros	765944	2014701	3753461	4820891
% added zeros	(21.63%)	(30.36%)	(19.02%)	(11.32%)
BPMS-CG 1-core	0.94	0.90	0.96	1.02
BPMS-CG 4-core	2.86	2.67	2.63	2.89

then used this parallel BPMS-SMVM kernel to accelerate the CG solver (BPMS-CG). The performance scaling with respect to 1-core BPMS-CG is shown in Fig. 2 for the 4 biggest test matrices. Near 3-times increase in performance (measured in GFLOPS) was obtained when running the accelerated BPMS-CG from 1 to 4-cores (see Table I). Table I also shows, that in general, as the non-zero entries of the matrix grow the added zeros due to padding drop, demonstrating the good scalability behavior of the new format. This work demonstrates that by using special sparse formats one can regularize these kernels and significantly increase their performance even when considerable zeros are padded. As an added benefit, the regularization process provides insight into the coarse partition boundaries that can be used for distributing data among processing cores. Full performance results for vectorized BPMS-CG will be presented at the conference and in the long version paper.

Abstract — This paper presents a new approach based on the use of interpolation for the electric potential which provides a significant increase in the accuracy of field calculation using the impedance method. In a rectangular three-dimensional grid we use a first order interpolation function to describe the distribution of electric potential within each voxel of the mesh. The electric field obtained analytically from this function is used as a solution of the continuity equation applied to each node of the mesh. The system of node equations is then solved and the resulting potential distribution obtained allows us to make the calculation of the electric field and current in each voxel.

I. INTRODUCTION

The impedance method and similar methods use lumped parameters of electric circuit to model the electric properties of the related materials [1,2]. Such methods have been applied in several important situations of electromagnetic modeling in linear materials, especially those involving excitation with sinusoidal sources, where the technique of phasor analysis can be applied [3,4]. These methods are simple to implement, because they basically involve a three-dimensional mesh of rectangular voxels. Naturally, as the method of finite differences, their biggest limitation is the representation of curvilinear surfaces.

The Impedance Method provides accurate results when the size of the medium is small compared with the wavelength of the electric field in the frequency of the source. This method is based on quasi-static approximations of Maxwell's equations, so the potential distribution can be obtained from the equations of the electric circuit theory. Thus, the conductivity and permittivity of the medium are modeled by lumped circuit elements as conductance and capacitance that connect the voxels of the discretization mesh. The impedance and admittance of connection between two neighboring voxels are defined by the following expressions (see Figure 1):

$$Z_{nm} = (V_n - V_m) / I_{nm} = L_{nm} / (\sigma_{nm} + i\omega\epsilon_{nm}) A_{nm} \quad (1)$$

$$Y_{nm} = I_{nm} / (V_n - V_m) = (\sigma_{nm} + i\omega\epsilon_{nm}) A_{nm} / L_{nm} \quad (2)$$

Where σ_{nm} and ϵ_{nm} are the conductivity and permittivity, respectively, in the region around nodes n and m and ω is the angular frequency. A_{nm} is the area of the face and L_{nm} is the distance between the geometrical centers of the neighbor voxels. With this approach one can easily model anisotropic and heterogeneous medium, such as biological materials which have significant differences in electrical conductivity and permittivity between different tissues and organs and in different directions of the applied field.

An important limitation of the impedance method lies in the fact that it allows the calculation of potential or current only in discrete positions of the mesh, which tends to intensify the discretization error. This problem can be minimized with

the use of interpolation to represent the distribution of potential within each voxel.

Fig. 1. Connection between two voxels in the Impedance Method.

The aim of this paper is to present a new strategy for numerical modeling with the impedance method that uses interpolation to describe the electric potential within the voxels of the discretization mesh. In this approach, in order to obtain a system of equations for the node potentials, we apply the equation of continuity for the total flow of current around each node.

II. METHOD

Based on the impedance or admittance model of the medium one can calculate the node potentials or the mesh currents in the equivalent circuit through the usual techniques of circuit analysis. Figure 3 shows a voxel with a local numbering of nodes in its vertices. This numbering is identical for all voxels of the mesh. Furthermore, each node is identified by a set of three indexes allocated in accordance with its position in relation to the origin of the reference system. The electric potential inside the voxel is described by the following function:

$$V = k_0 + k_1x' + k_2y' + k_3z' + k_4x'y' + k_5x'z' + k_6y'z' + k_7x'y'z' \quad (3)$$

in the intervals $0 \leq x' \leq \Delta x$, $0 \leq y' \leq \Delta y$, $0 \leq z' \leq \Delta z$.

The coefficients of equation (3) are determined by substituting this expression in each node of the voxel and solving the resulting system composed of eight equations. From equation (3) we obtain the electric field and calculate the current in each direction of the reference system in each voxel by integrating the current density under the assumption that conductivity and permittivity are uniform inside the voxel.

In order to obtain a relationship between the potential of nodes that meets the principle of continuity we establish that the sum of all components of current entering (negative) or leaving (positive) any node of the grid is zero. The resulting equation contains all the potential of nodes of the eight voxels that contains the common node (i, j, k) . That is, this equation relates potential of 27 nodes. It can be written in the following general form:

$$\sum_{n=-1}^1 \sum_{m=-1}^1 \sum_{r=-1}^1 a(n,m,r) V(i+n, j+m, k+r) = I_s(i, j, k) \quad (4)$$

where n, m and r are integers that can take the values 1, 0 or -1 and I_s is the current injected in the node (i, j, k) by the external source. The coefficients $a(n, m, r)$ relates the admittance of the eight voxels involved in each node equation.

The proposed method is to solve the system of equations described by (4) (one equation for each node of the mesh) aiming to obtain the potential of nodes according to the boundary conditions specified for the problem.

Fig. 2. Representation of a voxel with the numbering of its nodes.

III. RESULTS

As an example of application and adequacy of the proposed method, we analyze a case of simulation in a medium with high dielectric constant and low conductivity. These characteristics are similar to biological tissues. The example has simple geometry to allow obtaining an analytical solution that serves as a reference for the validation of the numerical method. It refers to a spherical region with admittivity four times greater than the external medium in a uniform electric field (see Figure 3). We used a regular grid with $140 \times 50 \times 50$ voxels with a mesh parameter of $100\mu\text{m}$. The electric field is applied through the imposition of fixed potentials of -1V and +1V on the boundary plans in x direction. On the other boundary surfaces we applied the homogeneous Neumann boundary condition. The analytical model for this system is easily obtained from the general solution of Laplace's equation in spherical coordinates with azimuthal symmetry. The potential inside and outside the sphere is given respectively by the following two equations:

$$V_i = -\frac{3\gamma_o}{\gamma_i + 2\gamma_o} E_o r \cos \theta \quad (5)$$

$$V_o = \left[\frac{a^3 (\gamma_i - \gamma_o)}{r^2 (\gamma_i + 2\gamma_o)} - r \right] E_o \cos \theta \quad (6)$$

Where $\gamma = \sigma + j\omega\epsilon$ and the indices i and o indicate internal and external media, respectively.

Fig. 3. Model used in the example.

Figure 4 shows the angular distribution of electric potential for four values of the radial distance from the centre of the sphere. The points refer to the simulation and continuous line refers to the analytical model. There is good agreement between these results. It is also presented the root mean square of the deviations of the numerical results in relation to the analytical model, including the results obtained using the traditional Impedance Method [1,2].

Fig. 4. Angular distribution of electric potential and mean square deviation in relation to the analytical model.

It is observed that for the three smaller radial distances the mean deviation from the analytical model in the simulation with interpolation is much smaller than in the conventional method simulation. The fact that the error is greater for smaller distances indicates great influence of spatial resolution of the mesh, ie there is a predominance of the discretization error in the conventional method. We concluded then that the use of interpolation in obtaining the equations of nodes in the proposed method significantly reduces the error of discretization. Finally, we note that the deviation increases in the vicinity of the radius of the sphere, and this is more an effect of discretization, because in the discrete space the form of the boundary between the two medium is considerably distorted in relation to the spherical shape in the continuum space.

Abstract — We present a simplified model for eddy current modeling in anisotropic thin multilayered plates. Under certain assumptions, the T - φ formulation is reduced to a simplified formulation involving only the normal component of the electric vector potential. As a validation, the two formulations are compared in a numerical example which consists in the evaluation of the impedance variation of an air cored coil above a thin composite multilayered plate.

I. INTRODUCTION

New synthetic materials such as carbon fiber reinforced polymer composites (CFRPs) are generally made of several anisotropic thin layers. The electromagnetic field modeling in these materials is a challenging problem because of their high anisotropy and scale effects. Dyadic Green's functions are often used when their geometries are simple [1]-[2]; however, these functions do not converge rapidly when the layers are very thin, and difficulties are encountered to derive them when a great number of layers are involved.

In a recent work [3], we developed a numerical model for eddy currents computation in carbon fiber reinforced polymer composites (CFRPs) based on the T - φ formulation. In this work, under certain assumptions, this formulation is simplified so as only the normal component (T_z) of the electric vector potential is retained. This makes the calculation faster and reduces considerably the memory space required for data storage. On the other hand, only the active parts are discretized which permits to overcome the problems related to the scale effects and offers an ease to handle the motion of the moving parts of the system. As a validation, the T - φ and T_z formulations are compared in a numerical example which consists in the evaluation of the impedance variation of an air cored coil above a thin composite multilayered plate. The reciprocity and energy conservation principles are used to evaluate the impedance variation of the coil.

II. FORMULATION

Consider the system presented in figure 1. A nonmagnetic thin multilayered CRFP plate is subjected to the influence of a magnetic field \vec{H}^s produced by an inductor where a current density \vec{J}^s variable in time is imposed. The electromagnetic field behaviour in the plate is described by the equations (1), (2) and (3) [3], involving the electric vector potential T the magnetic scalar potential φ , the resistivity tensor $\vec{\rho}$ of the composite plate, the free space permeability μ_0 and the angular frequency ω .

Fig.1. An inductor above a thin multilayered CFRP plate

$$\vec{\nabla} \times \vec{\rho} \vec{\nabla} \times \vec{T} + j\omega\mu_0(\vec{T} - \vec{\nabla}\varphi) = -j\omega\mu_0\vec{H}^s \quad (1)$$

$$\vec{\nabla} \cdot (\vec{H}^s + \vec{T} - \vec{\nabla}\varphi) = 0 \quad (2)$$

$$\vec{n} \times \vec{T} = \vec{0} /_{\Gamma} \quad (3)$$

We assume that the adjacent layers (plies) of the plate are electrically isolated and the eddy currents flow in plans parallel to the surface of the plate (i.e. $J_z = 0$), which is often the case in laminated composite materials such as CFRPs. On the other hand, if the used frequencies are such that the thickness of the plate is considered to be small compared to the skin depth, the derivatives of the electric and magnetic fields with respect to the thickness can be neglected. Also, as the plate is nonmagnetic, the magnetic scalar potential can be removed. With these assumptions, (1) is reduced to (4) involving only the normal component of the electric vector potential. The eddy currents are calculated by means of (6).

$$[\partial_x(\rho_{yx}\partial_y - \rho_{yy}\partial_x) - \partial_y(\rho_{xx}\partial_y - \rho_{xy}\partial_x) + j\omega\mu_0]T_z = -j\omega\mu_0 H_z^s \quad (4)$$

$$\vec{J} = [J_x \quad J_y]^T = [\partial_y T_z \quad -\partial_x T]^T \quad (6)$$

Each ply of the composite plate is constituted of carbon fibers embedded in a polymer matrix. The resistivity tensor of the plate is given by (7) [3], involving the conductivities parallel and transverse to the fibers ($\sigma_{//}$, σ_{\perp}), and the orientation θ of each ply with respect to a reference axis.

$$\vec{\rho} = \begin{pmatrix} \sigma_{//} \cos^2(\theta) + \sigma_{\perp} \sin^2(\theta) & \frac{\sigma_{//} - \sigma_{\perp}}{2} \sin(2\theta) \\ \frac{\sigma_{//} - \sigma_{\perp}}{2} \sin(2\theta) & \sigma_{//} \sin^2(\theta) + \sigma_{\perp} \cos^2(\theta) \end{pmatrix}^{-1} \quad (7)$$

Using the principle of the energy conservation [4], the impedance variation (ΔZ) of the inductor due to the eddy currents flowing in the plate can be calculated by (8), where

the magnetic term is reduced to T_z for the simplified formulation. In (8), Ω_p denote the plate volume and I_s the source current.

$$\Delta Z = \frac{1}{I_s^2} \int_{\Omega_p} \bar{J}^* \bar{\rho} \bar{J} + j\omega\mu_0 \|\bar{T} - \bar{\nabla}\phi\|^2 d\Omega_p \quad (8)$$

III. NUMERICAL EXAMPLE

The two formulations are compared in this numerical example which consists in the evaluation of the impedance variation of an air cored coil above a thin CRFP plate. The geometry of the modelled system is described in figure 2; the numerical values of the different parameters are given in Table I. Only the coil and the plate are discretized. The source field is calculated by the Biot and Savart formulae; (1), (2) and (4) are solved using the finite difference method in the plate [3].

Fig.2. The modeled system

TABLE I
THE NUMERICAL VALUES OF THE SYSTEM PARAMETERS

Regions	Parameters	Numerical values
Plate	Thickness (e) / Side (D)	0.25mm / 50mm
	Conductivities ($\sigma_{//}, \sigma_{\perp}$)	($10^4, 10^2$)S/m
	Number of plies / Orientations	2 / [0°, 90°]
Coil	Number of turns	500
	Inner radius (r_i) / Outer radius (r_e)	5mm / 10mm
	Height (h) / Lift off (l)	1mm / variable

Fig. 3. Repartitions of the real and imaginary parts of the eddy current density in the two plies obtained by the simplified formulation ($l=1mm$)

Figure 3 represents the repartitions of the real and imaginary parts of the eddy current density in the two plies obtained by the T_z formulation. We notice that the imaginary part is concentrated near the coil position whereas the real part is more stretched along the axis of the high conductivity.

For a fixed lift off ($l=1mm$), figure 4 shows the real and imaginary parts of ΔZ for different values of the frequency, obtained by the two formulations. Similarly, for a fixed frequency ($f=1MHz$), figure 5 shows the variations of the real and imaginary parts of ΔZ according to the lift off. As the lift-off decreases, the normal component of the source field becomes predominant and its tangential components decrease until cancellation at the limit when the lift off becomes nil. In this case, we notice a difference between the values of ΔZ obtained by the two formulations. This difference may be due to numerical errors in the $T-\phi$ model engendered by the fact of calculating quantities which are in reality nil.

Fig. 4. The variations of the real and imaginary parts of ΔZ according to frequency ($l=1mm$)

Abstract—The finite element method (FEM) is developed to solve the diffusion equation containing the moving term. For the solution of the large sparse non-symmetrical, the preconditioned biconjugate gradient stabilized (PBICGSTAB) method is presented, combining the ILU[p] preconditioner and BICGSTAB method. The magnetic field distribution of Permanent Magnet Linear Motor (PMLM) problems is calculated by the FEM electromagnetic package including the proposed PBICGSTAB algorithm. Then the results are compared to those from the commercial software ANSYS, showing the validation of this analysis technique. Comparisons between PBICGSTAB method and other widely used algorithms show that PBICGSTAB is speedy, applicable to solve system of large-scale non-symmetrical linear equations.

Index Terms—BICGSTAB Algorithm, Precondition technique, Permanent Magnet Linear Motor

I. INTRODUCTION

The study of moving PMLM through analytical methods requires many simplifications, leading to huge errors. Numerical methods have become progressively more important than analytical methods in the solution of nonlinearity, anisotropy and motion problems. Among various numerical methods, FEM is the most powerful one.

A non-symmetrical system with sparse matrix is obtained after Galerkin technique is applied to the convective-diffusion equation which involves the moving effect. In the previous papers, the linear equations were solved using the direct algorithm of Gaussian elimination. However, the cost in terms of computer operations and storage is unbearable when the number of equations is large enough. Iterative methods have become major methods for solving linear systems, especially for the large, sparse one. There are many iterative methods used for non-symmetrical linear systems, such as CGS, BICG, QMR and GMRES methods. However, CGS and BICG methods have irregular convergence behavior[1]. QMR method applies a least squares method to solve and update the BICG residuals, thereby smoothing out the irregular convergence behavior. Also, QMR avoids the breakdown that can occur in BICG, but transpose matrix is required[2]. GMRES method has monotonic convergence and only involves one matrix-vector product with the coefficient matrix, but the amount of storage and operation count increase as the iteration progresses[3]. Therefore, these methods have considerable limitations in the practical application.

The paper is arranged as follows. In section II, a new simulation model for magnetic field of a moving Permanent Magnet linear motor is developed and BICGSTAB algorithm

is expatiated in detail. In order to verify the proposed method, a single-sided PMLM problem is presented as an example in section III.

II. NUMERICAL SIMULATIONS

A. Simulation model

The electromagnetic fields in PMLM can be expressed with the Maxwell equations with the vector magnetic potential \vec{A} as the variable,

$$\nabla \times (\gamma \nabla \times \vec{A}) - \sigma \nabla \times \vec{A} = \vec{J}_s \quad (1)$$

Where; ∇ is the velocity of PMLM; σ and γ is the conductivity and reluctivity, respectively; \vec{J}_s is the equivalent current density for permanent-magnet.

If the PMLM is computed in two-dimensions and it moves along the x-axis, the formulation can be simplified as,

$$\frac{\partial}{\partial x} (\gamma \frac{\partial A}{\partial x}) + \frac{\partial}{\partial y} (\gamma \frac{\partial A}{\partial y}) = V \sigma \frac{\partial A}{\partial x} - J_s \quad (2)$$

By using the Galerkin method, (2) becomes an integral equation,

$$\int_s \nabla W_i \cdot \nabla A ds + V \sigma \int_s \frac{\partial A}{\partial x} W_i ds - \gamma \int_{\Gamma} W_i \nabla A ds = \int_s J_s W_i ds \quad (3)$$

where the weighting function W_i is set to be equal to an interpolation function. The last term on the left hand side is the integral on the boundary Γ enclosing the whole computation region. One can obtain the large sparse linear equations after discretizing (3) and imposing the boundary conditions,

$$[K][A] = [f] \quad (4)$$

where $[K]$ is a coefficient matrix of order n ; $[A]$ is unknown vector to be solved; $[f]$ is the source on the right hand side.

B. BICGSTAB algorithm

BICGSTAB algorithm is a variant of the BICG method. The algorithm can be considered as a product of the BICG method and the GMRES method. The residual vector is

minimized locally by GMRES method local step. BICGSTAB algorithm does not use the transpose of the matrix K in the calculation of the recurrences. This is advantageous for cases where the transpose of the matrix K is not readily available. However, when the GMRES step stagnates, the residual vector is not minimized and the algorithm breaks down.

The iterative formula of BICGSTAB method can be written as follow:

$$(1) \quad r_0 = f - K \cdot x_0, \quad \bar{r}_0 = r_0, \quad p_0 = r_0$$

$$(2) \quad MY_j = p_j, \quad \alpha_j = \frac{(r_j, r_j)}{(r_j, KY_j)}, \quad s_j = r_j - \alpha_j KY_j$$

$$MZ_j = s_j, \quad \omega_j = \frac{(KZ_j, s_j)}{(KZ_j, KZ_j)}$$

$$x_{j+1} = x_j + \alpha_j Y_j + \omega_j Z_j, \quad r_{j+1} = s_j - \omega_j KZ_j$$

$$\beta_{j+1} = \frac{\alpha_j \cdot (r_{j+1}, r_{j+1})}{\omega_j \cdot (r_j, r_j)}, \quad p_{j+1} = r_{j+1} + \beta_j (p_j - \omega_j KZ_j)$$

$$(3) \quad \|r_{j+1}\|_2 / \|r_0\|_2 < \varepsilon,$$

where matrix M is called a preconditioner obtained by ILU[0] method, that is incomplete LU factorization without fill-ins[4];

If (3) holds, final result x_{j+1} is got, and the computation is over. Otherwise, set $j = j + 1$, and go back to (2) until (3) is satisfied.

III. ANALYSIS OF A PMLM

In order to prove the validation of the proposed method, a single-sided PMLM moving at low speed is simulated. Then the results are compared to those from the commercial software ANSYS.

Fig.1 shows us the magnetic field distribution of PMLM when secondary moving relative to primary at a speed of 10cm/s. From Fig.1, one can see that secondary's velocity affects magnetic field distribution, called dynamic longitudinal end effect. It makes the magnetic field increase at entry end and decrease at exit end. The magnitude of effect depends on moving velocity.

Fig.2 shows the flux densities along the centerline of gap. X-axis component and Y-axis component of flux density is provided respectively. As a result of end effect, flux density unequal to zero in the air gap at the end of primary.

(a) Magnetic field distribution by proposed method

(b) Magnetic field distribution by ANSYS.

Fig. 1 The magnetic field distribution of PMLM

In order to compare the rate of convergence and the convergence characteristic, convergence curves of various

(a) Flux density along X-axis (b) Flux density along Y-axis
Fig. 2 The flux density along air gap

Fig. 3 Convergence curves of iterative methods

iterative methods is provided in the Fig. 3. As we can see in the figure above, the best method is PBICGSTAB method which converges rapidly to the precise results without oscillation. Also, through the contrast between BICGSTAB method and PBICGSTAB method, precondition techniques have been proved to be of great importance in the solution of large, sparse systems.

IV. CONCLUSIONS

In this paper, the mathematical model for magnetic field of moving Permanent Magnet linear induction motors has been developed. A new favorable iterative algorithm has been presented for solving large sparse non-symmetrical systems formed from discretization by finite element methods. A single-sided PMLM has been simulated with the proposed algorithm. The computed results are found to be in good agreement with those obtained from ANSYS shown in Fig. 1 and Fig. 2.

Abstract — The system resulting from FEM–BEM formulations inherits all characteristics of both finite element and boundary element equation system, i. e., the system is partially sparse and symmetric and partially full and nonsymmetric. Consequently, to solve the resulting coupled equation system is not a trivial task. This paper proposes a new efficient lifting-based two level preconditioner for the FEM-BEM global system. The proposed approach is applied to solve the coupled systems resulting from the electromagnetic scattering problem and its performance is evaluated based on the number of iterations and the computational time. Traditional methods based on incomplete and complete LU decompositions are used for comparison.

I. INTRODUCTION

The Finite Element and the Boundary Element Methods can be considered complementary to each other in many cases. It is particularly true to problems where the domain considered is formed by two (or more) regions where one of them is characterized by non-homogeneous material while the other is free space. This kind of problem is difficult to be solved by any individually method described above. Therefore, a combination of two the previous techniques comes up as a powerful way to solve it [1].

The system resulting from FEM–BEM formulations inherits all characteristics of both finite element and boundary element equation system, i. e., the system is partially sparse and symmetric and partially full and nonsymmetric [1],[2]. Consequently, the efficient solution of the FEM-BEM system has been object of many researches [3],[4]. In fact, most of the proposed approaches are based on some adaptations. In the algebraic multigrid context, for example, one should consider a fast matrix-by-vector multiplication for dense matrices and to use some matrix approximation technique for the BEM dense matrix. In particular, common smoother types do not work properly in the case of the single layer potential [5]. In face of that, this work proposes a new efficient two level preconditioner for the global FEM-BEM system based on the lifting technique. This proposed approach is applied to some real-life FEM-BEM coupled systems and its performance is evaluated based on the number of iterations and the computational time. Traditional methods based on incomplete and complete LU decompositions are used for comparison.

II. PROBLEM FORMULATION

The scattering problem was chosen to show the performance of the proposed approach. This kind of problem

occurs when an object is struck by an electromagnetic wave. To solve this problem by hybrid technique an artificial surface must be chosen, which allows divide scattering problems in two regions. The first, Ω_∞ , is the free space with permeability μ_0 and permittivity ε_0 . The second region Ω may consist in general of non-homogeneous material with permeability $\mu(x,y)$ and permittivity $\varepsilon(x,y)$. Once the two regions are known, the electromagnetic fields in each one can be formulated.

A. Finite element formulation

The Helmholtz differential equation describes the field behavior in region Ω . In general form, the Helmholtz equation could be written as [2]

$$\nabla \cdot (\alpha_1 \nabla u) + k_0^2 \alpha_2 u = 0, \quad (1)$$

where, $k_0^2 = w \sqrt{\mu_0 \varepsilon_0}$ represent the wave number. Also, for electric field polarization $\alpha_1 = 1/\mu_r$, $\alpha_2 = \varepsilon_r$ and $u = E_z$ while for magnetic field polarization $\alpha_1 = 1/\varepsilon_r$, $\alpha_2 = \mu_r$ and $u = H_z$.

The *weak formulation* given by (2) is well known and its derivation will be omitted here [2].

$$\int_{\Omega} \nabla w \cdot (\alpha_1 \nabla u^*) d\Omega - \int_{\Omega} k_0^2 \alpha_2 w \cdot u^* d\Omega - \int_{\Gamma} w \alpha_1 \frac{\partial u^*}{\partial n} d\Gamma = 0 \quad (2)$$

in which u^* is an approximation for u and w is the weight function.

Applying Galerkin's procedure in (2) the following general set of equations is determined [2],

$$[K]\{d\} + [C]\{k\} = 0 \quad (3)$$

where $[K]$ is a $n \times n$ square matrix and $[C]$ is a $n \times m$ rectangular matrix, with m and n representing the total number of the nodes on the boundary and the interior domain, respectively. Also, $\{d\}$ is a column vector for field arguments and $\{k\}$ is a column vector for the normal derivative field arguments.

B. Boundary element formulation

In free space, Ω_∞ , the field also are formulated by Helmholtz equation. The general formulation for both electric and magnetic fields is:

$$\nabla^2 u(\vec{r}) + k_0^2 u(\vec{r}) = f(\vec{r}) \quad \forall \vec{r} \in \Omega_\infty \quad (4)$$

in which, for electric polarization $u = E_z$, $f(\vec{r}) = jk_0 Z_0 J_z - \nabla \times M_i$ and for magnetic polarization $u = H_z$, $f(\vec{r}) = j(k_0/Z_0)M_i - \nabla \times J_z$. Where, Z_0 is the intrinsic impedance of the free space, J_z represents all currents that flow along z-axis and M_i is the impressed magnetic source.

Then, introducing the free space Green's function, the Sommerfeld radiation condition and applying the second scalar Green's theorem and Dirac properties for all nodes on the boundary, it produces [1],[2]

$$\{u\} = \{b\} + [H]\{d\} + [Q]\{k\}, \quad (5)$$

where, $[H]$ and $[Q]$ are $m \times m$ matrices obtained from the discretization and $\{b\}$ is a $m \times 1$ incident field column vector.

The system resulting from FEM-BEM formulations can be expressed in the in following form:

$$\begin{bmatrix} K & C \\ -H & -Q \end{bmatrix} \begin{Bmatrix} d \\ k \end{Bmatrix} = \begin{Bmatrix} 0 \\ b \end{Bmatrix} \quad (6)$$

which is partially sparse and symmetric and partially full and nonsymmetric [1],[2].

III. LIFTING BASED TWO-LEVEL PRECONDITIONER

The approach proposed here is based on a projection method. In this process an approximation for the solution of a linear system is extracted from a subspace \mathcal{K} of \mathbb{R}^n which is the search subspace. If m is the dimension of \mathcal{K} , then the residual vector $b - Ax$ is constrained to be orthogonal to the same subspace \mathcal{K} . Mathematically, denoting by V a $n \times m$ matrix whose column-vectors form a basis of \mathcal{K} , the approximate solution is written as

$$x = x_0 + Vy, \quad (7)$$

in which y is obtained solving the following system of equations from the orthogonality condition [6]

$$V^T AVy = V^T r_0 \quad (8)$$

Then, if the $m \times m$ matrix $V^T AV$ is nonsingular, the expression for the approximate solution \tilde{x} becomes,

$$\tilde{x} = x_0 + V(V^T AV)^{-1}V^T r_0 \quad (9)$$

In the lifting based approach, the matrix $V^T AV$ is obtained by the decomposition of the linear system A induced by the discrete lifting wavelet transform, with the Haar lowpass filter matrix V^T [7]. Therefore, this approach can be viewed as a two-level multigrid algorithm in which the $V^T AV$ matrix is formed by the detail coefficients obtained from the discrete lifting wavelet transform.

IV. NUMERICAL RESULTS

The Lifting based two-level method (LTL) was applied as a preconditioner for the Stabilized Bi-Conjugate Gradient

Method (BiCGStab) in the solution of two global coupled FEM-BEM systems. Both were obtained for a circular cylinder with 0.3λ diameter, $\epsilon_r = 3$ and wave length $\lambda = 1$. The cylinder is struck by a TM_z plane wave with incident angle of $\theta^i = 180^\circ$.

The results related to the number of iterations and setup and solver time are presented in tables I and II. The number of iterations corresponds to the number of BiCGStab steps necessary to reduce the Euclidean norm of the residual vector to the order of 10^{-6} . In the tests, the system with the $V^T AV$ matrix in LTL was solved by incomplete LU solver (LTL-1) and with a direct method (LTL-2). The Incomplete LU (ILU) preconditioner and the direct solver based on the complete LU decomposition were used for comparison.

TABLE I
RESULTS FOR A SMALL GLOBAL FEM-BEM MATRIX ($N=147, NZ=3867$)

Method	Setup time (seconds)	Number of iterations	Solver time (seconds)
LTL-2 and BiCGStab	0,03	24	0,28
LTL-1 and BiCGStab	0,08	28	0,33
ILU and BiCGStab	0,22	17	0,28
Complete LU	--	--	0,13

TABLE II
RESULTS FOR A MEDIUM GLOBAL FEM-BEM MATRIX ($N=2119, NZ=87133$)

Method	Setup time (seconds)	Number of iterations	Solver time (seconds)
LTL-2 and BiCGStab	37,83	93	37,47
LTL-1 and BiCGStab	7,11	118	49,03
ILU BiCGStab	42,81	101	46,42
Complete LU	--	--	306,45

V. CONCLUSIONS

The approach proposed in this work revealed to be very efficient and promising to solve the global systems of coupled FEM-BEM equations, mainly for the medium and large problems. The usual complete LU decomposition method is a good choice for small problems, but is very expensive for larger problems, as can be viewed in table II. For large problems, where an efficient preconditioner is required, the Lifting based two-level method give us the best results.

watanabe@ssi.ist.hokudai.ac.jp

Abstract — This paper discusses parallel computation of finite element (FE) analyses using domain decomposition. The overlapping domain decomposition method is an effective method for distributed memory computers. A preconditioner based on the Incomplete Cholesky decomposition is introduced for this method so as to improve the convergence of iteration. On the other hand, the hierarchical domain decomposition method is also known as a parallel computation method with high parallel efficiency. We compare a performance between the overlapping and hierarchical domain decomposition method. The numerical results show that the overlapping domain deposition method using stabilized conjugate gradient method has less computational cost than the hierarchical domain decomposition method.

I. INTRODUCTION

It is important to make fast computation of large scale finite element analyses in the development of electromagnetic machines. Although these analyses can be performed using expensive super computers, it is unacceptable in view of reducing the cost of development. Hence, the large scale analyses should be performed fast on popular computation environment such as PC clusters.

The parallel computation methods for electromagnetic field analysis have been investigated so far. The domain decomposition method is one of effective method so as to distribute the large system matrix to the PEs (Processor Elements) [1]. The incomplete Cholesky (IC) decomposition is a useful and stable pre-conditioner for preconditioned conjugate gradient (PCG) method. However, it is not suitable for domain decomposition method due to the cross components between divided sub domains. The simple solution of this difficulty is that the cross components are neglected. However, the convergence of PCG method with this preconditioner is considerably poor. The overlapping domain decomposition method has introduced in order to overcome this difficulty. The disadvantage of the overlapping method is increase of communication cost in the distributed memory environment.

The hierarchical domain decomposition method is another domain decomposition method for distributed memory computers [2-3]. In this method, a solution of governing equation is obtained to solve the unknowns about interface of sub domains (interface problem) and the unknowns about inner sub domains. This method has a significant high parallel efficiency. However, it is difficult to apply the strong preconditioner such as IC decomposition to the interface

problem, because the system matrix for interface problem is given implicitly. Therefore, this method has high computational cost.

In this paper, we compare performance between the overlapping domain decomposition and the hierarchical domain decomposition method on popular computational environment such as a PC cluster.

II. METHODS

A. Overlapping Domain Decomposition

Let us consider the electromagnetic field analysis using the finite element method with edge elements. In order to distribute the whole system matrix K to the PEs, the set of all edges G is divided into non-overlapping subset G_k ($k=1, 2, \dots, n_p$) where n_p is the number of sub domains, and $G_i \cap G_j = \emptyset$, $i \neq j$, i.e., there are no overlapped edges in G_k .

We define set of elements \tilde{E}_k which includes at least one edge in G_k . We also define the set of edges \tilde{G}_k as a set of edges contained in \tilde{E}_k . It is noted that G_k is a subset of \tilde{G}_k . We introduce the restriction operator R_k mapping from the space G spanned by all edges to the space spanned by G_k . The restriction operator \tilde{R}_k mapping from G to \tilde{G}_k is also defined. The preconditioned matrix M can be obtained as,

$$M = \sum_{k=1,2,\dots,n_p} \tilde{R}_k^T \tilde{M}_k \tilde{R}_k^T, \quad (1)$$

where \tilde{M}_k is the IC decomposition matrix corresponding to the overlapping restricted system matrix \tilde{K}_k . The preconditioner defined by (1) is a kind of Additive Schwarz Preconditioner. The convergence of PCG with this preconditioner is better than that of PCG using the simple IC decomposition of the non-overlapping system matrix $K_k \equiv R_k K R_k^T$.

Instead of (1), we introduce a following preconditioned matrix

$$M = \sum_{k=1,2,\dots,n_p} R_k R_k^T \tilde{R}_k^T \tilde{M}_k \tilde{R}_k^T. \quad (2)$$

It is known that the term $R_k R_k^T$ in (2) results in decrease the maximum eigenvalue and the condition number of M , hence, the convergence of PCG can be improved. Moreover,

9. Numerical Techniques

the cost of communication in (2) is less than that in (1). In compensation for these advantages, the matrix M in (2) is non-symmetric. As a result, linear solvers for non-symmetry should be used.

B. Hierarchical domain decomposition

The hierarchical domain decomposition method is an iterative domain decomposition method for improving parallel efficiency. The system equation can be separated as,

$$\begin{bmatrix} K^{II} & K^{IF} & K^{IB} \\ K^{FI} & K^{FF} & K^{FB} \\ K^{BI} & K^{BF} & K^{BB} \end{bmatrix} \begin{Bmatrix} x^I \\ x^F \\ x^B \end{Bmatrix} = \begin{Bmatrix} b^I \\ b^F \\ b^B \end{Bmatrix}, \quad (3)$$

where subscript I denotes inner regions, F denotes interfaces of sub domains, B is the boundary of whole domain [4]. Equation (3) is rewrite the following equations,

$$K^{II} x^I = (b^I - K^{IF} x^F - K^{IB} x^B), \quad (4a)$$

$$\begin{aligned} (K^{FF} - K^{FI} K^{II-1} K^{IF}) x^F &= b^F - K^{FI} K^{II-1} b^I \\ &- (K^{FB} - K^{FI} K^{II-1} K^{IB}) x^B, \end{aligned} \quad (4b)$$

Equation (4a) can be solved easily, however, the interface problem (4b) is hard to solve because the system matrix of (4b) is given implicitly. Therefore it is difficult to construct the preconditioner for (5b). As a result, the computational cost of this method is higher than that of the overlapping domain decomposition method.

III. NUMERICAL RESULTS

To compare the performance of the above described methods for domain decomposition, we analyze a perpendicular magnetic recording head model shown in Fig. 1. The IC decomposition with shift parameter ($=1.12$) is used as preconditioner. The numerical results described below are performed on a PC cluster consisting of 4 PEs (Pentium4 3.4GHz, 2GB RAM for each PE, two gigabit Ethernet are used for communication among PEs). The program code is written in C++ with MPI (Message Passing Interface).

Figure 2 shows an acceleration ratio normalized by the computation time in PE=1. The notation "ICCG" in the Figure is the CG method with the conventional preconditioner defined by (1), "GPBiCR" is a Generalized Product-type Bi-Conjugate Residual method combined with the preconditioner defined by (2). This ratio of these methods linearly increases with the number of PEs. Moreover, GPBiCR method shows good efficiency compared with the ICCG method.

Table I shows a computational time in PEs = 4. The computational time of the hierarchical domain decomposition method is significantly slower than that of other methods, because it takes much iteration to solve (4b). For this reason,

the overlapping domain decomposition method is suited on small size parallel computation environment.

Fig. 1. Analysis model of perpendicular magnetic recording head, (Number of elements = 266112).

Fig. 2. Parallel efficiency on PC cluster.

Kernel Regularization for Volume Integral Equations

Michael V. Davidovich
Saratov State University
Astrakhanskaya street, 83, Saratov, 410012, Russia
DavidovichMV@info.sgu.ru

Abstract— The methods of reducing of kernel singularity order for volume integral equations have been considered and some new kind of volume integral and integrodifferential equations with surface terms have been proposed.

I. INTRODUCTION

The regularization in the theory of singular integral equation (IE) [1-2] usually means the detachment of singular part of kernel with the posterior full or partial inversion of integral (integrodifferential) operator [1-2]. At that the first kind Fredholm singular IE is transformed into the second kind one. This approach is widely used for one-dimensional IE with Cauchy and logarithmical singularities. The term “regularization” is also used for the solutions of incorrect problems. In the works [3-6] the term “regularization” has been applied as the main kernel singularity detachment and reducing for two-dimensional immittance (impedance or admittance) IE, i.e. it aims only to kernels. The introducing of auxiliary potentials, the application of vector integral theorems, the integration over the observation point, and some other methods have been applied to realize this [3-6]. The reducing of kernel singularity allows one to use the more simple piece-constant or piece-linear base functions which is not applicable for initial IE owing to divergence of matrix elements.

There are volume IEs and integrodifferential equation (IDEs) in applied electrodynamics which may be obtained by several ways [7-10] and have strong nonintegrable singularities. In this work the method of tensor Green’s functions (GFs) has been used to realize this purpose. After the regularization the vector piecewise constant and linear volume finite elements may be applicable to solve the volume IE.

II. THE REDUCTION IE TO IDE

Let consider a dielectric body with volume V confined by regular surface S in the free space which is excited by incident harmonic in time field $\vec{E}_{inc}(\vec{r})$. Let the field sources are located outside the body i.e. the field $\vec{E}_{inc}(\vec{r})$ inside and near the body is solenoidal. Let also the permittivity $\varepsilon(\vec{r})$ is the continuously differentiable function inside the V and may have the jump discontinuity on the S . In the case of jump the normal component of permittivity also has the jump, therefore let denote its values on the inner and outer part of surface S as “-” and “+” correspondingly. The scattered field is determined by GF as

$$\vec{E}(\vec{r}) = \vec{E}_{inc}(\vec{r}) + j\omega\varepsilon_0 \int_V \Gamma^{ee}(\vec{r} - \vec{r}') (\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') d\vec{r}', \quad (1)$$

where the electrical tensor (dyadic) GF of electrical kind is introduced [10]:

$$\Gamma^{ee}(\vec{r} - \vec{r}') = \frac{\nabla \otimes \nabla + k_0^2 \hat{I}}{j\omega\varepsilon_0} G(\vec{r} - \vec{r}') = \frac{\nabla' \otimes \nabla' + k_0^2 \hat{I}}{j\omega\varepsilon_0} G(\vec{r} - \vec{r}'). \quad (2)$$

This GF is determined through the scalar GF of free space

$$G(\vec{r}) = (4\pi|\vec{r}|)^{-1} e^{-jk_0|\vec{r}|}. \quad (3)$$

Here the operation \otimes denotes the dyadic or tensor (direct) multiplying (thus $(\vec{a} \otimes \vec{b})_{kl} = a_k b_l$, $k, l = x, y, z$), \hat{I} is the unit tensor, $r \equiv |\vec{r}|$, $\vec{r}_0 = \vec{r}/r$ is the unit vector directed along the radius-vector, $d\vec{r} \equiv dV$ is the volume element, the operator ∇ acts on the observation point coordinates (without stroke), and ∇' - correspondingly on source ones. GF (2) may be presentable in the form

$$\Gamma^{ee}(\vec{r}) = \frac{-e^{-jk_0 r}}{4\pi j\omega\varepsilon_0 r} \left\{ \left(\frac{1}{r^2} + \frac{jk_0}{r} \right) (\hat{I} - 3\vec{r}_0 \otimes \vec{r}_0) + k_0^2 (\vec{r}_0 \otimes \vec{r}_0 - \hat{I}) \right\}, \quad (4)$$

and the volume IE (1) may be written as

$$\vec{E}(\vec{r}) = \vec{E}_{inc}(\vec{r}) + (\nabla \nabla \cdot + k_0^2) \int_V G(\vec{r} - \vec{r}') (\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') d\vec{r}'. \quad (5)$$

Here the operator $\nabla \nabla \cdot \equiv grad \cdot div$ is introduced. It acts on arbitrary vector \vec{a} as dyadic multiplication: $\vec{b} = (\nabla \otimes \nabla) \vec{a} = \nabla \nabla \cdot \vec{a} = \nabla \nabla \cdot \vec{a} = grad(div \vec{a}) = (grad \cdot div) \vec{a}$. The relation (1) is the consequence of equivalence the polarization currents to influence of body [7-9]. The strong singularity arises owing to double differentiation of weak singularity $|\vec{r} - \vec{r}'|^{-1}$. Our goal is to transfer the differentiation from not stroked coordinates to stroked ones, i.e. on integrand function. Therefore we want to transform the IE into IDE. Such transformation may lead to surface integrals. We will use the following identities:

$$\nabla G(\vec{r} - \vec{r}') = -\frac{(\vec{r} - \vec{r}') e^{-jk_0|\vec{r} - \vec{r}'|}}{4\pi|\vec{r} - \vec{r}'|^2} \left\{ \frac{1}{|\vec{r} - \vec{r}'|^2} - \frac{jk_0}{|\vec{r} - \vec{r}'|} \right\} = -\nabla' G(\vec{r} - \vec{r}'), \quad (6)$$

$$\nabla \cdot (G(\vec{r} - \vec{r}') \vec{a}(\vec{r}')) = -\nabla' \cdot (G(\vec{r} - \vec{r}') \vec{a}(\vec{r}')) + G(\vec{r} - \vec{r}') \nabla' \cdot \vec{a}(\vec{r}'). \quad (7)$$

Therefore

$$\vec{F}(\vec{r}) = \vec{F}_V(\vec{r}) + \vec{F}_S(\vec{r}) = \vec{E}(\vec{r}) - \vec{E}_{inc}(\vec{r}) - k_0^2 \int_V G(\vec{r} - \vec{r}') (\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') d\vec{r}' = \quad (9)$$

$$= \nabla \int_V \left[G(\vec{r} - \vec{r}') \nabla' \cdot \left[(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') \right] - \nabla' \cdot \left[G(\vec{r} - \vec{r}') (\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') \right] \right] d\vec{r}',$$

$$\vec{F}_V(\vec{r}) = -\int_V \nabla' \cdot \left[(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') \right] \nabla G(\vec{r} - \vec{r}') d\vec{r}'. \quad (9)$$

$$\begin{aligned} \vec{F}_S(\vec{r}) &= -\nabla \oint_S G(\vec{r} - \vec{r}') (\varepsilon^-(\vec{r}') - 1) \vec{r}' \cdot \vec{E}^-(\vec{r}') dS' = \\ &= \oint_S (\varepsilon^-(\vec{r}') - 1) \vec{r}' \cdot \vec{E}^-(\vec{r}') \nabla G(\vec{r} - \vec{r}') dS'. \end{aligned} \quad (10)$$

Here we list the several kind of IDE with integrable kernels. For sharp body boundary

$$\begin{aligned} \vec{F}(\vec{r}) = & - \int_V \frac{(\vec{E}(\vec{r}') \nabla' \cdot \varepsilon(\vec{r}')) \nabla' G(\vec{r} - \vec{r}')}{\varepsilon(\vec{r}')} d\vec{r}' + \\ & + \oint_S (\varepsilon^-(\vec{r}') - 1) (\vec{\nu}(\vec{r}') \vec{E}^-(\vec{r}')) \nabla' G(\vec{r} - \vec{r}') dS'. \end{aligned} \quad (11)$$

After the transferring the second derivative to source point

$$\begin{aligned} -\vec{F}_V(\vec{r}) = & \int_V \left\{ G(\vec{r} - \vec{r}') \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] \right\} - G(\vec{r} - \vec{r}') \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] d\vec{r}'. \end{aligned} \quad (12)$$

Using the theorem about gradient it may be transformed to

$$\begin{aligned} \vec{F}_V(\vec{r}) = & \int_V G(\vec{r} - \vec{r}') \nabla' \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] d\vec{r}' - \oint_S G(\vec{r} - \vec{r}') \vec{\nu}(\vec{r}') \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] dS'. \end{aligned} \quad (13)$$

Let the observation point is inside the S . Surrounding it by infinitely small sphere of radius ρ and using the relation (13) for S and sphere one can get in spherical coordinates coincided with center of sphere

$$\vec{I} = - \oint_{S_\rho} |\vec{r}|^{-1} \vec{\nu}(\vec{r}) f(\vec{r}) dS = - \rho \int_0^\pi \sin \theta d\theta \int_0^{2\pi} f(\rho, \theta, \varphi) \vec{r}_0 d\varphi$$

where $f(\vec{r}) = \text{div} [(\varepsilon(\vec{r}) - 1) \vec{E}(\vec{r}) e^{-jk_0|\vec{r}|}]$. To calculate the projection on the axis z it is necessary to change \vec{r}_0 on $\vec{r}_0 \vec{z}_0 = \cos \varphi$. Since $f(\rho, \theta, \varphi)$ is continuous and finite at $\rho \rightarrow 0$, then the angle integral is finite and the projection tends to zero. We consider that divergence is continuous up to inner side of S , so in the presence of permittivity jump the surface integral must be calculated on the inner side (it is zero on the outer side). Thus,

$$\begin{aligned} \vec{F}(\vec{r}) = & \int_V G(\vec{r} - \vec{r}') \nabla' \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] d\vec{r}' + \\ & + \oint_S [(\varepsilon^-(\vec{r}') - 1) (\vec{\nu}(\vec{r}') \vec{E}^-(\vec{r}')) \nabla' G(\vec{r} - \vec{r}') - \vec{\nu}(\vec{r}') G(\vec{r} - \vec{r}') \nabla' \cdot [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')]] dS'. \end{aligned} \quad (14)$$

Using the foregoing smoothing and calculating the integral over the slab with usage of formula for gradient from the inner product in the value

$$\vec{s}(\vec{r}) = \nabla \nabla \cdot [(\varepsilon(\vec{r}) - 1) \vec{E}(\vec{r})] = -\nabla \nabla \cdot \vec{E}(\vec{r}) = \nabla \frac{\vec{E}(\vec{r}) \nabla \cdot \varepsilon(\vec{r})}{\varepsilon(\vec{r})}$$

one can exactly get the surface integral in (14). Let's consider one more variant of initial equation transformation. Let there are the arbitrary differentiable vector functions $\vec{a}(\vec{r}')$ and $\vec{b}(\vec{r} - \vec{r}')$. Then $\nabla(\vec{a} \cdot \vec{b}) = \nabla'(\vec{a} \cdot \vec{b}) + (\vec{b} \nabla') \vec{a} + \vec{b} \times (\nabla' \times \vec{a})$. Let

$$\vec{F}(\vec{r}) = -\nabla \int_V (\varepsilon(\vec{r}) - 1) \vec{E}(\vec{r}') \nabla' G(\vec{r} - \vec{r}') d\vec{r}'$$

Applying the above relation and using the theorem about gradient, one can get

$$\begin{aligned} \vec{F}(\vec{r}) = & \oint_S \vec{\nu}(\vec{r}') [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}') \nabla' G(\vec{r} - \vec{r}')] dS' - \\ & - \int_V \left\{ \nabla' G(\vec{r} - \vec{r}') \cdot \nabla' [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] + \nabla' G(\vec{r} - \vec{r}') \times \nabla' \times [(\varepsilon(\vec{r}') - 1) \vec{E}(\vec{r}')] \right\} d\vec{r}'. \end{aligned} \quad (15)$$

III. THE DIRECT INTEGRATION METHOD

According to Helmholtz's theorem the arbitrary vector may be presented by its solenoidal and potential parts. Let's divide the electrical field into solenoidal and potential parts:

$$\vec{E} = \vec{E}_s + \vec{E}_p, \text{ or}$$

$$\vec{E}(\vec{r}) = \nabla \times \vec{C} - \nabla \Phi. \quad (16)$$

Our goal is to reformulate the equation (9) for \vec{C} and Φ . As \vec{E} is the polar vector that Φ is the scalar, and \vec{C} is the pseudovector (axial vector). The choice of this values is not single-valued as \vec{C} may be added by gradient of arbitrary pseudoscalar ψ , and the potential Φ may be defined accurate within arbitrary constant c_0 . In order to exclude the ambiguity in \vec{C} , let subjugate it by the conditions $\text{div} \vec{C} = 0$, i.e. consider it solenoidal. Thus, the introduced values satisfy relations

$$\nabla \cdot \vec{E}(\vec{r}) = -\nabla^2 \Phi, \quad (17)$$

$$\nabla \times \vec{E}(\vec{r}) = \nabla \times \nabla \times \vec{C} = (\text{grad} \cdot \text{div} - \nabla^2) \vec{C} = -\nabla^2 \vec{C}, \quad (18)$$

$$\vec{E}_{inc}(\vec{r}) = \nabla \times \vec{C}_0(\vec{r}). \quad (19)$$

The equations (17)-(19) have been integrated and, as the result, the new coupled IEs have been obtained for Φ and \vec{C} . The coupling is realizing by virtue of that the field normal component on S is defined by both parts of vector \vec{E} . The function Φ at $k_0 \rightarrow 0$ defines the own potential for charge density under the body polarization by incident field which must tend to zero at infinity. The Poisson equation arises as the result of transformations

IV. NUMERICAL RESULTS AND CONCLUSIONS

The proposed IEs and IDEs have been numerically investigated and used for numerous diffraction and eigenvalue problems. They demonstrate very high effectiveness.

Error Estimators based on Kriging Interpolation

Vanessa Gomes Cruz, Luiz Lebensztajn

Abstract — The calculation of electromagnetic fields, based on the finite element method, involves a judicious division of the domain under study. This division strongly affects the accuracy of numerical results. This work proposes three different error estimators, all based on Kriging interpolation. These estimators have a high ability to identify regions where the solution has high error in the numerical solution. Thus, it is possible to obtain, through a structure based on the computational paradigm of adaptive meshes, a strong improvement in the quality of the mesh and therefore increase the precision of the response of the problem under analysis.

I. INTRODUCTION

The solution of partial differential equations by the Finite Element Method (FEM) has become extremely popular and this can be observed on different branches of engineering. Most of this popularity is associated to the increase computer processing capacity, but the techniques which provide the automatic generation of finite elements also. The objective of this work is to examine a particular form of automatic generation: the adaptive approach. It is an iterative process, which is divided in the following steps [1]:

Step1) Build a finite element mesh

Step2) Solve the FEM problem.

Step3) Error evaluation of the FEM solution.

Step4) Treatment of errors.

Step5) Stopping criterion. If it is satisfied, the process ends.

Step6) A finite element mesh is refined, where high errors were detected to build a new finite element mesh. Go to Step 2

The fundamental problem is to define a robust estimator of errors, a reliable strategy for deal with the errors, an appropriate refinement technique and a good stop criterion. There are several attributes associated to an adaptive finite element mesh process. The definition of a robust error estimator is, probably, the most critical. Error estimation has a strong relationship with the physical phenomenon under study, i.e., there are some guidelines to obtain high precision in the MEF context, and this can be explained in several ways:

1- places where the variation of field is high, are more sensitive to error

2- places where the variation of the stored energy is more intense should be associated with a fine mesh and vice-versa. This is strongly correlated with the previous one.

3- the solution accuracy depends on the size of the element and its shape. Elements with small angles will be avoided [2].

II. THE ADOPTED ERROR ESTIMATORS

In this work, error estimators will be computed based on Kriging interpolation [3], a statistical tool, which has become

very popular in the electromagnetic field community, particularly on works, which deals with optimization.

The error estimators were developed from three different concepts: the error associated to the flux of the magnetic induction vector, the gradient of the magnetic energy with respect to the position and the difference between the two ways of calculating the field. In all three cases, Kriging functions were adopted to perform the error on the FEM solution. With the Kriging interpolation of the magnetic potential vector, it is easy to find the values of the magnetic induction vector.

A. The error associated to the flux of the magnetic induction vector

This adopted error estimator is highly connected to the physical phenomenon. If the solution found by the FEM has high reliability, then a Kriging approximation performed on this solution must also to be a good candidate to solve the differential equation, which governs the phenomenon. Thus, applying the equations of Maxwell on the Kriging approximation is a criterion to measure the FEM solution accuracy. One way to measure this accurately is to observe, for example, the value of the flux of the vector magnetic induction in a closed line, as proposed in [4]. By the nature of the adopted formulation (magnetic vector potential and first order finite element), the FEM will always furnish a null flux for the magnetic induction vector in a closed surface. Nevertheless, the Kriging approximation tends detect any small error on the potential, i.e., when calculating the flux of the magnetic induction vector in a closed area a non-zero value is obtained. This value could be associated with the error in the FEM solution. The choice of the closed surface is quite natural: the triangular element. So the error in each element could be written as:

$$e = \int_{\Delta} \vec{B} \cdot d\vec{s} \quad (1)$$

Where \vec{B} is the induction calculated based on Kriging interpolation of the magnetic vector potential.

B. The error estimator based on the gradient of energy

This error estimator can be obtained by analyzing the regions where changes in stored energy on the field more intense. In these regions, it is desirable that the size of the finite element is small. Thus, the norm of the gradient of the stored magnetic energy could detect regions, where the refinement of the mesh of finite elements should be high. This estimator is consistent with that proposed in [5] to calculate the sensitivity of energy in relation to the nodal position. Here, the proposed estimator has a change in the conceptual point of view with respect to [5]: the Kriging interpolation provides a

direct estimate of the value gradient of magnetic energy stored in any position without any need for approaches to calculate the derivative of magnetic induction as presented in [3], [10].

$$e = \|\nabla W_{mag}\|. \quad (2)$$

C. The error estimator based on the difference between fields

Another way to estimate the error is based on the difference between the field calculated by FEM and calculated by the Kriging approximation. It could be calculated through the following expression, valid for each element:

$$e = \int_{\Omega^e} \langle \vec{B}_{calc} - \vec{B}_{est}, \vec{B}_{calc} - \vec{B}_{est} \rangle d\Omega, \quad (3)$$

where \vec{B}_{calc} is the magnetic induction vector, calculated by FEM and \vec{B}_{est} is the magnetic induction vector, calculated by the calculation of spatial derivatives of the Kriging estimation on the values of field element and $\langle x, y \rangle$ is the scalar product between the vectors x, y.

III. RESULTS

The L-shaped region is an interesting problem for finite element mesh generation. It is a magnetostatic problem and the magnetic vector potential was used. The boundary conditions are shown in Fig.1.

Fig 1 The L-Shaped region

The adaptive mesh will always begin with a coarse mesh, just enough to describe the basic geometry of the problem. With the error estimator based on the flux of the magnetic induction vector, it was necessary 7 iterations to achieve a high correlation between the values of field calculated by FEM and Kriging. Fig. 2 shows the distribution of elements at the end of the process and the evolution of the stored magnetic energy with respect to the iterations.

Fig 2 Final Mesh and energy convergence: first estimator

The same problem was analyzed with an estimator that uses the concept of gradient of magnetic energy on the position. The mesh generation starts with the same initial mesh of the previous item. Fig. 3 shows the final mesh (after 5 iterations) and the evolution of the stored magnetic energy with respect to the iterations.

The error estimator, based on the difference the fields, was also used to improve the mesh of the L-shape problem. Kriging interpolation of the magnetic vector potential was

used to compute an approximation of the magnetic induction for each triangle. For this estimator, the behavior of stored magnetic energy is shown in Fig. 4, which is very similar to Fig.2 and Fig.3

Fig3 Final Mesh and the energy convergence: second estimator

Fig. 4 Final Mesh and the energy convergence: third estimator

The benchmark proposed in [6] to force evaluation is a problem of simple geometry, as shown in Fig. 5. The current on the coil is equal to 1 A, so there is a small force on the iron part. This problem is highly dependent on the mesh due to the different permeability values and the corners. Table I shows the obtained values, for five approaches. Three of the results use the proposed adaptive scheme based on a Kriging interpolation.

Abstract— In micro-positioning devices with ironcore permanent magnet linear synchronous motors (PMLSM), the detent force needs compensation and, therefore, needs to be identified accurately. Different approaches have been proposed to account for the detent force in such devices using 2D finite element methods. In this paper, an analysis of the impact of the thickness of an eggshell layer used in the force calculations is presented. Precisely, the Maxwell Stress Tensor (MST), the Virtual Work Method (VWM) and the Weighed Stress Tensor (WST), also called Eggshell Method, are compared using several mesh sizes, and a special attention is given to the eggshell layer around the PMLSM mover. The accuracies of these force calculation technique are compared and analyzed with regard to the meshes.

I. INTRODUCTION

Permanent Magnet Linear Synchronous Motors (PMLSM) are widely used in many applications, such as micro-positioning devices [1]. In position controlled drive systems, they offer very reliable performances in terms of accuracy and speed. However, at low speeds, they suffer from the existence of detent forces (due to the interactions between the magnets and the mover part), which causes positioning errors at the end of the strokes. Even with optimized actuator designs, a residual force remains. To balance it, the detent force has to be taken into account in the control strategy. Unfortunately, this force is difficult to obtain experimentally and Finite Element simulations are required. In a previous paper [2], a 2D finite element software has been used to calculate the detent force in the magnetostatic case. An approach has been proposed to reduce the discretization errors in the force calculation by using an eggshell layer surrounding the mover.

The purpose of this paper is to present an analysis of the impact of the eggshell layer thickness on the force calculations. First, the studied PMLSM is presented and its main features are given. Then, different force calculation methods are explained. Thirdly, the benefit of the eggshell layer is justified. Finally, numerical results obtained with the force calculation methods are given and compared.

Fig. 1. 2D cutting view of the studied PMLSM [3]

II. DESCRIPTION OF THE STUDIED PMLSM

The studied system is a LMD10-050 linear motor from the ETEL Company, used in many high-precision, high-speed positioning applications, such as Pick-and-Place systems in the semiconductor industry. Figure 1 gives a 2D cutting view of the structure and Table 1 summarizes its main features.

This actuator consists of two parts: the primary part, above, is the mobile one. It is toothed and includes the three-phase concentrated windings. The secondary part, below, is fixed and composed of a set of alternating NdFeB magnets mounted on the surface of a massive ferromagnetic yoke.

TABLE I
Specifications of the LMD10-050 [4]

Parameters Name	Value	Parameters Name	Value
Rated Current	2 Arms	Maximal Current	7.9 Arms
Rated Force	130 N	Maximal Force	554 N
Peak Detent Force	5 N	Attraction Force	177 0N

III. FORCE CALCULATION METHODS

Resultant electromagnetic forces and torques acting on rigid bodies in electrical systems can be calculated using different methods [5]. The most widespread methods in FEM codes are the Maxwell Stress Tensor (MST) [6], the Virtual Work Method (VWM) [2], and the Weighted Stress Tensor [7].

A. The Maxwell Stress Tensor

In the case of the Maxwell Stress Tensor (MST) method, the following tensor is calculated:

$$T_{ij} = \mu_0 (H_i H_j - \frac{1}{2} \delta_{ij} H^2) \quad \text{with } i, j = x, y, z, \quad (1)$$

$H(H_x, H_y, H_z)$ the magnetic field given by its values in the Cartesian frame (x, y, z) , δ_{ij} the Kronecker symbol ($\delta_{ij} = 1$ if $i = j$ otherwise $\delta_{ij} = 0$).

The force is obtained by means of a surface integration over an arbitrary surface Γ in the air region enclosing the moving body:

$$F = \oint_{\Gamma} \mu_0 ((\mathbf{H} \cdot \mathbf{n}) \mathbf{H} - \frac{1}{2} |\mathbf{H}|^2 \mathbf{n}) ds \quad (2)$$

The vector \mathbf{n} is the normal vector to the Γ surface.

B. The Virtual Work Method

This approach is based on the transformation of magnetic energy into mechanical energy. It can be shown that the total force F_s in a direction s is obtained from the magnetic energy variation W of the system after a displacement in this direction. The motion is performed at constant flux [5], [8], [9]. A similar expression can be deduced from the variations of the co-energy W' at a constant current i , with the co-energy W' calculated using an integration over a volume v inside a domain D of the induction b and the magnetic field h .

$$F_s = \frac{\partial W'}{\partial s} \quad | \quad i = cst, \quad \text{with} \quad W' = \int_D \int_0^h b \, dh \, dv \quad (3)$$

C. The Weighted Stress Tensor in the software FEMM

The method implanted in the FEMM software [7] is inspired from the approaches developed in [6] and [10]. The WST method automatically selects a set of elements of the air region forming a thick boundary, or an eggshell, around the moving part. On that set of elements, weighting functions are obtained with an additional Laplace equation and a modified volume integral of the Maxwell Stress Tensor is performed. This method is generally more accurate than one using the Maxwell Stress Tensor [7].

IV. MESHING CONSIDERATIONS

A. Mesh design

The aim is to obtain accurate results on the force calculations. So, particular care is taken with the mesh size of each component. Figure 2 shows a zoom on the mesh designed for the actuator (LMD10-050).

To reduce the number of elements, it seems better to finely mesh only the zones with high gradients of the flux density. Zone 4 is the eggshell and is composed of a thin meshed layer, which is particularly efficient for the force calculation [2]. Indeed, this eggshell allows a more accurate representation of the bending of the flux lines in the magnets' vicinity (Figure 3b). The other zones are defined with a larger mesh size than the air-gap, with an auto-adaptation of the mesh to connect with the finer meshed Zone 4 of the eggshell.

Fig. 2. Geometry with mesh size of 0.3 mm [2].

B. Calculation principle

To validate the mesh quality, force calculations are performed at no-load at a position where the detent force should be zero. As previously described, in the classical case, the mesh in the airgap is usually very fine and the windings are supposed to fill the slots entirely (Figure 3a).

Fig. 3. Contour plot of the WST calculation for the PMLSM a) in the classical case b) with eggshell case.

TABLE II
FEM Results of the detent force calculation

Parameters Name	Classical	Eggshell
Nodes number	130158	132230
Elements number	259692	263994
x-axis Force Error	0.3909 N	0.0221 N
Zone 3 mesh size	0.3 mm	0.8 mm
Zone 4 mesh size	-	0.1mm

V. CONCLUSION

The presented FEM results confirm that the eggshell layer helps to improve the detent force calculation of a PMLSM at no-load using 2D FEM Software. Indeed, with approximately the same number of elements, the accuracy on the detent force calculation is greatly improved (Table 2).

The full paper will present more results on the force calculation using the MST, the VWM and the WST methods. A comparison of the accuracy of these methods regarding the mesh size of the eggshell layer around the PMLSM mover will be added.

VI. ACKNOWLEDGEMENT

This work has been supported by Ralph Coleman of ETEL's Motion Control Research Team.

Abstract—There are some determination techniques of magnetizing current density such as the method using the current vector potential with tree co-tree decomposition, the electric scalar potential obtained from boundary value problem, and so on. However high current density is estimated in inner curve for the cause of solving homogeneous boundary value problem. In this paper, we present the effective method for the computation of magnetizing current density which is uniformly distributed and assured stable ICCG convergence by means of regularization.

I. INTRODUCTION

The data of magnetizing current density in finite element analysis has to be prepared in advance. The distribution of current density should be uniformly modeled to describe the stranded winding. However, inner curved current density is highly estimated when conventional technique such as the solution of homogeneous boundary problem is applied. Some effective methods [1] - [3] for realizing the uniform current density were developed.

In this paper, we propose a new uniform distribution technique for magnetizing current density. The uniform current density is temporary evaluated by using the conventional electric scalar potential method [4] at first. Next, regularization is applied to temporary current density in order to realize the stable ICCG convergence characteristic. The effectiveness of proposed method is investigated by using the inductance value in the IEEJ coil model.

II. DETERMINATION METHOD OF UNIFORM CURRENT DENSITY

A. Determination of current density direction

Firstly temporary vector of current density is determined by using conventional electric scalar potential method [4] in the step 1 as shown in Fig. 1. The weighted residual G_i of the equation of current density continuity using nodal shape function N_i is given as follows:

$$G_i = -\iiint_V \nabla N_i \cdot \mathbf{J}_0 dV + \iint_S N_i \mathbf{J}_0 \cdot \mathbf{n} dS = 0 \quad (1)$$

where \mathbf{J}_0 is the current density vector, and \mathbf{n} is the external unit normal vector. Here, \mathbf{J}_0 is composed of electric scalar potential ϕ as follows:

$$\mathbf{J}_0 = -\sigma \nabla \phi \quad (2)$$

where σ is conductivity, which is considered as homogeneity in the coil region. At the step 2, intensity of \mathbf{J}_0 is normalized as I/S in the center point of all elements as follows:

$$\mathbf{J}_{0_init} = (I/S) \mathbf{t} \quad (\because \mathbf{t} = \mathbf{J}_0 / |\mathbf{J}_0|) \quad (3)$$

where S is the cross-sectional area of current input surface, and the direction of \mathbf{J}_{0_init} is the same of \mathbf{J}_0 . Here the intensity of \mathbf{J}_{0_init} is completely uniform, however \mathbf{J}_{0_init} doesn't satisfy the weak form of equation of continuity.

B. Regularization

The characteristic of ICCG method in edge-based FEM will diverge when the equation of continuity ($\nabla \cdot \mathbf{J}_0 = 0$) is not weakly satisfied [5]. Therefore, the discontinuous vector \mathbf{J}_{0_init} should be corrected by using correction vector \mathbf{J}_{0c} to improve poor ICCG convergence of magnetic field analysis as follows:

$$\mathbf{J}_{0r} = \mathbf{J}_{0_init} + \mathbf{J}_{0c} \quad (\because \mathbf{J}_{0c} \equiv -\nabla \delta \phi) \quad (3)$$

where \mathbf{J}_{0r} is the corrected vector, and $\delta \phi$ is the correction potential. Substituting \mathbf{J}_{0r} for the equation of current density continuity, the weak form is obtained as follows:

$$G_i = \iiint_V \nabla N_i \cdot \nabla \delta \phi - \nabla N_i \cdot \mathbf{J}_{0_init} dV + \iint_S N_i (\mathbf{J}_{0_init} + \mathbf{J}_{0c}) \cdot \mathbf{n} dS = 0 \quad (4)$$

where the second term about the boundary integration is equal to the input current I when the equi-unknown boundary condition is imposed on the correction potential $\delta \phi$ on the input surface. (4) is solved about $\delta \phi$ at the step 3. Next $\delta \phi$ is substituted for (3) at the step 4, and then continuous \mathbf{J}_{0r} can be utilized in magnetic field analysis.

Fig. 2 shows the effectiveness of regularization for the flat motor coil in the case of substituting \mathbf{J}_0 obtained from the two-scalar potential method [1] for \mathbf{J}_{0_init} in (4). The ICCG

Fig. 1. Flow chart of uniform distributed current density.

Fig. 2. ICCG convergence using two-scalar potentials.

convergence characteristic of magnetic field analysis is improved by the additional process of regularization.

III. VERIFICATION

A. Analyzed results

Fig. 3 shows the finite element mesh of IEEJ coil model. The number of elements, nodes, and unknowns of the first order hexahedral edge elements are 268,202, 278,832, and 791,101, respectively. The target value of uniform current density is 400×10^3 kA/m² in this model.

The correction vector is mostly distributed for imposing the \mathbf{J}_{0_init} continuity in the connection area of the straight and curved region as shown in Fig. 4. The maximum intensity of correction vector is 25.2 kA/m². The uniformity of current distribution is improved by using proposed method as shown

Fig. 3. Finite element mesh.

TABEL I
COMPUTATION RESULTS OF IEEJ MODEL

method	electric scalar potential	two-scalar	proposed	Biot-Savart	measured
uniformity	1.89	1.00	1.07	—	—
L [mH]	33.77	34.10	34.10	34.18	34.65
inductance error [%]	2.54	1.59	1.59	1.36	—
ICCG ite.	594	595	594	—	—
CPU time [s]	255.8	253.1	259.1	—	—

CPU Intel Xeon X5482 processor / 3.2 GHz & 3.25 GB RAM

ICCG convergence criterion $\|\mathbf{r}_n\| / \|\mathbf{r}_0\| < \epsilon_{cg}$

$\epsilon_{cg} = 10^{-15}$ (current density computation), 10^{-6} (magnetic field analysis)

in Fig. 5. The ICCG convergence characteristics in three methods are similar distributions as shown in Fig. 6.

TABLE I shows the computation results obtained from various techniques. The inductance value is close to measured one by using the two-scalar or proposed method. While two-scalar method is applicable to only the coil with rectangular surface of current inflow, proposed method is effective to arbitrary input surface. And the CPU time of proposed method is a little longer than that of the electric scalar potential method for the cause of double computation of same size equation.

B. Iterative process

Iterative process of proposed method is investigated in order to make the current distribution more uniform in IEEJ coil model. Iterative process is composed of the step 2 – step 4 and the process of substitution of \mathbf{J}_{0r} for \mathbf{J}_0 in Fig. 1. Fig. 7 shows the changes of current density intensity. Fig. 8 shows the changes of uniformity and inductance value in five iterations. Inductance value is gradually changed according to the improvement of uniformity. The sufficient solution is obtained at the first step, and then the single computation will be needed in the practical use.

Abstract — The Finite Integration Technique (F.I.T) is used to compute the electromagnetic phenomena. This technique is efficient if the mesh is generated by a regular hexahedron. Moreover the matrix system, obtained from a regular mesh can be exploited to use the parallel direct solver. In fact, in reordering the unknowns by the nested dissection method, it is possible to construct directly the lower triangular matrix with many processors without assembling the matrix system. In this paper, the parallel direct solver is described and the efficiency is shown as a function to the number of processors.

I. INTRODUCTION

To compute the electromagnetic phenomena many methods can be used, such as the finite element method (F.E.M), the finite integration technique (F.I.T) [1]-[2]. These methods provide a large system which is usually solved by iterative methods (Krylov) associated to a preconditioner. If the system is very sparse, the Krylov method is very interesting because the utilization of memory is low and consequently the method is fast. Recently, the memory capacity has been increased and can accommodate a larger full system. Moreover, as the CPU clock frequency stagnates, the number of processors increases to keep a constant acceleration of computing power. Nowadays, large systems can be solved by parallel direct methods. In this paper, the F.I.T is used to compute the electromagnetic phenomena for which it's necessary to use a regular mesh. The system obtained has some priorities of regularity which will be used for the parallel computing. In order not to use a large memory, the reordering technique (Nested Dissection [3]) is implemented to minimize the fill-ins during the factorization elimination process. This technique keeps the regular structure of the matrix whose it is easy to extract efficient parallel computing without latency. Due to these conditions, we propose in this paper to compute an academic problem with the F.I.T using a parallel direct solver.

II. THE FINITE INTEGRATION TECHNIQUE

This method is based on the same theory as the F.E.M. But in case of F.I.T, there are no shape function cause a diagonal mass matrix. Also, to construct the model it is necessary to define a dual mesh. It appears that if the primal mesh is regular then the dual mesh should also be regular. Therefore, it is easy to build. In this paper, both potential (scalar end vector) formulations of the electrokinetic problem are treated. In the case of scalar potential formulations the matrix system obtained is :

$$G^T M_{je} G \varphi = -G^T M_{je} G \alpha \quad (1)$$

Where G is the incidence matrix node-edge, M_{je} the mass matrix, φ the electrical scalar potential and α the scalar potential source. With the help of a scalar potential source, a voltage between two electrodes can be imposed.

For the vector potential formulation the matrix system obtained is :

$$R^T M_{ef} R T = -R^T M_{ef} R T_s \quad (2)$$

Where, R is the incidence matrix edge-facet, M_{ef} the mass matrix, T the electrical vector potential and T_s the vector source. With this formulation a current density is imposed through the conductor.

For both formulations a gauge must be defined to solve the numerical system with a direct solver. For the φ -formulation just one unknown is fixed to zero. However a T -formulation is classically gauged with a tree technique. In these conditions both matrix systems (1) and (2) are symmetric positive definite (S.P.D). The matrix given by the φ -formulation (1) have at most 7 non-zero elements in each line and column. On the other side, the T -formulation gives a matrix with a possible 13 non-zero elements in each line and column.

In this paper, for solving both systems, it is proposed that the matrices should be assembled and factorized at the same time. For minimizing the fill-ins in the factorization, the reordering technique Nested Dissection of the nodes is done.

III. NESTED DISSECTION METHOD

The goal of the reordering techniques is to decrease the amount of fill-in and reduce the number of operations in the factorization and resolution of linear systems. The two most classically used reordering methods are the Minimum Degree [5] and the Nested Dissection [3]. The minimum degree algorithm is a local heuristic that performs its pivot selection by selecting from the graph a node of minimum degree. Nested Dissection is a method of finding an elimination ordering. The algorithm uses a divide and conquer strategy on the graph of the matrix. The basic idea of Nested Dissection is to bisect the graph by finding and removing a node separator and labeling the nodes of the two resulting sub-graphs by applying the same technique recursively. Labeling the nodes of the separator after the nodes of the sub-graphs have been labeled (i.e., the separator nodes receive a higher label than any of the nodes of the sub-graph). The recursion terminates when the sub-graphs become too small. The minimum degree algorithm is known to be a very fast and general purpose algorithm, however, the algorithm is intrinsically sequential. On the other hand, the nested dissection is easily parallelizable. In practice, nested dissection produces

orderings which, in terms of fill-in and operation count, give the same results as the ones obtained with minimum degree. Moreover, the elimination trees induced by nested dissection are broader, shorter, and better balanced, and therefore exhibit much more concurrency in the context of the parallel Cholesky factorization.

With a single node separator, a matrix system is split into the following form

$$\begin{bmatrix} A_{11} & 0 & A_{31}^T \\ 0 & A_{22} & A_{32}^T \\ A_{31} & A_{32} & A_{33} \end{bmatrix}$$

A_{33} is the matrix corresponding to the nodes in the node separator, A_{11} corresponds to the first sub-graph, and A_{22} corresponds to the second sub-graph. Since these two sub-graphs are not joined by any edges, A_{21} is zero. Otherwise, A_{11} and A_{22} can be assembled in parallel. With this new reordering, a block matrix system should be obtained, it is shown in figure1.

Figure 1. The Matrix to solve with reordering

Figure 2. Lower Matrix with reordering

IV. PARALLEL DIRECT SOLVER

A typical direct solver for systems with SPD matrix is Cholesky factorization [4]. Here, the problem is to compute the solution of the linear equation system $Ax = b$, where A is a sparse and S.P.D matrix. The Cholesky factorization consists to decompose A as $A = LL^T$, where L is a lower triangular with positive diagonal elements. We propose here to generate directly the matrix L (figure 2) in parallel because its block structure allows it. Finally, the solution is computed by solving two triangular systems. $Ly = b$ is solved by forward elimination followed by solving $L^T x = y$ with backward substitution. These two substitutions are parallelized because some set of unknowns are independents.

V. APPLICATION

As example, a sample electrokinetic problem is treated. It is an electrical conductor cube. Inside this cube, a rectangular part is placed with smaller electrical conductivity. To increase the efficiency of the method, a regular mesh is used with 64000 hexahedrons. For the ϕ -formulation a voltage of 1V is imposed in the conductor and the system contains 65559 unknowns. In the case of the T -formulation, a current of 1A is imposed through the conductor. As the T is computed on the edge, the system is larger (188759 unknowns). For both formulations, the value of the resistance is computed. We obtained for ϕ -formulation 1.282 m Ω and 1.258 m Ω for the T -formulation. To illustrate the problem, the current density inside the conductor is shown on the figure 3.

Figure 3 : Distribution current density inside the conductor

In the following table, the acceleration in accordance with the number of processors is shown for the assembling of the matrix L .

Number of processors	1	2	4	8
Speed-up ϕ - formulation	1	1.59	1.97	2.26
Speed-up T - formulation	1	1.69	2.86	4.06

VI. CONCLUSION

In this paper, it is shown that it's possible to generate directly and in parallel the lower triangular matrix L , which guarantees the acceleration of the resolution method. In the final paper, the method will be more developed and many examples will be treated and the results discussed.

Computation of forces using mean and difference potentials

A. F. Licarião Nogueira

Universidade do Estado de Santa Catarina

Campus Universitário Prof. Avelino Marcante, Joinville, Santa Catarina, 89223-100, Brazil

antonioflavio@ieee.org

Abstract — The paper addresses an alternative method for the calculation of global forces. The mean and difference potentials technique is physically related to the virtual work principle, but relies on a reformulation of the computation sequence. The technique is the result of exploiting superposition in magnetically linear systems, and can be applied to any sequence of boundary-value problems which differ only in the placement of their excitations. The method has been successfully applied to solve interior problems with translational symmetry. The present work investigates its performance when used to solve an unbounded axisymmetric problem. Computed forces by the method under investigation are compared to results obtained by two reliable methods: weighted Maxwell stress tensor and Lorentz force.

I. INTRODUCTION

Calculation of forces and torques from numerical field solutions is subject to large numerical errors because their computations are usually based on magnetic flux densities, not to the scalar or vector potential values. The potential distribution produced by conventional finite element analysis represents only a numerical approximation to the true potential distribution, i.e. there is an inherent error in the values of potentials, commonly referred to as error in the approximation function. The evaluation of forces and torques invariably involves some kind of numerical differentiation, and all familiar sources of errors are present in numerical differentiation. Errors in the approximation function are the most critical, even when small, because they are magnified by differentiation algorithms.

In numerical problems involving both differentiation and integration, errors will be minimized if the order of the operations can be so rearranged that all integrations are done numerically, all differentiations analytically [1]. Since numerical integration is a robust process and analytic differentiation is error-free, the results can be expected to be numerically stable. The method of mean and difference potentials is physically related to the virtual work principle and relies on this reformulation of the computation sequence. The method is detailed in [2]-[3] and has been applied to solve interior problems with translational symmetry. The present work investigates the performance of the method when used to solve the unbounded axisymmetric problem proposed by Meeker [4]. The problem concerns the computation of the force acting on an iron ball at various positions relative to an excited wound, air-cored coil. An outline of the problem geometry is shown in Fig. 1. In this drawing, it is shown the configuration where the iron ball is located 1.5" from the center of the coil.

Fig. 1. An excited coil attracts the iron ball; dimensions in inches.

II. METHOD OF ANALYSIS

A sequence of magnetic vector potential solutions is used to simulate the movement of the coil relative to the iron ball. The reaction force acting on the coil is computed by three different methods: (i) mean and difference potentials; (ii) weighted Maxwell stress tensor; (iii) Lorentz force $\mathbf{J} \times \mathbf{B}$.

Were the virtual work approach to be used, there would be two boundary-value problems in A_1 and A_2 corresponding to positions 1 and 2 of the coil. Both problems differ only in the placement of the current distributions J_1 and J_2 , and are subject to the same boundary conditions. The subtraction of the system's total energy at the two coil positions gives the energy difference

$$\delta W = \frac{1}{2} \int_{\Omega} A_1 J_1 d\Omega - \frac{1}{2} \int_{\Omega} A_2 J_2 d\Omega, \quad (1)$$

where Ω denotes the problem region.

If the problem is magnetically linear, superposition can be exploited and, instead of working with the two boundary-value problems in A_1 and A_2 , two other boundary-value problems may be defined. The difference problem, expressed in terms of potentials A_d and current densities J_d , is obtained as half the difference of the two problems above, and is subject to homogeneous boundary conditions as a result of the subtraction. The mean problem, expressed in terms of potentials A_m and current densities J_m , is obtained as half the summation of the two problems, and is subject to the same

boundary conditions of the problems which represent the two consecutive positions. Rewriting the energy difference expressed in (1) in terms of the other two problems yields

$$\delta W = \int_{\Omega} A_d J_m d\Omega + \int_{\Omega} A_m J_d d\Omega. \quad (2)$$

III. TESTS AND RESULTS

To test the method set out above, a magnetic field analysis program [5] has been used to solve the field problems. An outline of the axisymmetric structure is shown in Fig. 2.

Fig. 2. Regions of the numerical model

To model the unbounded field problem, asymptotic boundary conditions have been used for the field solutions representing the mean problems, as well as for the solutions by the other two methods. For the difference problems the potentials are equal to zero at the semicircular boundary. The numerical model includes several rectangular regions that allow flexibility for simulating the coil movement. In this drawing, it is shown the field problem that represents the iron ball situated at the center of the wound coil; this position represents the stable equilibrium point for the iron ball and the system’s stored energy is maximum. According to the reference frame used, at this position, $z=0$. As the coil moves upwards from the centered position, the force on the iron ball increases up to its maximum value, and this occurs when ball starts to leave the coil region. Further increases in the distance imply a reduction in the force and this starts to vanish when the ball is approaching 1.5” from the centre of the coil.

The coil movement in steps of 0.15” (10% of the total excursion) is simulated by redefining material properties. Different current distributions are the basic feature distinguishing the eleven geometrically distinct problems solved by the other two methods. For these methods, there are force estimates at two consecutive coil positions, as illustrated in Fig. 3(a)-(b). In the mean and difference potentials technique, there are force estimates for the intermediate positions. Here, two distinct field problems are solved to obtain the energy difference δW given by (2), so there are altogether 20 program runs for the new technique. The current distributions of the problems representing half the difference and half the summation of two consecutive coil positions is

illustrated in Fig. 3(c)-(d). Since a single finite-element mesh is used for all computations, the pre-processing script is basically a series of commands to edit the material identification labels attached to the different regions.

Fig. 3. Current distributions: (a)-(b) Excitations at two consecutive coil positions; (c) Half their difference; (d) Half their summation

Preliminary test results are presented in Fig. 4. Computed forces by mean and difference potentials are marked with “o” whilst results from the weighted tensor method are marked with “*”. These characteristics clearly reproduce the analysis results previously published in [4]. A closer observation of the graph shows that both characteristics trace similar courses, especially along the first half of the simulated path. Given the reliability of the weighted tensor method, the results from the new method are completely satisfactory.

Abstract— The problem of the image reconstruction in Electrical Impedance Tomography (EIT) is a highly ill-posed inverse problem. There are mainly two categories of image reconstruction algorithms, the direct algorithm and the iterative algorithm which was used in this publication. The forward problem can be solved by the finite element method, immersed interface method or boundary element method. The iterative algorithm is based a combination of the level set methods with one of numerical methods. The representation of the shape of the boundary and its evolution during an iterative reconstruction process is achieved by the level set method.

I. INTRODUCTION

In this paper was proposed a method based on the combination level set idea and a few numerical methods to solve the inverse problem arising from electrical impedance tomography. The representation of the boundary shape and its evolution during an iterative reconstruction process is achieved by the level set method [6]-[8]. The shape derivatives of this problem involve the normal derivative of the potential along the unknown boundary.

II. ELECTRICAL IMPEDANCE TOMOGRAPHY

Electrical impedance tomography is a widely investigated problem with many applications in physical and biological sciences [2]-[4]. It is well known that the inverse problem is nonlinear and highly ill-posed. The forward problem in EIT is solving by Laplace's equation:

$$\operatorname{div}(\gamma \operatorname{grad} \varphi) = 0 \quad (1)$$

where φ - electric potential, γ - conductivity.

The following functional is minimized:

$$F = 0.5 \sum_{j=1}^p (\Phi - \mathbf{V}_0)^T (\Phi - \mathbf{V}_0) \quad (2)$$

where p is the number of the projection angles.

III. NUMERICAL ALGORITHMS

A. Level set method

The level set method is known to be a powerful and versatile tool to model evolution of interfaces. The idea is

merely to define a smooth function ϕ , that represents the interface and has the following properties (fig.1):

$$\begin{aligned} \phi(x, t) &> 0 \text{ for } x \in \Omega \\ \phi(x, t) &< 0 \text{ for } x \notin \Omega \\ \phi(x, t) &= 0 \text{ for } x \in \partial\Omega = \Gamma(t) \end{aligned} \quad (3)$$

Fig. 1. Level set function.

B. Mumford-Shah model

The Mumford-Shah algorithm set formulation and minimization problem in image processing, to compute piecewise-smooth optimal approximations of a given image. The proposed model follows and fully generalizes work [1], where there was proposed an active contour model without edges based on a 2-phase segmentation and level sets γ_1 and γ_2 . Conductivity γ is represented as:

$$\gamma = \gamma_1 H(\phi) + \gamma_2 (1 - H(\phi)) \quad (4)$$

where H is the Heaviside function.

The derivative of F with respect to γ is given by

$$\frac{\partial F}{\partial \gamma} = - \sum_{j=1}^p \nabla \varphi_j \nabla \bar{\varphi}_j \quad (5)$$

Level set function is updated the following iterative scheme:

$$\phi^{k+1} = \phi^k - \mu \frac{\partial F}{\partial \phi} \quad (6)$$

where coefficient $\mu > 0$ and

$$\frac{\partial F}{\partial \phi} = \frac{\partial F}{\partial \gamma} \frac{\partial \gamma}{\partial \phi} = \frac{\partial F}{\partial \gamma} (\gamma_1 - \gamma_2) \delta(\phi) \quad (7)$$

where δ is the Dirac delta function.

Conductivities are calculated as:

$$\gamma_1^{k+1} = \gamma_1^k - \beta \frac{\partial F}{\partial \gamma_1} \quad (8)$$

$$\gamma_2^{k+1} = \gamma_2^k - \beta \frac{\partial F}{\partial \gamma_2} \quad (9)$$

where coefficient $\beta > 0$.

The delta function $\delta(\phi)$ and Heaviside function $H(\phi)$ are calculated as:

$$\delta_\varepsilon(\phi) = \frac{\varepsilon}{\pi(\phi^2 + \varepsilon^2)} \quad (10)$$

$$H_\varepsilon(\phi) = \frac{1}{\pi} \tan^{-1} \left(\frac{\phi}{\varepsilon} \right) + \frac{1}{2} \quad (11)$$

where $\varepsilon > 0$.

IV. IMAGE RECONSTRUCTION

Figures 2,3,4 presents model of computer simulation an image reconstruction. The numerical model was inserted in the inside of the examined object. The grid was used by 16x16 elements solution.

V. CONCLUSION

Application was presented in this paper of the level set function for identifying the unknown shape of an interface in a problem motivated by electrical impedance tomography. Level set methods with Mumford-Shah model give good results. The error of the image reconstruction is caused the rare discretisation.

Abstract— The methodology of Systems Dynamics is presented as an alternative to visualizing and learning the operation of physical systems. The objective of this article is to show the applicability of this technology in computer simulation involving an Electromagnetic Contactor. A simulation model based on causal loops and flow diagrams was developed with Powersim® Studio Enterprise 2003, taking the device parameters into consideration. The timely graphical output display becomes a tool in aiding the teaching-learning process, highlighting the importance of the simulation so that students can rethink their models of certain dynamic processes.

I. INTRODUCTION

According to Vygotsky [1], learning is the cornerstone of human development and it includes the interdependence of the individuals involved in the process. With this approach in mind, a more profound modeling reference is anchored, because as proposed by Vygotsky, “language shapes thought”. The issue of modeling in teaching can be approached in, at least, three different perspectives: (a) construction of knowledge, (b) explication and refinement of mental representations of knowledge, and (c) perception of the world through the eyes of dynamic systems. The dynamic systems theory can be interpreted as a “new” way to understand our day-to-day dynamic phenomena, taking into account not only the causal relations between sets of variables, but also system behavior as a whole [2]. From the educational standpoint, the understanding and application of these concepts enable students to comprehend complex dynamic systems and to focus on the models of any given system, as well as the reason why these systems change through time. Human thought is completely dependent on models. Mental concepts are abstractions in our experience and this experience is filtered and modified by our individual perception. Mathematical simulation models belong to the ample class of abstract models that resort to mental images. The dynamic behavior is one of the most important characteristics of a linear electromagnetic device, such as an electromagnetic contactor [3]. In this work, the Powersim® Studio Enterprise software was applied in the construction and exploration of an Electromagnetic Contactor model.

II. SYSTEMS AND MODELS

A system is comprised of a collection of interacting elements (or components) to fulfill a purpose. The Electromagnetic Contactor is a device that is commonly used for switch-controlling induction motors in industrial

processes. Thus, the parts of a Contactor make up a system, albeit each isolated component not even resembles the system of which it constitutes. However, if any of these components were missing, the system would be impaired and unable to execute the functions for which it was originally designed, as a whole. Therefore, when the word Electromagnetic Contactor is mentioned, the student will most certainly be interested in a simplified system capable of simulating some significant characteristics of an actual Contactor.

III. DYNAMIC MODELING OF THE AC CONTACTOR

According to the Maxwell Tensor [4], the instantaneous electromagnetic force that produces the contactor’s closing action movement can be expressed in Newton/Pole by:

$$F_1 = \frac{\phi_1^2 \sin^2 \omega t}{2\mu_0 S_1} \quad (1)$$

$$F_2 = \frac{\phi_{21}^2 \sin^2 \omega t}{2\mu_0 S_{21}} + \frac{\phi_{m1}^2 \sin^2(\omega t - \alpha)}{2\mu_0 S_{22}} \quad (2)$$

Where “ S_1 ” represent the area of the magnetic pole-face 1, “ S_{21} ” and “ S_{22} ” represents the external and internal section fluxes of the ring, respectively; “ ϕ_1 ”, “ ϕ_{21} ” and “ ϕ_{m1} ” represent Magnetic Fluxes in the respectively Air Gaps; “ μ_0 ” represents the magnetic permeability of the air; “ α ” is the angle between two fluxes (coil and short-circuit ring).

The total instantaneous electromagnetic force (half part of the nucleus) is given by $F_e = F_1 + F_2$.

Differential equations are formulated for calculation and behavior analysis of the AC Contactor. The description of the equations system includes mechanical movement (position, velocity and acceleration), circuit current and magnetic flux, simultaneously solved by numerical integration method. Fig. 1 shows the equivalent electric circuit referent to the main coil.

Fig. 1. Equivalent Electric Circuit

In these circuits, “ R_1 and R_2 ” represent the resistance of the coil and of the short-circuit ring, “ Ld_1 , Lmd_1 and Ld_2 ” represent the inductances of coil dispersion and of the short-circuit ring, and Lm_1 represents mutual inductance [5].

All the inductances in this model are detected by software of finite elements methods (FEM), reproducing nonlinear flux behavior (inductance). The equations for current states i_1 e i_2 (x_1 and x_2), are respectively, [5]

$$\begin{bmatrix} Lm_1+Ld_1 & -Lm_1 \\ -Lm_1 & Lm_1+Ld_2 \end{bmatrix} \cdot \begin{bmatrix} \dot{x}_1 \\ \dot{x}_2 \end{bmatrix} = \begin{bmatrix} -R_1 & 0 \\ 0 & -R_2 \end{bmatrix} \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} V_1 \\ 0 \end{bmatrix} \quad (3)$$

where $Ld = Ld_1 + Lmd_1$. At each time step, a new inductance matrix is calculated.

Based on Newton’s Second Law, the motion equation is obtained:

$$M \frac{d^2 x}{dt^2} = Fel - Fm - B \frac{dx}{dt} \quad (4)$$

Where “ Fel ” and “ Fm ” represent the resulting electromagnetic and mechanical forces (coil and springs), respectively; “ B ” is the buffering coefficient (shock absorbing); “ M ” is the mass of the moving part and “ x ” is the displacement.

The equations for motion and velocity states are determined from (4). The system of equations (5) is resolved by step-by-step time integration (Runge-Kutta 4th Order Method).

$$\begin{cases} \dot{x}_3 = x_4 \\ \dot{x}_4 = \frac{1}{M}(Fel - Fm - Bx_4) \end{cases} \quad (5)$$

The mechanical force is obtained from the resulting sum of all forces pertaining to Normally Open Springs, Normally Closed Springs and the principal springs.

IV. RESULTS

The analyzed contactor has springs assumed to behave in accordance to Hooke’s Law, with the condition that the strength of the spring varies in relation to the movement “ x ”.

It can be observed in the model on Fig. 2 that: the variables “ x ” for position and “ vx ” for velocity are established in the system dynamics representation; the model’s stock or level, where dx_dt and dvx_dt are rates.

Fig. 2. Stock and flow diagram – Interaction of the contactor forces

The results contemplate, qualitatively and quantitatively, the expected behavior of variables, configuring good modeling performance, as will be explained in full paper.

Fig. 3. Behavior of total electromagnetic force

Fig. 3 illustrates the behavior of total electromagnetic force, obtained by the simultaneous effect of currents in the main coil and short-circuit ring. It is perceptible that the force is always positive and greater than zero, allowing the contactor to always remain in the closed position, when of the passage of current or flux by zero.

Therefore, the systems dynamics tool is attributed to be a strong instrument in the study of complex physical systems, in the presence of transitory phenomena, formulated through differential equations. The qualitative vision of the behavior of a physical system is very important in the teaching-learning process, by the mental representation necessary for the compliance of causal loops and by equations system assembly and the respective resolution by numeric methods.

V. CONCLUSION

Simulating a model can be cognitively demanding. The interpretation of movement dynamics requires from the students, besides a mental representation of the physical, a profound mathematical knowledge, mastery of circuit analysis and of numerical methods. System dynamics, through software applications, allow students to interact with these concepts and to establish the possibility of a user-friendly interface for simulation and display of graphical output. The utilization of computer modeling is extremely pedagogical, for it enables students to structure certain concepts or collection of concepts and, within the phenomenon, to establish an alternative pattern of organized learning, thus allowing students to apply knowledge with much greater ease.

Educational Software for the Numerical Correction of the Experimental Magnetization Curves

Valentin Ionita and Emil Cazacu

Electrical Engineering Dept., University "Politehnica" of Bucharest
Spl. Independentei 313, RO-060042, Bucharest, ROMANIA
vali@mag.pub.ro, cazacu_emil@yahoo.com

Abstract — The proposed software allows students to perceive the importance of the experimental data accuracy in magnetism. A common error source for the magnetization curves (including hysteresis cycles) is the demagnetization effect and the influence of the magnetic sensor position. Our software helps the user to understand the principle and the effect of each correction method. The graphical user interface (GUI) is designed as a wizard, assisting the student to decide which the best correction procedure is and to obtain the intrinsic magnetic material characteristic to be used in electromagnetic field computation.

I. INTRODUCTION

A modern Electrical Engineering education includes more practical activities during the undergraduate, Master or Ph.D. studies. Consequently, many students learn to work with complex equipment for the experimental characterization of magnetic materials [1], and then use these material data in electromagnetic CAD. However, any measurement is influenced by many factors and the student must know how he/she could correct the experimental data. Therefore, it is useful to have a well-structured educational tool, which helps the user to compare the effect of different correction methods and to choose the best one. The proposed software is based on the correction procedure presented in [2] and has a GUI developed in MATLAB[®].

II. BACKGROUND THEORY

The measured magnetic material curve could be corrected taking into account the sample geometry, its magnetic behavior, the equipment configuration and the measurement probe position. The main influence, especially in open sample measurements, is due to the demagnetization effect: for a non-ellipsoidal sample, the internal magnetic field and the magnetization cannot be simultaneously uniform and an average correction must be performed. The computation of this demagnetizing factor was proposed for rectangular prisms [3] [4], cylinders [5] [6], or ring cores [7].

Another approach is the computation of more accurate factors using the finite element method (FEM) for the experimental device simulation. This procedure allows computing both the demagnetizing factor and the field correction factor, which depends on the position of the magnetic field probe [2]. These correction factors are computed and stored in dedicated files, which can then be visualized by the user. Three measurement types are considered: closed circuit with sample between poles (e.g. hysteresisgraph), closed circuit with surrounding coil (e.g.

single sheet tester) and open circuit (e.g. vibrating sample magnetometer). The sample could be an ellipsoid, a cylinder, a rectangular prism or it could have an arbitrary shape.

III. SOFTWARE DESIGN

The workflow that may be followed by a student for performing several corrections and for selecting the best one is represented in Fig. 1 as an activity diagram, using the modeling language UML (Unified Modeling Language) [8]. The graphical interface is designed in Matlab[®] like a wizard, with successive windows, which guides the student to the final goal: selecting the best correction of the experimental curve, as seen in the window presented in Fig. 2.

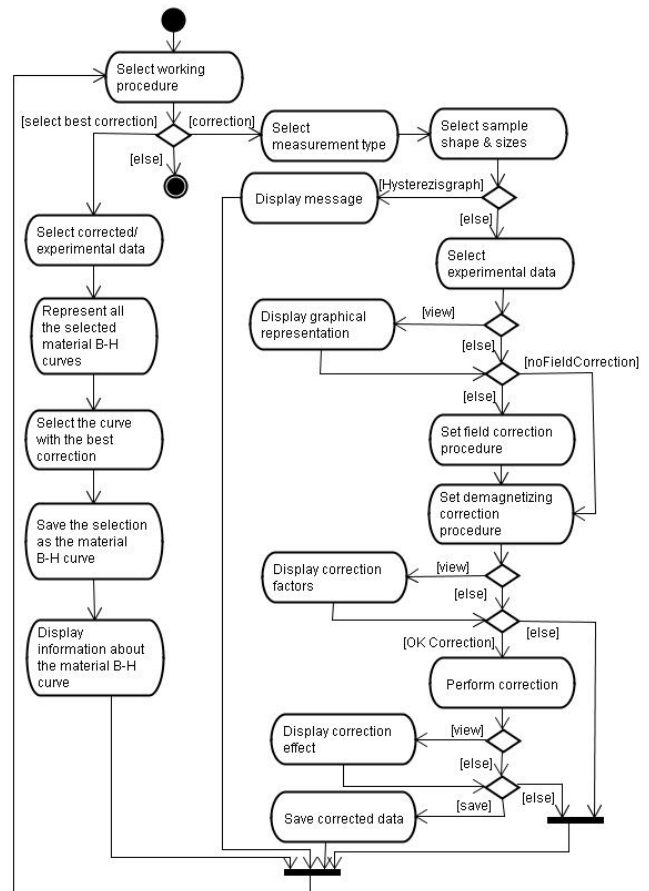

Fig. 1. Activity diagram, using UML

Fig. 2. Visualization of the correction effect for different methods

Each step is assisted by a link to the help file, where the student can find information both about the software commands and about the correction theory. The correction setup includes the choice of the measurement type, sample shape and sizes (Fig. 3). The user can choose between several field correction procedures (considering 2D or 3D simulation of the simplified or of the entire geometry of the experimental device) and between different demagnetizing correction methods: computation of a constant factor; extraction of a constant factor or of a susceptibility-dependent factor from a database. The corresponding files are loaded (using the window presented in Fig. 4) and the user can also visualize the correction factors.

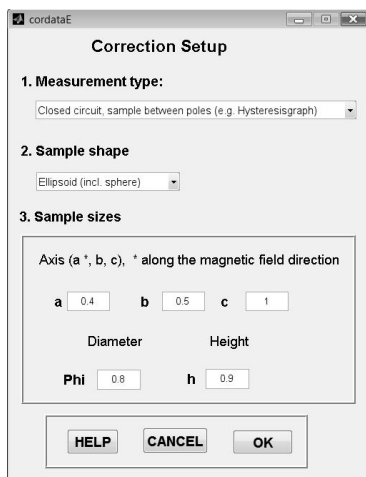

Fig. 3. Setting the correction parameters

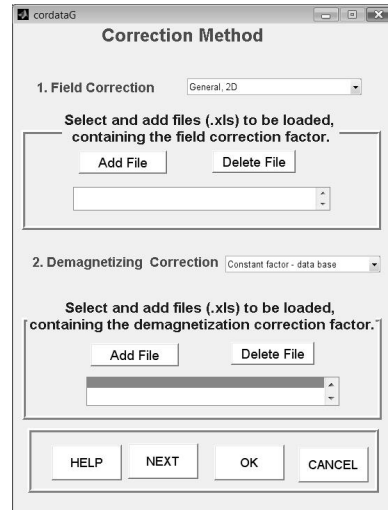

Fig. 4. Setting the correction method

The selected parameters of the correction method are parsed by the corresponding computation subroutine, which saves the corrected data in a dedicated file, the correction effect being analyzed in the graphical window presented in Fig. 2.

For the robustness of the design, the user has the possibility to return to the previous decision at any moment.

IV. CONCLUSIONS

This educational software is useful for understanding the way from the experimental measurement to the final material characteristic. The extensible software architecture allows the development of correction procedures for any other equipment, using new numerical techniques. This integrated correction technique is used in our Laboratory of Technical Magnetism for Master courses. The next step of the software development will be its integration with the dedicated software of each experimental device, in order to have a real-time correction during the measurement.

Application of the Method of Residues in Comparison to TLM Method in a Practical Case

Sérgio H. L. Cabral and Sávio L. Bertoli
 FURB – Fundação Universidade Regional de Blumenau
 Rua São Paulo, 3250 CEP 89030-000 Blumenau - SC
 scabral@furb.br savio@furb.br

Abstract—Computer programs have become indispensable for solving complex problems of Electromagnetism. Thus, analytical studies of correlated problems have become even more important for establishing bases for the understanding of computational analyses. Thus, the aim of this work is to reinforce the applicability of a very simple analytical method that is the Method of the Residues. This method has already been presented by the authors in previous article through a theoretical example. Now, its applicability is presented through a very practical problem. Comparison to the numerical method TLM is also done. Concordance with TLM and experimental data confirms the proposal of the method of residues as applicable to a wide range of problems of Electromagnetism.

I. INTRODUCTION

Since every power transformer is inherently vulnerable to incidence of lightning voltage surges, several studies regarding effects like these have been published ever since transformer has been put in use [1]. In consequence, several numerical tools and software have been developed for better studying this theme in different degrees of complexity [2]. For its turn, no matter how complex are the design of any transformer and the computational tool, the analysis of the behaviour of any of its winding is often based upon a classical study. This classical study consists in the analytical solution in time-domain of the differential equation that governs the voltage distribution along a continuous and homogeneous winding submitted to a step voltage [1]. Since MR-Method of Residues has been successfully applied to classical study[3], this work presents its applicability to a practical case that is an air-core winding submitted to a practical step voltage. The result is that MR demonstrates to be a very interesting and practical tool for obtaining analytical solution in studies that serves as the fundamental basis for more complex problems that require computational tools. For the sake of a better comparison TLM results are also presented.

II. A PRACTICAL STUDY AND ITS NUMERICAL AND ANALYTICAL SOLUTIONS

In accordance with [1], when a voltage surge hits a continuous winding of a transformer, it is likely to cause an insulation failure. This is due to a sudden voltage distribution that is established along it and that invariably implies into high values of electric field along its former turns. This sudden voltage distribution is ruled by parasitic capacitances. Then, if no failure happens, the voltage distribution along this winding will oscillate, due to changes of energies among charged capacitances and the inductances of the winding. Thus, voltage

oscillations will also cause voltage stresses due to overvoltage along several points of the winding, until steady state is reached. This well-known case has been experimentally investigated in [2], in which test apparatus for applying step voltage was made. Schematic diagram of that apparatus is shown in Fig. 1.

Fig.1. Schematic diagram of the test apparatus

Still in accordance with [2], TLM modelling and simulation of this problem consists in dividing equivalent circuit of the winding into several segments with related capacitances and inductances. In this way it is somehow possible to represent partially those unavoidable non-homogeneities of any winding by setting slightly different values of capacitances and inductances within different segments. Fig. 2 shows the aspect of a well-known circuit for TLM modelling and simulation of a winding like presented in Fig. 1.

Fig.2. Equivalent circuit for practical winding

For its turn, analytical solution of this problem consists in considering winding as homogeneous and thus solving the following classical equation[1,3]:

$$\frac{\partial^2 V(x,t)}{\partial x^2} = R_s \left(C_g \frac{\partial V(x,t)}{\partial t} + \frac{C_s \ell}{N} \frac{\partial^3 V(x,t)}{\partial t \partial x^2} \right) + L_s \left(C_g \frac{\partial^2 V(x,t)}{\partial t^2} + \frac{C_s \ell}{N} \frac{\partial^4 V(x,t)}{\partial t^2 \partial x^2} \right) \quad (1)$$

In which $V(x,t)$ is voltage to ground along time and length of the winding, R_s is its longitudinal resistance, L_s its effective series inductance, C_g its distributed capacitance to ground, C_s its capacitance between two adjacent turns, N its number of turns and ℓ its length. This winding lies along the x -axis, it is grounded at its end, $x = \ell$, and a step voltage V_o is applied at $x = 0$. The analytical solution by the MR proposed is[3] :

$$V(x,t) = V_o \left(\frac{\ell-x}{\ell} \right) - \frac{2V_o}{\pi\beta_2} \sum_{n=1}^{\infty} \left[\frac{\sin\left(\frac{n\pi x}{\ell}\right)}{n} \left(\left(\frac{\beta_1 A_{n_1} + \beta_2}{\beta_1 A_{n_1} + s_1} \right) s_1 \beta_1 A_{n_1} e^{s_1 t} + \left(\frac{\beta_1 A_{n_2} + \beta_2}{\beta_1 A_{n_2} + s_2} \right) s_2 \beta_1 A_{n_2} e^{s_2 t} \right) \right] \quad (2)$$

For which

$$\beta_o \equiv \frac{NC_g}{\ell C_s}; \quad \beta_1 \equiv \frac{R_s}{L_s}; \quad \beta_2 \equiv \frac{N}{L_s C_s \ell}; \quad A_{n_1} \beta_1 \equiv 1 + s_1; \quad A_{n_2} \equiv 1 + \frac{s_2}{\beta_2} \quad (3)$$

And s_1 and s_2 are obtained from

$$s_{1,2} = \frac{-\beta_1}{2} \pm \sqrt{\left(\frac{\beta_1}{2} \right)^2 - \frac{\beta_2 \left(\frac{n\pi}{\ell} \right)^2}{\beta_o + \left(\frac{n\pi}{\ell} \right)^2}} \quad (4)$$

Thus, since homogeneity is inherent, effects like those due to the existence of tangential components of magnetic or electric fields cannot be taken into account.

III. COMPARISON BETWEEN EXPERIMENTAL DATA AND MR METHOD

For the sake of evaluation of the performance of the MR method a practical air-core winding was experimented. This winding has $C_g = 4\text{nF/m}$; $\ell = 0.4\text{ m}$; $C_s / N = 6.37\text{ pF.m /turn}$; $L_s = 0.4\text{ mH/m}$; $R_s = 0\ \Omega/\text{m}$ and $n = 21$, for (2). Fig. 3 presents the behaviour of voltage to ground at first quarter of the winding that corresponds to tap 3, in Fig. 1. TLM simulation is also presented for the sake of a better comparison. It is important to mention that although effects of non-homogeneity could be considered for the TLM modelling of this winding, they were not made since the aim is to compare to MR under same conditions, as done in [3] and in [4]. Thus, in accordance with Fig.3 it can be seen that results between TLM and MR are very close, while experimental results present a small but natural difference in comparison to

both. This difference is principally due to inherent non-homogeneity of the real winding and to the fact that real voltage source is not a step voltage. In consequence, stray capacitances and inner resistances contribute for a time delay for the practical response. Nevertheless, besides time-delay results from all three simulations have a significantly coherence.

Fig. 3 Voltage to ground along time for the first quarter of the winding.

Also, comparison shows that MR results presents higher peak values of voltage for former oscillations, while lower peak values for following oscillations, in such a way that they compensate themselves under an average point of view. Some reasons for these differences are probably due to chosen number of segments for representing winding, in accordance with Fig. 2, as well as due to value set for n in the series presented in (2).

IV. CONCLUSION

Presented results from a practical simulation of transformer winding show how effective the proposed method of the residues can be for solving analytically classical problems of Electromagnetism. Although real concerns are not taken into account, MR still presents coherent results. In thus way, obtained results encourage future studies for evaluating the influence of terms of series as in (2) as well as studies in which air core winding is substituted by a really practical one, with ferromagnetic core. These presented results also encourage application of the method in other areas of Electromagnetism in view of consolidating this important and simple method.

Semi-Analytical Solution of 2-D Rotor Eddy-Current Losses due to the Slotting Effect in SMPMM

F. DUBAS and C. ESPANET

ENISYS Department, FEMTO-ST Institute, CNRS UMR 6174, F90010 Belfort, France

E-mail: FDubas@gmail.com

Abstract — In this abstract, the authors present the determination of two-dimensional (2-D) rotor eddy-current losses due to the stator slot-openings in surface mounted permanent-magnet (PM) motors (SMPMM). These parasitic losses are resistance-limited and only determined in the PMs from a new 2-D semi-analytical solution of the magnetic field taking into account the slotting effect. The 2-D rotor eddy-current losses due to the slotting effect have been compared with the finite element analysis (FEA) and calculated both for radial and parallel magnetization. The analytical results are in quite satisfying agreement with those obtained by the FEA.

I. INTRODUCTION

In the SMPMM, the rotor (i.e., the conducting retaining sleeve, the PMs, and the rotor yoke back-iron) is exposed to high order flux density harmonics which are not synchronous with the rotor. The 2-D rotor eddy-current losses computation, caused by these non-synchronous magnetic fields, is a well known problem in conventional synchronous machines design. These parasitic losses have two origins which can coexist. At no-load (at $I = 0$ A with I the RMS value of stator current), they are caused by the reluctance variation due to the slotting effect, while on load these losses in the turning parts result from both stator slotting permeance harmonics [1] and magnetomotive force (MMF) harmonics which are of two types [2]: i) MMF harmonics caused by the discrete positions of stator winding conductors; ii) MMF harmonics caused by time harmonics in the stator current, which result from six-step commutation and Pulse-Width-Modulation (PWM).

The main scientific contribution of this paper deals with by the 2-D rotor eddy-current losses due to the slot-openings, which are little discussed in the literature. These parasitic losses are usually assumed to be resistance-limited (i.e., the influence of the eddy-current reaction field is neglected) and are determined in the PMs from a new 2-D semi-analytical solution [3], which determines the no-load magnetic field distribution in the air-gap taking account into the slotting effect. This new calculation of 2-D eddy-current losses in the PMs due to the slotting effect requires less hypotheses than the method proposed by [1] which uses the 2-D permeance functions, in the sense that the solutions takes into account the real waveform of the teeth and do not use an approximate permeance function. However, the price to pay is the resolution of the Cramer's systems described in [3].

The 2-D eddy-current losses in the PMs evaluation predicted by this new approach of the slotting effect (and calculated for both radial and parallel magnetization) have been compared with the FEA. The semi-analytical results are in quite satisfying agreement with those obtained by the FEA.

II. A 2-D NEW SEMI-ANALYTICAL SOLUTION [3]

A. Problem Description and Assumptions

Fig. 1 shows the geometric representation of the multi-pole SMPMM for the new 2-D semi-analytical solution used to study the effect of the stator slotting. The main parameters of this geometry are given in the Table I.

The usual assumptions of all models in the literature are: i) End-effects are neglected; ii) The stator and rotor back-iron is infinitely permeable (i.e., the magnetic saturation is neglected); iii) The electrical conductivity of the PMs is assumed to be null to calculate the no-load magnetic vector potential (i.e., no resolution of Diffusion's equations); iv) The PMs are assumed to be nonoriented (with no particular direction of magnetization), isotropic, and having a linear demagnetization characteristic (rare earth magnets); v) Radial slot faces on the stator.

B. No-load Vector Potential Determination

The new semi-analytical solution is based on 2-D analysis in polar coordinates, and involves the solution of Laplace's equations in the air-gap (i.e., concentric region: Region 2) and in the slots on the stator (i.e., non-concentric regions: Regions i) and the solution of Poisson's equations in the PMs (i.e., concentric region: Region 1) [see Fig. 1] with constant magnetic permeabilities. The no-load magnetic field solutions with the slotting effect are obtained by using the Fourier's series and the method of separating variables. However, it now caters for i) internal rotor motor topology; ii) radial and parallel magnetization; iii) curvature effect; iv) depth of the slots.

The no-load magnetic flux density, in each region, has been compared to the FEA calculations, and the agreement was very good considering both amplitude and waveform. The no-load vector potential in Region 1 can be expressed by

$$A_{z1} = B_{rm} \cdot R_m \cdot f_{z1n}(E_{1n}, G_{1n}, r, \Theta_s), \quad (1)$$

where r and Θ_s are respectively the radial position and the mechanical angular position of the stator; n is the spatial harmonic orders, and f_{z1n} is the function in Fourier's series which depend on the integration constants E_{1n} & G_{1n} .

The integration constants of no-load local quantities (i.e., the magnetic flux density and vector potential), in each region, are determined by numerically solving the linear equations (i.e., the Cramer's system) for each Θ_{rs} (with Θ_{rs} the mechanical angular position between the rotor and the stator). The Cramer's system, detailed in [3], for each Θ_{rs} is based on $6 \cdot (n_{max} + 1) + Q_p \cdot (v_{max} + 1)$ equations and unknowns with n_{max} and v_{max} terms in the Fourier's series for the computation of the no-load local quantities.

III. 2-D EDDY-CURRENT LOSSES IN THE PMs CALCULATION

According to Maxwell's equation (i.e., the Faraday's law, the Coulomb's gage and the Ohm's law) and by using (1), the 2-D eddy-current losses in the PMs at the resistance-limited due to the stator slot-openings are given by

$$P_m^{slot} = k_{nsfd} \cdot k_e \cdot N_0^2 \cdot B_{rm}^2 \cdot M_m, \quad (2)$$

where N_0 is the speed of rotation, $M_m = \rho_{vm} \cdot V_m$ is the PMs mass with $V_m = \pi \cdot \alpha_p \cdot L \cdot (R_m^2 - R_r^2)$ is the volume of the PMs, k_e is the eddy-current losses coefficient in the PMs

$$k_e = \frac{\pi^2 \cdot \sigma_m \cdot L^2}{6 \cdot \rho_{vm}}, \quad (3)$$

and k_{nsfd} is the harmonic coefficient of the non-sinusoidal magnetic flux density produced by the PMs due to the slotting effect. This harmonic factor, given in the extended paper, depend principally on E_{1n} , G_{1n} , E'_{1n} & G'_{1n} . The integration constants E'_{1n} & G'_{1n} are determined by numerically solving the derivative of Cramer's system detailed in [3].

Fig. 2. Variation of 2-D eddy-current losses in the PMs due to the slotting effect versus the speed of rotation.

It can be noted that the harmonic coefficient k_{nsfd} is equal to zero for the slotless motors equipped with PMs.

IV. COMPARISON WITH FINITE ELEMENT SIMULATIONS

The evaluation of P_m^{slot} has been applied to a SMPMM, whose main characteristics are given in the Table I. Fig. 2 shows the influence of the rotor speed on P_m^{slot} , with radial and parallel magnetized PMs, calculated numerically by FEA and semi-analytically by the 2-D new approach with the slotting effect. It can be seen that, although the semi-analytical solution assumes to be resistance-limited, good agreement is obtained. It can be noted that P_m^{slot} calculated semi-analytically, at high fundamental frequencies, are significantly over-estimated in relation to those calculated numerically. These differences are due to eddy-currents effect on the no-load magnetic field which is not taken into account in the new 2-D semi-analytical model developed in [3].

V. CONCLUSION

A new 2-D semi-analytical solution of the magnetic field with the slotting effect has been used to determine the 2-D eddy-current losses in the PMs at the resistance-limited in SMPMM. This new calculation of these parasitic losses is mathematically more rigorous and requires less hypotheses than the method proposed by [1]. The new semi-analytical solution takes significantly less computing time than the FEA. In this comparison, the Cramer's system in [3] has of 486 elements (i.e., with $n_{max} = 49$ and $v_{max} = 30$) which is much smaller than the FEA having 6,000 surfaces elements for the studied SMPMM. Moreover, the semi-analytical solution can be a useful tool for design and optimization of multi-pole SMPMM, e.g., to minimize the 2-D rotor eddy-current losses due to the slotting effect.

Abstract- This paper investigates the effect of source replacement on both the iron loss and flux inside solid magnetic steel plates and laminated silicon steel sheets. The working conditions of the proposed models described in the paper are very different from the conditions usually found when modeling the material properties. Therefore, a zoned (3-D and 2-D eddy current sub-regions) approach is employed in the 3-D FEM analysis.

I. INTRODUCTION

Material modeling is usually carried out under certain standard conditions. The material and/or the device, however, work in various complex and non-standard environments. Therefore, the usual material property data cannot be used everywhere in the solved region and special zoned treatment is suggested, in particular, for the lamination configuration which is excited by a perpendicularly applied field.

In this paper, the verification models are proposed in which the magnetic steel component is excited by different sources. The effect of the source replacement on both the iron loss and the flux inside the solid and the laminated magnetic steel configurations is examined in detail.

II. VERIFICATION MODEL

Two verification models, namely P21-B and P21-M1, are established. P21-M1 is a simplified model based on the original benchmark model of P21^c-M1, in which the solid steel plate is removed and the laminated sheets (30RGH120, total 20 sheets) are driven by the exciting source of twin coils (coil 1 and coil 2). Four search coils (20 turns each) are inserted at the specified positions around the laminated sheets of interest. The number of sheets included in each search coil (e.g., no.1 to no.4) is different, as shown in Fig.1. P21-B (coil and solid magnetic steel plate) is a member-model of the Problem 21 Family.

There are three test cases based on the exciting current in coils 1 and 2. Table I lists the current configuration for each test case where the exciting current in the coil ranges from 0A to 25A (rms, 50Hz).

III. MODEL SIMPLIFICATION

The advance experiments to measure the magnetic flux and the loss inside the solid plate or the laminations of the verification model under different excitation conditions have been designed in order to simplify the models. For example, the test results based on P21-M1 show that the average magnetic flux density in the laminations closest to the exciting

source is considerably higher than those far away from the exciting source. The average magnetic flux density quickly drops with the increase in the number of the laminated sheets. The strong eddy currents within a thin layer closest to the source must be considered in the FEM analysis.

Fig.1. Verification model and search coils (sketch).

TABLE I
DIFFERENT EXCITATION CONDITIONS

Cases	Exciting currents (A, rms, 50Hz)		Main property of flux
	in Coil 1	in Coil 2	
I	J	-J	Perpendicular to steel
II	J	J	Parallel to steel
III	J	0	Partly perpendicular, partly parallel

According to the obtained results, it is found that the entire analyzed region of P21-M1 can be divided into two zones, i.e., the 3-D eddy current region of a thin layer including a few of the silicon sheets with a fine mesh, e.g. 0.15mm thick mesh layer as an initial calculation, and a 2-D eddy current region, treated as a bulk of laminated sheets, in which the eddy currents flow along the planar sheets without the normal component. The nonlinearity and electric and magnetic anisotropy of the laminations are taken into account.

In this zoned modeling the total iron loss W can be expressed as (1)

$$W = \sum_{i=1}^{NE_{2d}} [W_h^{(e)}(B_{mi}^{(e)}) + W_e^{(e)}V_i^{(e)}] + \sum_{i=1}^{NE_{3d}} W_t^{(e)}(B_{mi}^{(e)})V_i^{(e)} \quad (1)$$

Where $W_h^{(e)}$ and $W_e^{(e)}$ denote the specific hysteresis and eddy current loss per element respectively for the 3-D eddy current region; while $W_t^{(e)}$ represents the specific total iron loss per element for the 2-D eddy current region. The W_h - B_m and W_e - B_m curves used in (1) can be measured in advance. $B_m^{(e)}$ and $V^{(e)}$ are the peak value of the flux density and the volume per element respectively; NE_{2d} and NE_{3d} are the numbers of elements of the 2-D and 3-D eddy current regions.

The measured and calculated total iron loss results of P21-M1 (20 sheets) and P21-B are shown in Table II and Table III respectively, and they are in practically good agreement.

TABLE II
TOTAL IRON LOSS UNDER DIFFERENT EXCITING SOURCE (P21-M1)

Current (A, ms, 50Hz)	Case I (W)		Case II (W)		Case III (W)	
	Measured	Calculated	Measured	Calculated	Measured	Calculated
10.0	2.2	2.14	0.66	0.62	0.59	0.57
15.0	5.3	5.15	1.43	1.33	1.39	1.26
20.0	10.2	9.58	2.71	2.45	2.99	2.76
25.0	16.8	15.47	4.72	4.49	5.19	4.91

TABLE III
TOTAL IRON LOSS UNDER DIFFERENT EXCITING SOURCE (P21-B)

Currents (A, ms, 50Hz)	Case I (W)		Case II (W)		Case III (W)	
	Measured	Calculated	Measured	Calculated	Measured	Calculated
10.0	11.97	12.04	11.61	12.83	6.15	6.57
15.0	26.89	27.12	26.52	26.98	13.70	14.43
20.0	49.59	50.92	47.16	47.52	24.73	25.49
25.0	82.39	84.78	74.40	76.30	39.92	40.12

From Table II and Table III the essential difference between P21-M1 and P21-B in iron loss under different excitations can be summarized as follows:

- 1) For the lamination-based model, P21-M1, one can see that

$$\begin{cases} Loss(Case I) \cong 3.5 \times Loss(Case II \text{ or } Case III) \\ Loss(Case II) \cong Loss(Case III) \end{cases} \quad (2)$$

- 2) For the solid plate-based model, P21-B, the results are quite different from that of P21-M1,

$$\begin{cases} Loss(Case I) \cong Loss(Case II) \\ Loss(Case I \text{ or } Case II) \cong 2 \times Loss(Case III) \end{cases} \quad (3)$$

The iron loss results suggest that the eddy current loss induced within a thin layer is strongly dependent on the exciting pattern, such as the cases described in Table I, and on whether the magnetic steel is solid or laminated. There is a complicated relationship between the loss and the exciting sources.

The measured and calculated results of the magnetic flux inside the magnetic steel plate of P21-B are shown in Table IV. To validate the analysis method further, the measured and calculated results of the magnetic flux density at the specified positions in air ($y=0.0\text{mm}$, $x=3.76\text{mm}$, see the coordinate in [2]

or in the definition of Problem 21 at www.compumag.co.uk) under different exciting conditions have been obtained for P21-M1. Fig.2 shows the distributions of B_x of the Case II and Case III. The measured and calculated results are in good agreement.

TABLE IV
FLUX UNDER DIFFERENT EXCITING SOURCE (P21-B)

Current (A, ms, 50Hz)	Case I (mWb)		Case II (mWb)		Case III (mWb)	
	Measured	Calculated	Measured	Calculated	Measured	Calculated

IV. CONCLUSION

The effect of the source replacement on both the iron loss and flux inside the solid magnetic steel plates and the laminated silicon steel sheets is examined in detail based on the proposed models, taking account of both the electric and magnetic anisotropy of the material.

The zoned approach (involving with 3-D and 2-D eddy current sub-regions) is efficient in dealing with the lamination configuration, which is validated by comparing the calculated and measured results.

The different electromagnetic behavior of the magnetic steel components with either laminated or solid geometries is shown.

An Adaptive Equivalent Circuit Method for TEAM Problem 28: An Electrodynamic Levitation Device

Wei Li, Jiang Lu, and Chang Seop Koh, *Senior Member, IEEE*
 Chungbuk National University
 Chungbuk National University, Cheongju, Chungbuk, 361- 763, Korea
 liwei@chungbuk.ac.kr

Abstract — An adaptive equivalent circuit method is developed for analyzing the TEAM Problem 28. The problem is solved by transferring the system to an equivalent circuit model which is set up by adaptively divided the plate into a series of segments based on the field continuity condition at the interface of segments. The performance is obtained by solving the circuit equations combined with motional equations with Runge-Kutta-Fehlberg method. The accuracy and efficiency of the proposed method are verified by comparing with FEM calculation and experimental results.

I. INTRODUCTION

TEAM problem 28 is an electrodynamic levitation system utilizing the eddy current induced in conducting plate. This is a complex system involves electric circuits, magnetic fields and mechanical movements. This kind of repulsion system is being involved in many engineering applications due to its very fast response via small inductance. Typical examples are electromagnetic launcher, electromagnetic brake, actuator of circuit breaker and arc eliminator. In order to analyze this kind of system, finite element method (FEM) coupled with circuit and motional equations have been used widely. The FEM, however, require huge computing time related with transient time-stepping analysis. Especially if it is related with parameter optimization of the system, it can be hardly adopted.

For reducing the computing time, hence, paying attention to the fact that the system does not contain any magnetic material, equivalent circuit methods have been developed [1]-[2]. These methods, however, still depend on FEM for parameter calculation with a lot of computing time, and do not explain how to divide the conducting plate for accurate analysis.

In this paper, an adaptive equivalent circuit method is developed, where the conducting plate is adaptively divided into a series of segments considering the field continuity condition at the interface of segments. The accuracy and efficiency of the proposed method are investigated through comparison with FEM and experimental results for TEAM problem 28.

II. ADAPTIVE EQUIVALENT CIRCUIT METHOD

Fig. 1 shows the configuration of the TEAM problem 28 where a cylindrical aluminum plate, of which mass is 0.107(kg), is located above two cylindrical coils. When a sinusoidal current source is supplied to the inner and outer coils, the conducting plate will experience a repulsive force along z direction due to the eddy current induced in the conducting plate.

A. Equivalent Circuit Method

In order to approximate the distribution of eddy currents in the conducting plate, the plate is divided into a series of segments as shown in Fig. 2(a), and the eddy current, in each segment, is assumed to have uniform distribution. Each segment, then, physically corresponds to a conductive ring, as shown in Fig. 2(b), with its circuit parameters of resistance and inductance as shown in Fig.2(c). In this approximation, the whole system can be transformed into equivalent circuits as shown in Fig. 2(d).

The circuit equations of the equivalent circuits are as follows:

$$I_i R_i + d\lambda_i / dt = 0, \quad i = 1, 2, 3, \dots, N. \quad (1)$$

$$\frac{d\lambda_i}{dt} = \sum_{s=1}^2 L_{is} \dot{I}_s + \sum_{j=1}^N L_{ij} \dot{I}_j + \sum_{s=1}^2 I_s \frac{\partial L_{is}}{\partial z} \frac{dz}{dt}, \quad i = 1, 2, \dots, N. \quad (2)$$

where the subscript s denotes the exciting coil, N is the number of segments, R_i , I_i , λ_i are the resistance, eddy current and flux linkage of the i -th segment, respectively, L_{is} is the mutual inductances between i -th segment and exciting coil. The derivative of inductance L_{ij} between segments is zero. Since the inductances depend only on the geometric configuration, they can be computed analytically using Bartky's transformation [3].

The dynamic state equations are obtained by combining (1)-(2) and motional equations as follows:

Fig. 1. The dimension of the TEAM Workshop 28 Problem

Fig. 2. Equivalent circuits of the TEAM problem 28.

$$\sum_{j=1}^N L_{ij} \dot{I}_j = -I_i R_i - \sum_{s=1}^2 L_{is} \dot{I}_s - \sum_{s=1}^2 I_{N+2} I_s \frac{\partial L_{is}}{\partial z}, \quad i=1, \dots, N \quad (3-a)$$

$$\dot{I}_{N+1} = I_{N+2} \quad (3-b)$$

$$\dot{I}_{N+2} = (F_{em} - F_G)/M \quad (3-c)$$

where I_{N+1} , I_{N+2} and M are the position, speed and mass of the plate, respectively, F_{em} and F_G are the electromagnetic and gravitational forces acting on the plate, respectively. In the solution of (3), I_i ($i=1,2,\dots,N$) and F_{em} are found from the previous time-step, and Runge-Kutta-Fehlberg method is introduced to control the step-size automatically.

After finding the eddy currents in each segment, the electromagnetic repulsive force is computed as follows:

$$F_{em} = -\sum_{s=1}^2 \sum_{i=1}^N I_s I_i \frac{\partial L_{si}}{\partial z} [N] \quad (4)$$

B. Adaptive Segmentation of the Conducting Plate

The efficiency and accuracy of the proposed algorithm strongly depend on the segmentation of the conducting plate since the distribution of the eddy currents in conducting plate is a lot affected by the segmentation just like mesh refinement in FEM. According to the electromagnetic field theory, the tangential component of electric field intensity should be continuous at the interface of two segments. From this, together with Ohm's law, we get, at the interface of segments, the condition of $J_{1t} = J_{2t}$. In this paper, local field continuity error for a segment (e), shown in Fig. 3(a), is defined as follows:

$$e^{(e)} = \int_{t_1}^{t_2} \left(\sum_{k=1}^{N_e} |J^{(e)} - J_k| \cdot l_k / \sum_{k=1}^{N_e} l_k \right) dt \quad (5)$$

where N_e is the number of the neighboring segments of e -th segment, $J^{(e)}$ and J_k are the eddy current densities of the e -th segment and the k -th neighboring segment, respectively, l_k is the length of the overlapped interface between e -th segment and the k -th neighboring segment as shown in Fig. 3 (a). After computing the local error for all segments, the segments with local error of $1.1\bar{e} \leq e^{(e)} \leq 1.5\bar{e}$ is refined into two, and those with $e^{(e)} \geq 1.5\bar{e}$ into four segments, respectively, as shown in Fig. 3(b) and Fig. 3(c).

C. Solving Procedure

The overall solving procedure of the proposed method is summarized as follow:

- Step 1. Divide the conducting plate into several uniform segments.
- Step 2. Calculate all circuit parameters, and set up the state equations.
- Step 3. Solve the state equations in time domain, and calculate the local field continuity error for all segments.
- Step 4. Stop if the final displacement is converged. Otherwise

Fig. 3. Segment refinement. (a) before refinement, (b) into two segments, (c) into 4 segments.

refine the segments and go to Step 2.

III. NUMERICAL RESULTS

Fig. 4 shows the distribution of the segments with eddy current density in each segment at different iterations, and Fig. 5 compares the distribution of the eddy current density at the plane of $z=4.6\text{mm}$ as the plate is refined. It is observed that the proposed algorithm gives very smooth eddy current distribution compared with uniform segments. The numerical efficiency and accuracy of the proposed method are shown in Fig. 6 and Table I by comparison with FEM and experimental results. As it is seen from the comparison, the proposed method is much more efficient than FEM and uniform refinement, and also has a good accuracy.

In the version of full paper, the proposed algorithm will be applied to the performance analysis of a Thomson-coil actuator for a high-speed circuit breaker, and the results will be discussed.

Proposal of a Benchmark for Multi-Level Optimization with 3D Finite Element Model

T. V. Tran, S. Brisset, and P. Brochet, *Members, IEEE*

L2EP, Ecole Centrale de Lille, Cité Scientifique, BP 48, 59651, Villeneuve d'Ascq Cedex, France

Abstract—A benchmark is proposed in order to compare algorithms for multi-level optimization. The device is a safety transformer. The discrete design variables are belonging to standard values for lamination, frame, and wire leading to 246,078,000 feasible solutions. Two models are available to compute the objectives and constraints: a 3D FE fine model and a lumped model. Their computation times are 2 hours and 50 ms, respectively. Combining their properties during the optimization greatly reduce the computation time.

Index Terms—Multi-level optimization, discrete optimization, space mapping technique, benchmark, 3D FEA

I. INTRODUCTION

Nowadays, the finite element (FE) method is often used to model electromagnetic devices with a high accuracy. The FE models in two or three dimensions (2D, 3D) are considered as virtual prototypes. However, the multi-physical coupling and the great number of unknowns in 3D FE models are very time consuming.

In the design of electrical devices, discrete design variables occur naturally in the optimization problem formulation. For instance, the numbers of slots and magnets are integers, and the type of materials and structure are discrete. However, discrete optimization requires different concept than the conventional continuous problems. Derivatives do not directly apply to the combinatorial optimization problem. So the amount of model evaluations during the discrete optimization is much higher than the continuous one.

Applying directly the optimization methods to 3D FE models may lead to an excessive computation time going from several days to few months. So replacing the 3D FE model by a surrogate model that is less time consuming is an interesting way to reduce the computation time of optimization. However, the quality of the solution should be as good as the one found with the FE model.

According to the state of the art, the global optimization with a FE model and its surrogate version can be done in two steps. The first step consists in the progressive building of a response surface. New points are added in the areas where the surrogate model is not accurate enough. The global optimum is found in the second step with any algorithm requiring a high number of evaluations such as genetic algorithms (GA). Several methods are used to build the surrogate model: diffuse element method [1], Kriging methods [2], artificial neural networks [3]-[5], and radial basis functions [6]. The surrogate model has the advantages to be fast to compute, smooth, and to have explicit derivatives at low cost. Other approaches use an inaccurate surrogate model that is progressively refined where temporary

optimums lie [7]. In the EGO method [8], the surrogate model is also refined with points belonging to areas where the accuracy is low. Unfortunately, all those methods require a high the number of evaluations of the FE model to build the surrogate model. This is cancelling the benefits of the optimization with the surrogate model because the total time of identification and optimization is often similar to the time of a direct optimization with the FE model.

To reduce significantly the number of FE model evaluations, the surrogate model has to contain initially some knowledge. It can be analytical equations describing the physical phenomena within the device or a lumped model. This model is called coarse model and can be improved locally thank to the FE model that is called fine model. Combining both models is called multi-level optimization and the space-mapping techniques are very effective to solve them [9]-[11].

The COMPUMAG TEAM workshops propose two benchmarks for optimization with FE models [12]-[13]. The models are 2D static magnetic and require few minutes for each evaluation. Thanks to them, continuous, discrete, and multi-objective optimization algorithms have been proposed and compared. Unfortunately, no coarse model is available for the superconducting magnetic energy storage system and the die press.

In many electromagnetic devices such as motors, transformers, electromagnets, etc. it is possible to build a lumped model and a FE model. Therefore, this paper proposes a benchmark for multi-level optimization with both models. The device is a transformer and a 3D FE model with a fine mesh is required to have accurate results on the leakage inductance, for instance. The computation time of the fine and coarse models are 2 hours and 50 ms, respectively.

In the next sections, the optimization problem, the fine model and the coarse model are described. A first result is shown in section IV. Finally, some conclusions are given.

II. OPTIMIZATION PROBLEMS

The safety isolating transformer uses grain-oriented E-I laminations. The primary and secondary windings are both wound around the frame surrounding the central core (Fig. 1).

The optimization problem contains 7 discrete design variables: three parameters $\{a, b, c\}$ for the shape of the lamination; one for the frame $\{d\}$; two for the section of conductors $\{S_1, S_2\}$ and one for the number of primary turns $\{n_1\}$ (Fig. 1). There are 24 types of lamination E-I, 62 types of frame F and 63 types of enameled wire W given in standard catalogues. The number of primary turns n_1 is integer but only 1,000 values are allowed, leading to 246,078,000 possible combinations.

Fig. 1. Geometry of the transformer problem in 3-D.

There are 7 non-linear inequality constraints. The copper and iron temperatures T_{co} , T_{ir} respectively should be less than 120°C and 100°C . The efficiency η should be greater than 80%. The magnetizing current I_μ/I_1 and drop voltage $\Delta V_2/V_2$ should be less than 10%. Finally, the filling factors of both coils f_1, f_2 should be lower than 0.5 for round wire.

The objective function aims to minimize the mass of iron and copper materials. So the problem can be expressed as:

$$\begin{aligned}
 \min \text{ mass}(X) & \quad \text{s.t.} & \quad \eta \geq 0.8 \\
 X = \{a, b, c, d, S_1, S_2, n_1\} & \quad T_{co} \leq 120^\circ\text{C} & \quad I_\mu/I_1 \leq 0.1 \\
 \{a, b, c\} \in \text{E-I} \quad d \in \text{F} & \quad T_{ir} \leq 100^\circ\text{C} & \quad \Delta V_2/V_2 \leq 0.1 \\
 S_1, S_2 \in \text{W} \quad n_1 \in \text{N} & \quad f_1 \leq 0.5 & \quad f_2 \leq 0.5
 \end{aligned} \quad (1)$$

One of the constraints, e.g. the efficiency, may be changed to an objective in order to set up a multi-objective optimization problem: minimize *mass* and maximize η .

III. MODELS

A. 3D finite element "fine" model

Thermal and magnetic phenomena are both modeled by using 3D FEA on one eighth of the transformer due to the symmetries. For the electromagnetic modeling, all magnetic and electric quantities are assumed sinusoidal. Full load and no-load simulations are used to compute all the characteristics. The iron loss is computed with Steinmetz formula and the leakage inductances are calculated with the magnetic co-energy. The magneto-thermal coupling requires about 2 hours.

B. Lumped "coarse" model

The modeling hypotheses are uniform distribution of induction in the iron core and no voltage drop due to the magnetizing current. The thermal assumptions are the same than the 3D FE model except that the temperatures are uniform within the coils and the lamination. The lumped model contains five elements and the computation time about 50 ms.

IV. FIRST RESULT

One algorithm combining Branch-and-Bound method with Output Space-Mapping obtain a solution by using 4 evaluations

of FE model and 127,852 evaluations of lumped model [14]. The total time for optimization is then less than 10 hours.

V. CONCLUSION

A benchmark is proposed in order to compare algorithms for multi-level optimization. The device is a safety transformer. The discrete design variables are belonging to standard values for lamination, frame, and wire leading to 246,078,000 feasible solutions. Two models are available to compute the objectives and constraints: a 3D FE model and a lumped model. Their computation times are 2 hours and 50 ms, respectively.

This benchmark meets the requirements of engineers and scientists working on the design of electromagnetic devices by using 3D FE models. It is dedicated to highlight the most effective multi-level optimization methods.

Abstract— This paper presents a visualization method of magnetic flux lines applying Tube System. Incomplete visualization of magnetic flux lines leads to misunderstanding about the magnetic field and the phenomenon to an observer. We have already proposed a method to compute the magnetic flux lines analytically from edge finite element results. In this paper, a method to appropriately allocate the magnetic flux lines in 3-D space applying the Tube System is discussed. In the proposed method, the tube's radius depends on the strength of the magnetic field, which regulates the density of the lines. The proposed method can generate the appropriate visualization of the magnetic flux lines, thus allowing the observer to correctly interpret the magnetic field and the phenomenon.

I. INTRODUCTION

A huge amount of numerical data results from electromagnetic field analysis, with improvement of computer performances and development of analysis methods in recent years. From the huge data, it is difficult to interpret the physical phenomenon and to mine the valuable information. Some ways of electromagnetic field visualization are, therefore, used, such as contour, distribution and vector maps, as a tool of magnetic field analysis software. These ways are effective to quantitatively visualize the field on an arbitrary 2-D plane, but unsuitable for 3-D field visualization. The magnetic flux line visualization is the most effective way to grasp the magnetic field in 3-D space, so it offers the observer the qualitative understanding about the characteristics.

A few methods to visualize the magnetic flux line have been proposed [1], [2]. In [1] and [2], the magnetic flux lines are computed analytically from the tetrahedral and hexahedral edge finite element results. These works, however, do not deal with the problem to appropriately allocate the magnetic flux lines, in proportion to the magnetic flux density. The demands for the visualization of the magnetic flux lines are:

- (i) the density of magnetic flux lines is proportional to the strength of the magnetic flux density, $|\mathbf{B}|$ [T],
- (ii) the tangential direction of magnetic flux line is the same as the direction of the magnetic field at each point.

It is necessary to draw the magnetic flux lines according to the demands mentioned above. The demand (i) reveals that the magnetic flux lines must be allocated in proportion to the magnetic flux density.

In this paper, a method to appropriately allocate the magnetic flux lines applying the Tube system is proposed on demands of magnetic flux line visualization. The Tube System is newly developed for 3-D magnetic flux line visualization based on the Dynamic Bubble System, [3], [4], which is used

for mesh generation. It deals with a sphere, called the *bubble*. However, a magnetic flux line cannot be represented by the sphere. In the newly developed Tube System, a tube surrounding a magnetic flux line is employed. The tube diameter and the attractive force between tubes, called the *tube force*, depend on the magnetic flux density. The tubes move until the distribution reaches a closely-packed configuration.

II. ALLOCATION OF MAGNETIC FLUX LINES

The allocation of magnetic flux lines must obey the demands given in Section I, so that the observer can qualitatively grasp the magnetic field direct from the lines. Before, the method to allocate the magnetic flux lines was proposed in [5]. It has a difficulty to specify a plane intersecting with all the magnetic flux lines by hand. On the intersecting plane, the Dynamic Bubble System [3], [4] is applied to allocate the magnetic flux lines, as shown in Fig. 1. It requires a difficult labor for user and it has the problem that the allocation of magnetic flux lines cannot be obtained when the plane intersecting with all the magnetic flux lines does not exist in the analysis domain.

Fig. 1. The previously proposed method has a problem for user to specify a plane which intersects with all the magnetic flux lines.

In order to address the problem, we have developed the method applying the Tube System, which is unnecessary to specify the plane intersecting with all the magnetic flux lines.

In the Tube System, a virtual tube is supposed to surround a magnetic flux line, as shown in Fig. 2. According the demands (i), the radius of tube, R , is in proportion to the strength of magnetic field;

$$R \propto \frac{1}{\sqrt{|\mathbf{B}|}}, \quad (1)$$

where $|\mathbf{B}|$ is the magnitude of magnetic flux density on the center of tube. Thus, the radius of tube changes with the location. In order to effectively visualize the magnetic field,

the tube radius R is controlled by multiplying an arbitrary constant value c ;

$$R = \frac{1}{\sqrt{|B|}} \times c \quad (2)$$

When c is too large, the number of the magnetic flux lines drawn is too small for the user to grasp the phenomenon. In order for the user to effectively grasp the magnetic field, the value of the constant c must be suitably controlled.

Fig. 2. An example of surrounding tubes and magnetic flux lines generated from a permanent magnet.

In order to closely-packedly allocate the magnetic flux lines, the tubes must move by the tube force, which depends on the tubes' radius and their distance. The tube force is categorized as follows:

- (i) attractive force when $l > r_A + r_B$,
- (ii) zero force when $l = r_A + r_B$,
- (iii) repulsive force when $l < r_A + r_B$,

where l is the distance of tubes, r_A and r_B are the radius of the magnetic flux lines A and B , respectively, as shown in Fig. 3. The function of the tube force [3], [4] is given as

$$F(l) = \alpha l^3 + \beta l^2 + \gamma l + \delta, \quad (3)$$

where $F(l)$ is shown in Fig. 6. The coefficients α , β , γ and δ are obtained from $F(l_0) = 0$, $F'(l_0) = 0$, $F(0) = M$ and $F'(0) = 0$, $l_0 = r_A + r_B$, u_{l_0} and M are the effective range of tube force and the maximum force, respectively.

III. MAGNETIC FLUX LINE VISUALIZATION

A. Permanent Magnet and Iron Model

An example is shown in Fig. 5, where the magnetic flux lines are analytically computed from the FEA result of the

Fig. 3. The tube force acting between magnetic flux lines A and B depends on the radii r_A , r_B and the distance l .

Fig. 4. The tube force is calculated from $l_0 = r_A + r_B$, the maximum force M , and the effective range of the force u_{l_0} .

model consisting of a permanent magnet and an iron plate in Fig. 1. Fig. 5(a) shows the result with $c = 50$ in (2), the number of the drawn magnetic flux lines is 32. In Fig. 5(b), 79 magnetic flux lines are drawn with $c = 100$. It is easy to control the number of the drawn magnetic flux lines. In both results, the rational allocations of the magnetic flux lines are achieved.

B. Permanent Magnet Motor Model

The proposed method is applied to a surface permanent magnet motor. It is difficult to visualize the magnetic flux lines since the rotor rotates. Fig. 6 shows the magnetic flux lines of the rotating motor. As the result, it is possible to represent the smoothly changing magnetic flux lines while the rotor is rotating.

(a) 32 lines with $c = 50$ (b) 79 lines with $c = 100$
Fig. 5. The magnetic flux lines are visualized.

(a) 0 deg. (b) 33.3 deg. (c) 66.7 deg.
Fig. 6. The magnetic flux lines of the rotating motor.

IV. CONCLUSION

We have proposed the method to rationally allocate the magnetic flux lines utilizing the Tube System. The proposed method and two examples are shown. The magnetic flux line visualization helps us to interpret the magnetic field and the phenomenon.

Abstract – A strategy for the parallel 2D Delaunay refinement algorithm is proposed in this work. The implementation approach is based on the decomposition of the initial coarse mesh into smaller subdomains which are refined in parallel. The developed parallel method presents few message-passing operations and low communication costs due to application of a preresinement and a discretization of the segments along the boundaries.

I. INTRODUCTION

Nowadays, the immense technological progress provides access to powerful computers for problem resolution, mainly in areas such as Computational Fluid Dynamics (CFD) and Computational Electromagnetics (CEM) that require larger meshes [1].

Methods such as Delaunay Algorithm [2], [3] or Advancing Front [4] can be applied for 2D quality grid generation. Nevertheless, the mesh generation grows with the problem size, thus the triangulation produces very large meshes with millions of elements, increasing the processing time and, in some cases, exceeding the memory capacity.

The advent of the cluster brought a new programming strategy: the parallel programming. Parallel mesh refinement decomposes the initial mesh into smaller submeshes which are refined in parallel. However, this induces unpredictable communication costs with degree of dependency or synchronization [5].

An alternative to overcome this problem is the application of two strategies in order to minimize the synchronization between the subdomains.

First of all, the initial coarse mesh is preresefined by eliminating the extremely obtuse triangles generating a less poor “initial mesh” [6]. Second, the discretization of the boundary segments along neighboring partitions decrease the coupling between them [5].

II. PARALLEL 2D DELAUNAY REFINEMENT

Typically, a Delaunay mesh refinement finds an initial mesh starting from a collection of vertices and segments, also known as *Planar Straight Line Graph* (PSLG). In a triangulation, only the half-lines of the input PSLG will be considered segments, while the other ones are edges [3].

This work was supported in part by the CNPQ under Grand No. 140226/2002-8

The next stage is to decompose the coarse grid into smaller subdomains using METIS, a popular partitioning program from the University of Minnesota [7].

The partitions are distributed over the nodes of the cluster, where each submesh is refined concurrently. If a boundary segment is split, the neighboring subdomains are updated for this split by means of messages [8], ensuring the conformity of the mesh along the interfaces.

However, this synchronization strategy has high coupling, presenting high communication costs.

III. COMMUNICATION STRATEGY

The main insight of this algorithm is to attempt to reduce the communication and synchronization, through improvements in the initial mesh, resulting in submeshes nicely subdivided with minimal interaction among processors, which enables a weak coupled between shared subsegments.

The algorithm does not divide the initial coarse mesh; firstly, a preresinement, method developed by the authors [6], was used to try to eliminate triangles whose apex angle is extremely obtuse, generating an “initial mesh” with fewer small angles, instead.

Therefore, the preresinement strategy improves the coarse grid allowing the METIS to get submeshes with few extremely obtuse triangles in the boundary segments, decreasing the encroached subsegments and, consequently, less refinement is necessary in these places [6].

Fig. 1. Traditional domain decomposition (a) and with reduced communication strategy (b).

Another important optimization is the discretization of the segments along their common boundary. The goal of this step is to anticipate the addition of the necessary vertices to guarantee a boundary conforming along the shared segments, decreasing more and more the number of the message-passing between them.

The discretization proposed differs from others in that, instead of generating a constrained Delaunay triangulation, it ensures that all elements are Delaunay.

As Fig. 1a shows, the submeshes have very small angles in boundary segments due partition of the initial coarse mesh of an electromagnet. In Fig. 1b, a few small angles are generated by prerenement application.

IV. RESULTS

The examples approach the final parallel mesh of an electromagnet with 4 partitions. In Fig. 2 a traditional parallelism is accomplished, while Fig. 3 illustrates the mesh with low synchronization obtained by the developed method, i.e., with weakly coupled parallelism.

The comparison of the traditional algorithm and the communication strategy execution for an electromagnet with 4 partitions is shown in Tables I and II. Table I summarizes the number of message-passing for the traditional parallel refinement. Similarly, Table II presents the results for the method proposed.

Fig. 2. Parallel mesh of an electromagnet without reduced communication strategy.

Fig. 3. Parallel mesh of an electromagnet with reduced communication strategy.

TABLE I: PARALLEL REFINEMENT WITHOUT COMMUNICATION STRATEGY.

Process	No of triangles	No of sent messages	No of received messages	Time (s)
P_0	386	9	35	<2
P_1	313	6	9	<2
P_2	170	9	36	<2
P_3	208	65	9	<2

TABLE II: PARALLEL REFINEMENT WITH COMMUNICATION STRATEGY.

Process	No of triangles	No of sent messages	No of received messages	Time (s)
P_0	578	2	2	<1
P_1	367	2	7	<1
P_2	637	4	5	<1
P_3	392	11	5	<1

V. CONCLUSIONS

The presented strategies provided substantial improvements in the communication reduction in parallel 2D Delaunay refinement. The experimental results showed that the algorithm is weakly coupled or even decoupled according to the problem.

The prerenement generates a less poor “initial mesh”, so supplying quality submeshes with low degree of dependency, by decreasing the number of encroached subsegments. In addition, the discretization of the common boundary “predicts” the local of futures vertices, thus minimizing or eliminating the amount of necessary communication to ensure the conformity along the shared segments.

Another possibility to reduce more and more the communication is to smoothing the boundary between the subdomains, i.e., if an element has more neighbors in a neighboring partition, then the element is transferred from original partition to this neighboring subdomian.

Future works intend to smooth the boundaries, and, besides, to extend the developed strategies to a three-dimensional version. The key idea is to apply the diametral sphere and equatorial sphere techniques [2] to extend the prerenement process for 3D.

Abstract-The purpose of these papers is to answer a basic problem of finite element method that is how do the elements which have determined shapes form the element grid which has determined structure. In order to study this problem, a method called chain-making and chain-coupling is established. Through this method the quantitative relationships between the geometric structures of the element grid and the geometric structures of its elements are founded. This problem is studied both in 2-D and 3-D cases and here is the second part of 2-D case conclusions.

I. INTRODUCTION

In order to answer the problem of how do the elements which have determined shapes form the element grid which has determined structure, a method called chain-making and chain-coupling is established. In the method, the relationships between elements in an element grid are classified according to their topological relationships. Then through defined steps the element grid which has complicated relationships between its elements can be disassembled to another element grid which just has a single kind of 0-dimension relationship between its elements. The disassembled element grid is called chain, and the disassemble procedure is called chain-making.

In a chain, elements have simple relationships of 0-dimension, so the quantitative relationships between the geometric structures of the chain and the geometric structures of its elements can be found relatively easily.

On the other hand, the 0-dimension relationships between the elements in a chain are inherited from the original element grid, so the original element grid can be reassembled from its chain. The procedure about how does the original element grid to be reassembled from its chain is called chain-coupling. By studying the chain-coupling procedure, basic properties about how do the elements in a chain form the original element grid are found, and the quantitative relationships between the geometric structures of the element grid and the geometric structures of its elements are found. So the problem of how do the elements which have determined shapes form the element grid which has determined structure are answered

II. NARROW SENSE CHAIN-MAKING AND CHAIN-COUPLING THEOREM OF 2-D GRID

Definition 2-1: Vertex Chain

On a set N which consists of elements with a number of n , a function f can be defined as following:

1. The first element e_1 just has one 0-dimension relationship with the second element e_2 through a common vertex v_{12} ;
2. The i th ($1 < i < n$) element e_i has one 0-dimension relationship with the $(i-1)$ th element e_{i-1} through a common vertex $v_{(i-1)i}$, and it has one 0-dimension relationship with the $(i+1)$ th element $e_{(i+1)}$ through a common vertex $v_{i(i+1)}$;
3. The n th-element e_n just has one 0-dimension relationship with the $(n-1)$ th element $e_{(n-1)}$ through a common vertex $v_{(n-1)n}$;

Thus the elements in set N are mapped to a vertex chain through function f .

Theorem 2-1: The first chain-making theorem in 2-D grid

In a 2-D triangle grid, if there are not cut-vertex, cut-edge and interior boundary in it, this triangle grid can be made into a vertex chain.

Theorem 2-2: The second chain-making theorem in 2-D grid

In a 2-D rectangle grid, if there are not cut-vertex, cut-edge and interior boundary in it, this rectangle grid can be made into a vertex chain.

Theorem 2-3: In a 2-D vertex chain, if the element number is n , the edge number of every element is m , then the total edge number in the chain is $l_c = n \times m$ and the total vertex number in the chain is $v_c = (n \times m) - (n - 1)$.

Theorem 2-4: Narrow sense chain-coupling theorem in 2-D grid

In a narrow sense chain-makeable 2-D grid among the number of elements: n , the edges of every element: m , total number of edges of the grid: l , number of boundary edges: l_b , number of interior edges: l_i ; total number of vertexes of the grid: v , number of interior vertexes: v_i , the following quantitative relationships hold:

$$l_i = (n \times m - l_b) / 2 \quad (1)$$

$$l = (n \times m + l_b) / 2 \quad (2)$$

$$v = l - (n - 1) \quad (3)$$

$$v_i = l - (n - 1) - l_b \quad (4)$$

The concern concepts and the demonstration of these theorems can be found in reference [1].

III. BROAD SENSE CHAIN-MAKING THEOREM

As shown in reference [1], the condition and procedure for narrow sense chain-making and chain-coupling are quite strict

and complicated. At the same time, along with these discussions, a very important property of chain-making and chain-coupling can be found, that is when the chain-coupling property of the n th element on a vertex chain is studied, the continuity of the n th element in the $(n-1)$ th order chain-making grid and n th order chain-coupling grid are required. But when this continuity is satisfied, it is not required that the original element grid could be made into a entire vertex chain, and there could be some branches in the making out vertex chain.

Definition 3-1: Branched Vertex Chain

A function f can be defined on a set N which consists of elements with a number of n , if it makes the i th ($i \leq n$) element e_i in the j th ($j \geq 1$) branch has one 0-dimension relationship with the $(i-1)$ th element e_{i-1} through a common vertex $v_{(i-1),j}$, then the elements in set N are mapped to a branched vertex chain through function f .

Definition 3-2: Branching Element in a Branched Vertex Chain

If branches appear on an element of a branched vertex chain, this element is called a branching element of the branched vertex chain.

Theorem 3-1: Chain-making Theorem in 2-D Grid

A 2-D grid can be made into one branched vertex chain at least.

IV. BROAD SENSE CHAIN-COUPLING THEOREM

Theorem 4-1: Theorem of Branched Chain-coupling

Branches in a branched vertex chain have no influence on the result of chain-coupling.

Theorem 4-2: In a 2-D branched vertex chain consist of elements of m edges and with element number of n , there are n element, $l_c = n \times m$ edges and $v_c = (n \times m) - (n - 1)$ vertexes in it.

Theorem 4-3: If there are x class touch vertexes with order of d_u ($1 \leq u \leq x$) and number of n_u ($1 \leq u \leq x$) for each class, in a 2-D grid with boundary edge number of l_b , then number of

boundary vertex in it is $v_b = l_b - \sum_{u=1}^x n_u \times d_u$.

Theorem 4-4: Chain coupling theorem in 2-D grid

In a 2-D grid if there are x class touch vertexes in it, among the number of elements: n , the sides of every element: m , the number of interior boundary i , the order of the x class touch point d_u ($1 \leq u \leq x$), the number of d_u order touch point: n_u ($1 \leq u \leq x$), total number of sides of the grid: l , number of boundary sides: l_b , number of interior sides: l_i ; total number of vertexes of the grid: v , number of interior vertexes: v_i , the following quantitative relationships hold:

$$l_i = (n \times m - l_b) / 2 \quad (1)$$

$$l = (n \times m + l_b) / 2 \quad (2)$$

$$v = l - (n - 1) - i \quad (3)$$

$$v_i = l - n - i + \sum_{u=1}^x n_u \times d_u - l_b + 1 \quad (4)$$

The concern concepts and the demonstration of these

theorems would be given in full paper.

Fig.1. Sample grid in 2-D case

In fig.1 three sample grids are shown. In fig1(a) $n=24, m=4, l_c=96, v_c=73, i=0, \sum_{u=1}^x n_u \times d_u=4, l_b=44, l_i=26, l=70, v=47, v_i=7$. In fig1(b) $n=19, m=6, l_c=114, v_c=96, i=0, l_b=52, l_i=31, l=83, v=65, v_i=13$. In fig1(c) $n=33, m=4, l_c=132, v_c=100, i=3, \sum_{u=1}^x n_u \times d_u=3, l_b=62, l_i=35, l=97, v=62, v_i=3$.

V. CONCLUSIONS

The goal of our work is to find out the numerical relationships among the number of geometric structures of the FEM grid and its elements. This task is rather difficult and interesting in 3-D case and the results can be used to verify FEM grid directly especially for automatic FEM grid generation.

On the other hand, during the analysis topological relationship between FEM elements in a FEM grid is studied thoroughly. Thus many further researches and application can be performed. In the end an unified description of FEM procedure based on these numerical relationships can be gained, and this is especially effective for large FEM software programming.

Abstract—Block matrix type linear systems often appear in many numerical resolution of electromagnetic problems and coupling problems. This paper deals with the evaluation of some adapted programming solutions for building and for inverting this kind of algebraic systems. One pays a particular attention to three criteria : development time, computation time and facility of use.

I. INTRODUCTION

BLOCK matrix is a current structure of linear system obtained when a numerical resolution is applied for an electromagnetic problems or more generally for multiphysics problems. For example, this kind of algebraic system appears in the implementation of the dual magnetodynamic potential finite element formulations, the mortar method implementation, a piezoelectric problem solved with finite elements method, the introduction of shell finite elements, or mixed formulations using boundary elements and finite elements, etc... In the last case, according of the nature of matrix blocks, different mode storages can be used full and sparse. In this paper three programming solutions are evaluated to implement this kind of linear systems in a finite element context. First by a MATLAB approach is presented on the 2D mortar method. The second solution is the use of a compiled language based on an oriented object approach. Finally an alternative solution based on a combined Python and C++ approach is proposed.

II. MATLAB APPROACH

The Matrix based languages such as commercial software MATLAB, or equivalent Open Source Free Software such as OCTAVE or SCILAB seem to be the more adapted solution. No type declaration is necessary and they don't need compilation.

In Matlab environment, once the blocks are made, the language allows great flexibility for manipulating block matrix. In particular, the user has two options to perform conjugate gradient method. As an example we can consider a 2D rotating electrical motor simulation with a mortar method approach [1]. The first option consists to assemble blocks to form a single global matrix. This option allows indifferently the use of iterative or direct solvers (based on the Gauss method) for the inversion of the linear system.

```
MatMortar = [A2ii CrossMortarBlock' Block0
             CrossMortarBlock DiagBlock A1Gammai
             tBlock0 A1iGamma A1ii];
Sol = pcg(MatMortar,SdMembre);
```

with the direct solver the resolution line becomes

```
Sol=MatMortar \ SdMembre;
```

The previous example shows the synthetic and digest writing of Matlab. The block matrix are manipulated as scalar variables.

A second option is to call the iterative method directly with the function defining how the matrix-vector product must be performed "MulMortar".

```
Sol = pcg(@MulMortar,SdMembre);
```

But Matlab code is interpreted during runtime and the computing time depends directly of the vectorization capability of the algorithm. If the different parts of the elements loop can be easily vectorized in a finite elements program, this operation is impossible for the elements loop itself. This drawback may be critical for a large 3D problem. It can be solved by the use of compiled subprograms (Fortran or C++ for example) directly interfaced with MATLAB through the dedicated interface process named mex-files or indirectly through files exchange cross the hard disk. This approach come to the loss of two main advantages of MATLAB as program readability and portability. One other critic is the poverty of the C++ interface.

III. OBJECT ORIENTED APPROACH

To reduce computational time for the resolution of important 3D problems, a compiled code is developed. An Object Oriented Programming (OOP) approach well adapted to finite element method is used with the C++ language. The time performance of this language is closed to Fortran one of the most popular and most efficiency language in scientific computing. A lot of libraries for scientific computing using this language already exist. For example in the code developed, the Array Class RNM of the free Open Source Software Freefem++ is used for managing multidimensional arrays [2]. The main goal of our code architecture is to guarantee no anticipation on the matrix structure of the algebraic system and its mode of

associated storage. The matrix can be an one block or a multi-block matrix with different storage modes for each block. The resolution of the algebraic system is based on iterative method as one of the most popular : the conjugate gradient. These methods are well adapted to this matrix structure because the iterative product can be performed for each block independently. Furthermore using specify functionality of the C++ language as the mechanism of "template", the implementation of the iterative resolution function can be made only once. The mechanism of "template" make the implementation of algorithms independent of data types. This is not possible in Fortran. The figure below presents a simplified scheme of the software architecture. The linear system resolution part uses the same principle seen previous with the definition of the function MulMortar in the Matlab example.

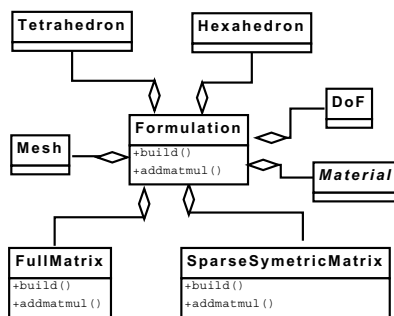

Fig. 1. Class aggregation

Each storage mode has its own class with its associated methods like constructors, pointers building, assembling, take into account boundary conditions, and obviously how performs the matrix-vector product.

To illustrate the code performance, a classical 3D Non Destructive Testing Problem (air Coil over a conducting plate) [3] is considered. Using a finite element modelling with combined potential formulation A-V (570 000 degrees of freedom), the computation time is about 420 s CPU on a pentium 2.66 GHz Processor. For the linear system resolution, the method of conjugate gradient is used with a Jacobi preconditionner (615 iterations). It can be observed that computation time is reduced of a factor 10 comparing to a Matlab Program. In the other hand, time for developement can be more disavantageous than in Matlab language. Furthermore the introduction of the problem data is more difficult.

IV. PYTHON APPROACH

An alternative solution is the use of the Python language developed in the 90s. It is a dynamic object-oriented programming language that can be used for many kinds of software development. Like Matlab, it has tools dedicated to a specific domain named "modules". In the last years, Scientific module (SciPy) for scientific functions and linear algebra, numerical module (NumPy) for multidimensional arrays management or a module for sparse matrix management (PySparse) have been developed. But the fundamental difference with Matlab is the number of solutions to encapsulate compiled languages [4]. Most languages offer the possibility to call programs written

in other languages but in Python this is particularly easy and smooth process. One reason is that Python was initially designed for being integrated with C and extended with new C codes. Several very powerful tool such as Swig, f2Py or Python Weave have been developed in this aim. It allows particularly to preserve existing Fortran, C or C++ solvers and to nest different codes in a multiphysics context [5]. Using Python script with NumPy, SciPY and PySparse modules for finite element method implementation, a computational time similar to the Matlab code is obtained. But using C++ encapsulation tool such as Swig allows to reduce computation time by a factor of more than 10. A complete example using several techniques to interface C++ with Python will be detailed and compared in the final paper. The Python script below shows that using dedicated modules for scientific computing, finite element method can have a Python implementation close to the Matlab implementation.

```

# element loop
for ielt in range(nbelt) :
    .....
    # Computation of the Elementary Stiffness matrix (analytic integration)
    MatElmt = (Grad.transpose()*InvJac.transpose()*InvJac)*Grad*double(DetJac/2./mu[idom])
    RHSElmt = ones(3,double)*J[idom]*DetJac/6.
    .....
# end of the element loop
.....
# inversion.
S = MatMef.to_sss().
K_ssr = precon_ssr(S, 1.9)
info, iter, relres = itsolvers.pcg(S, RHS, Az, tol, 100, K_ssr)
  
```

Fig. 2. Python script example

V. CONCLUSION

Recent numeric tools developed in Python make that this Free Open Source language can be a good alternative to Matlab for very fast numerical methods evaluating. Furthermore it seems to be very efficiency to encapsulate compiled language. These properties will be developed in the final paper to prove Python performance. Actually, it is more and more used in an agile programming process in software engineering and in numerical modelling.

Abstract – This work aims to present a visualization based simulation methodology of potentials and electric fields distribution applied to a pin-type polymeric insulators used in electric power distribution lines. The methodology is based on obtaining a three dimensional tomography of the part, generating three dimensional surfaces by the Marching Cubes algorithm, generating a STL (Stereolithography) file and, from it, obtaining the solid in order to simulate the electric field and potential applied on it. The advantage of this methodology is in the obtainment of the defect volumes such as they were produced in the parts, making the simulation closer to the use conditions.

I. INTRODUCTION

The use of polymeric insulators in the electric power distribution and transmission lines has constantly grown in the last years [1]. These components have advantages such as resistance to hydrophobicity in the presence of saline mist and rain, reduced mass, low cost and contamination resistance. On the other hand, we can cite the existence of defects in its interior, originated from the manufacture process as the main disadvantage [1]-[2]. A test used to verify these defects is the X-ray tomography [2]. It can provide a view of the forms of the object internal structure, such as the forms of the defects in the tested components.

Tomographic measurements techniques have their origin in the medical applications from the 60's. Nowadays, it has been used widely in engineering and science [2]-[3].

Reconstructions of three dimensional surfaces of objects offer a valuable diagnostic tool such as the anatomic form of the reconstructed object and volume measurements or surface area [2]. Knowing the volume of a defect, for instance, may help in the decision making regarding the suitable measurements in relation to the tested part (change or not).

The aim of this work is to present a methodology that uses the three dimensional tomography to create the real volume of polymeric insulators used in distribution lines to simulate and measure the electric field in these components.

II. GENERATION OF THE THREE DIMENSIONAL TOMOGRAPHY

The acquisition of the tomographic slices was carried out in the Instituto de Tecnologia para o Desenvolvimento – LACTEC, through an industrial tomography system

(Gilardoni). The images of the reconstructed surfaces are generated from multiples two-dimensional slices that compose the volume to be reconstructed. The Marching Cubes algorithm [4] was used in the tomographic images (slices in the bitmap format) for the generation of the three dimensional surfaces. The algorithm implementation was done in Java with the Open Source VTK (Visualization Toolkit) library in Linux 64 Bits platform. The Marching Cubes algorithm is based on two steps: (i) Surface detection corresponding to the assigned value as the parameter, (ii) normal calculation [4].

The surfaces generated by the algorithm are generally represented by a considerable number of triangles. The quantity of these triangles, presented in meshes, determines the quality and the processing time of the geometric model. However, meshes that present a high number of triangles are not adequate to real time applications. Thus, before generating the STL file, the number of polygons present in the 3D tomography must be reduced. In this work, the `vtkDecimatePro` class from the VTK library was used. The Decimation, proposed by Schroeder et al. [5], is a process that reduces the number of triangles in a mesh, preserving its characteristics as much as possible.

III. SOLID GENERATION FOR THE FINITE ELEMENTS SIMULATION

The finite elements method requires a solid for the generation of the simulation mesh. The model generated by the tomography in STL mesh (Stereolithography, 3D Systems, Valencia, California) was transferred to a CAD software type Solidworks (Solidworks Corporation, Dassault Systems, France) and through the “Scan to 3D” supplement, the model was edited and reconstructed from the STL file to a file of solid in the parasolid format (Siemens PLM Software, Berlin, Germany). This transformation was necessary in order to enable the processing of the model by the Comsol Multiphysics[®] analysis software.

This conversion enabled the removal of undesirable geometries resultant from noises in the computerized tomography, such as tips and other anomalies, as well as the reduction of processing computational costs, and the promotion of the discretization process in the future simulation

10. Software Methodology

by the transformation of a mesh surface in a solid model. The mesh surfaces are constituted of poly faces that have triangular borders and are exclusively flat, while the surfaces of solid models can be round and register protuberances or other geometry irregularities in the same face. In the present insulator model, it was possible to transform 270842 poly faces in a solid model with 1200 faces, with a minimal geometric distortion, as seen in Fig. 01 and Fig. 02.

Fig. 1. Left: Mesh with poly faces, Center: reconstructed solid model and Right: overlapping of the mesh with the solid model showing a low distortion of the process.

Fig. 2. Comparison of different models. Left: mesh with 270842 poly faces, Center: mesh with 1200 poly faces and Right: solid body with 1200 faces.

IV. SIMULATIONS WITH THE COMSOL MULTIPHYSICS® SOFTWARE

In order to identify electric field concentration on critical points, computational simulations using the Comsol Multiphysics® software were made, using the file generated from the three dimensional tomography of an insulator with bubble. The simulations are represented through a decreasing chromatic scale where the red color represents the highest intensity of the electric and potential field.

The configuration used for the simulations of the pin type polymeric insulator is shown in Fig. 3.

Fig. 3. Configuration used for the simulations of the pin type polymeric insulator.

The material of the pin type polymeric insulator is the high density polyethylene (HDPE), which must have maximum ϵ permissivity equal to 3. The electric potential applied to the cable was 8 kV. The metallic pin is grounded. Involving the system, it was inserted a box with air of $\epsilon = 1$ permissivity, in order to compose the limits of the considered system. The air bubble (defect) inside the insulator has $\epsilon = 1$ permissivity.

The simulation of electric potential applied to the insulator is shown in Fig. 4. Fig. 5 illustrates the distribution of the electric field. The black arrow points to the bubble.

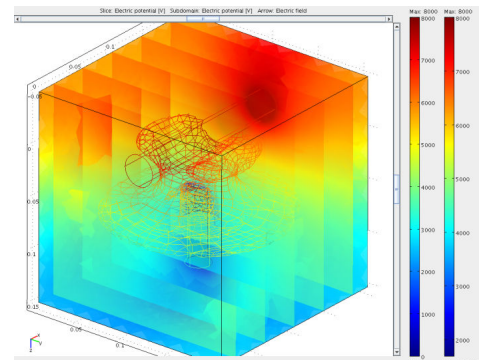

Fig 4. Simulation of the electric potential distribution.

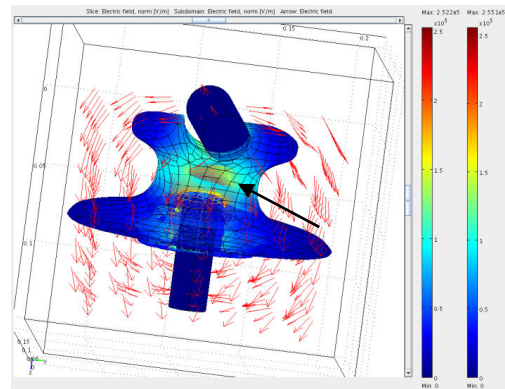

Fig 5. Simulation of the electric field distribution.

The simulated potential has a higher value in the region of the insulator that is near to the energized cable. The value of the electric field found inside the largest bubble is 114 kV/m. This value is above the electric field of the points that surround it, indicating the highest electric field concentration in this area. The existence of heterogeneity of the materials permissivity that composes the simulated system generates the electric field concentration in certain points. This electric field concentration may lead to the occurrence of internal partial discharges that erode the cavities inside the dielectric until its perforation [6].

The Cross-Entropy Method and its Application to Inverse Problems

S. L. Ho¹, and Shiyou Yang^{1,2}

¹Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong

²College of Electrical Engineering, Zhejiang University, Hangzhou, 310027, China

Abstract—This paper explores firstly the potential of a new evolutionary method - the Cross-Entropy (CE) method in solving continuous inverse problems. For this purpose, a CE based metaheuristic algorithm is proposed and evaluated on both low- and high-frequency engineering problems with promising results.

I. THE CROSS-ENTROPY METHOD

In the study of inverse problems, the evolutionary algorithm plays an important role because of the multimodal nature of the objective functions of inverse problems. In this regard, the simulated annealing, genetic, tabu search, particle swarm optimization, and ant colony algorithms have all been developed and applied in the computational electromagnetics community to solving typical inverse problems. Nevertheless, there is no universal algorithm according to the no-free-lunch theorem. Consequently, it is essential to guarantee the diversity of available evolutionary algorithms. In this regard, the cross-entropy (CE) method is worthy of further studies.

The CE method is firstly developed by Rubinstein for estimating the probabilities of rare events as an adaptive importance sampling algorithm [1], and soon it is extended to solve both combinatorial and continuous optimal problems [2]. The significance of the CE method is that it defines a precise mathematical framework for deriving fast and yet ‘optimal’, to a certain extent, updating/learning rules which are based on advanced simulation theory [3]. In finding the global optimum f^* of the following maximization problem

$$\max f(x): X \in R^n \rightarrow R, \quad (1)$$

the CE method will firstly randomize the problem according to a family of *probability density functions* (pdf) $\{g(\cdot; \mathbf{v}), \mathbf{v} \in \mathcal{V}\}$ on X , and (1) is then transformed to the so-called *associated stochastic problem* (ASP) to estimate the following probability

$$I(\gamma) = P_u(f(\mathbf{X}) \geq \gamma) = E_u I_{\{f(\mathbf{X}) \geq \gamma\}} \quad (2)$$

where, E_u denotes the corresponding expectation operator, \mathbf{X} is a random n -dimensional vector with the pdf of $g(\cdot; \mathbf{u})$ for some $\mathbf{u} \in \mathcal{V}$, γ is an adaptively updating parameter.

For the ASP problem, the CE method adaptively updates $g(\cdot; \mathbf{u})$ based on the Kullback-Leibler cross entropy, resulting in a set of degenerated pdfs $g(\cdot; \mathbf{u}), g(\cdot; \mathbf{v}_1), g(\cdot; \mathbf{v}_2) \dots$, which will quickly converge to the global optimal probability density function $g(f^*; \mathbf{v}^*)$. Consequently, the CE method comprises generally of the following two phases:

- (1) Generate a set of candidate solutions according to a predefined probability density function;
- (2) Update the parameters of this pdf by using only the

elite solutions to steer the search towards the global optimal in subsequent iterations.

In this paper, the normal distribution function $N(\mu, \sigma^2)$ with its mean μ and standard deviation σ is selected as the pdf of $g(\cdot; \mathbf{u})$. For the conditions as described, μ and σ will converge, respectively, to the global optima f^* and zero efficiently; and the corresponding iterative procedures of the proposed CE method are summarized as:

Algorithm based on CE method for Continuous Optimizations

1. Initialize: Set: N -size of the population, ρ -rarity parameter (which are small constant thresholds of the elite solutions for updating the parameters of pdf), $\mu_0, \sigma_0, \alpha_0, t = 0$.

2. Repeat

- 2.1 $t = t + 1$, Generate a population of feasible solutions according to the normal distribution pdf $N(\mu_{t-1}, \sigma_{t-1}^2)$;

- 2.2 Select elites, let \mathbf{I} be the indices of the ρN best samples (elites);

- 2.3 Update μ and σ . For all $j=1, \dots, n$, compute

$$\mu_{ij} = \sum_{i \in \mathbf{I}} x_{ij} / (\rho N), \quad \sigma_{ij}^2 = \sum_{i \in \mathbf{I}} (x_{ij} - \mu_{ij})^2 / (\rho N)$$

- 2.4 Smooth

$$\mathbf{u}_t = \alpha_t \mathbf{u}_t + (1 - \alpha_t) \mathbf{u}_{t-1}, \quad \boldsymbol{\sigma}_t = \alpha_t \boldsymbol{\sigma}_t + (1 - \alpha_t) \boldsymbol{\sigma}_{t-1}$$

- 2.5 Test for the stop criterion. If the stop criterion is satisfied, set the Stop-criterion:='true';

3. Until Stop-criterion:='true'.

The CE programming algorithm is very simply in code programming. Only a few parameters such as the size of the population and the rarity parameter need to be predefined and most of the key parameters are adaptively updated in the iterative process. For example, the performance parameter γ as used in (2) is automatically designated to the worst solution of the ρN best elites. On the other hand, the smoothing parameter α is updated automatically from its minimal to maximal values as the iterative number increases. Also, some small values of perturbations are deliberately and randomly added to σ to enhance the global search ability of the proposed CE method.

II. APPLICATIONS

A. Case Study One

The proposed CE method is firstly used to optimize a completely non-uniform antenna array, as depicted in Fig. 1, with the minimal number of elements being exploited to produce a satisfactory or acceptable pattern of the desired field, which is a shaped beam with a cosecant variation, as defined in [4]: the field will vary following a cosecant function in the

interval $\cos \theta \in [0.1, 0.5]$ and has a Maximum SideLobe Level (MSLL) of less than -25 decibel in the residual intervals. Mathematically, the desired pattern is expressed as:

$$F_{desired}(\cos \theta) = \begin{cases} \text{cosecant}(\cos \theta) & (0.1 \leq \cos \theta \leq 0.5) \\ 0 & (\text{elsewhere}) \end{cases} \quad (3)$$

$$MSLL_{desired} \leq -25 \text{ dB}$$

Fig.1. The schematic diagram of a linear antenna array of Q punctiform and omnidirectional elements along the z axis.

Fig.2. Comparison of the field patterns of the optimized (non-)uniform arrays by using different optimal algorithms

To optimize the non-uniform antenna array, the following objective function is defined and used:

$$\min f = \sqrt{\frac{\sum_{i=1}^N [f_{desired}^{norm}(\theta_i) - f_{designed}^{norm}(\theta_i)]^2}{\sum_{i=1}^N [f_{desired}^{norm}(\theta_i)]^2}} \quad (4)$$

where, $f_{desired}^{norm}(\theta_i)$ is the value of the normalized desired radiation pattern at the sampling point θ_i , $f_{designed}^{norm}(\theta_i)$ is the value of the radiation pattern produced by a designed array of Q elements.

To produce a field pattern which is close enough to the desired one using the proposed method (CE), a 19 element non-uniform antenna array is selected and used to optimize the complex excitations and locations of each element in order to find the global optimal solutions of these decision parameters. For performance comparison purpose, the matrix pencil method (MPM) [5] is also employed in this case study. The final solutions of the location (given in relative values with reference to the wavelength λ), amplitude (Ampl) and phase (Phas in degree) of each element of the optimized array by using the CE method are tabulated in Table I. The radiation patterns for the optimized arrays obtained using different algorithms as well as the results of a 30 uniformly spaced antenna array, which has been optimized using a modified tabu search algorithm [4], are depicted in Fig. 2.

From these numerical results it is obvious that a non-uniform antenna array with a minimal number of 19 elements optimized using the proposed CE method can produce a satisfactory radiation pattern which is almost the same as that of a 30 element uniform array obtained using the tabu search method, whereas the results for the same non-uniform array optimized using available MPM technique are not acceptable.

B. Case Study Two

As a last example, the Team Workshop problem 22 of a superconducting magnetic energy storage (SMES) configuration with 8 free parameters as reported in [6] is solved by using the proposed CE method. Table II gives the performance comparison of the proposed CE algorithm and the best ones searched so far by IGTE [6]. Again, this case study confirms positively the feasibility of the proposed algorithm in solving low frequency inverse problems.

Abstract—A Graphics Processing Unit (GPU) cluster optimized implementation of Maxwell’s equations discretized with a higher-order Discontinuous Galerkin Finite Element Method (DG-FEM) in the time domain is presented. DG-FEM is used because its characteristics are matching the parallelization design aspects of the NVIDIA Compute Unified Device Architecture (CUDA) programming model. Asynchronous file transfer is introduced to minimize parallelization overhead and improve scalability.

Index Terms—GPU-computing, GPGPU, CUDA, Discontinuous Galerkin, FEM, High Order.

I. INTRODUCTION

Efficient numerical simulation of electromagnetic devices strongly depends on short simulation time, which requires efficient solvers running on fast hardware. In addition to multicore parallelization, GPU computing has gained attention for accelerating volume based simulation methods. In [1] and [2], FDTD and FEM computations on GPUs are presented. First DG-FEM simulations on GPUs are reported in [3]. First multi-GPU configurations for the DG-FEM solution of Maxwell’s equations in time domain are considered in [4]. In this paper, the performance of DG-FEM discretized Maxwell’s equations computed on a NVIDIA GPU cluster is analyzed. A 3-level parallelization strategy is presented using the NVIDIA CUDA programming model as well as a linux pthread implementation [5] on the CPU level. The focus of this publication is the CUDA adapted DG-FEM discretization and its scalability when using more than a single GPU.

II. DISCRETIZATION

Electromagnetic wave propagation in lossless medium can be described using Maxwell’s curl equations

$$\frac{\partial \vec{D}}{\partial t} = \nabla \times \vec{H}, \quad (1)$$

$$\frac{\partial \vec{B}}{\partial t} = -\nabla \times \vec{E}. \quad (2)$$

Here, \vec{D} and \vec{B} denote the electric and magnetic flux density, respectively, whereas \vec{H} and \vec{E} identify the magnetic and the electric field strength. A nodal variational form of Maxwell’s equations is derived in [6], where the unknown field vectors are approximated using local high-order multi-dimensional

Lagrange polynomials. The DG-discretization of (1), (2) leads to a system of ordinary differential equations, reading

$$\frac{d}{dt} \varepsilon \mathbf{E} = \mathbf{M}^{-1} \mathbf{S} \mathbf{H} + \mathbf{M}^{-1} \mathbf{F} (\hat{\mathbf{n}} \times (\mathbf{H}^* - \mathbf{H}^-)), \quad (3)$$

$$\frac{d}{dt} \mu \mathbf{H} = -\mathbf{M}^{-1} \mathbf{S} \mathbf{E} - \mathbf{M}^{-1} \mathbf{F} (\hat{\mathbf{n}} \times (\mathbf{E}^* - \mathbf{E}^-)). \quad (4)$$

A special characteristic of DG-FEM is that the DG-operators \mathbf{M} , \mathbf{S} and \mathbf{F} , leading to mass-, stiffness and flux-matrices, respectively, have compact support only within each element’s boundary. As a consequence, \mathbf{M} is locally defined on the reference element and can be inverted without much numerical effort. This provides the opportunity of using explicit time integration schemes, e.g. the 4th order low storage explicit Runge-Kutta scheme or local timestepping schemes. Furthermore, the first term of the right-hand side (RHS) is purely local, i.e. each element can be computed separately. This part of the RHS can be specified as volume kernel since it refers to the volume integration of the curl operator applied on the degrees of freedom inside each element. The second term in the RHS identifies the fluxes from one element to its adjacent elements. Fluxes combine all local element solutions to a global solution and control unphysical components. Here, not all values are element-local since the flux terms \mathbf{H}^* and \mathbf{E}^* are a linear combination of face values at neighboring elements. Regarding elementwise parallelization, these adjacent values have to be supplied additionally.

III. PARALLELIZATION STRATEGY

The NVIDIA CUDA programming model incorporates two parallelization levels. The computational work is associated with a CUDA grid. In the coarse level, this grid is divided into CUDA blocks, which are computed in parallel on the multi-processors (MP). The fine grained level is associated with CUDA threads which are computed on the streaming processors (SP) cores of each MP. Regarding DG-FEM discretization, the computational domain is an unstructured mesh, divided into finite elements. On these finite elements, degrees of freedom are defined. Consequently, to match CUDA design aspects for DG-FEM implementation, it is a natural approach to associate the CUDA grid with the DG unstructured mesh and to map each DG-element to a CUDA block and each degree of freedom to a cuda thread. For detailed information

about CUDA parallelization of DG-FEM discretization, see [3]. In case of multiple GPUs, a further top layer parallelization level can be introduced with help of a METIS domain decomposition of the set of finite elements, [7]. Each subdomain can be computed on one of the GPUs as the computational data of all subdomains are independent of each other, except for the flux data at the METIS boundaries. These flux terms have to be synchronized after each timestep. The overhead of the flux gathering can be minimized using the asynchronous file transfer feature of current Nvidia TESLA GPUs. It provides concurrent CUDA kernel and CUDA memcopy execution. Since the volume kernel execution is numerically expensive and purely element-local, flux gathering can be hidden behind the volume kernel execution, at least for a small amount of METIS subsets compared to the global amount of elements.

IV. FIRST NUMERICAL RESULTS

As a first numerical benchmark, the enclosure of a mac-mini has been discretized using 201 765 tetrahedra.

Fig. 1. Mac-mini model hit by a wave front

The coupling of a TEM wave into the device via its ventilation slots as presented in Fig. 1 has been computed on hardware listed in Table I. In Fig. 2, the GPU performance is compared to a floating point single precision CPU computation for different polynomial orders. In summary, 4 GPUs can

Fig. 2. Comparison of the computational performance

perform about one order of magnitude faster than a current CPU setup with four quad cores. Regarding hardware costs, a 4 GPU setup can be realized much cheaper than a 4 CPU configuration, at almost the same power consumption, including host computer. The resulting performance per cost ratio is considerably higher using graphics hardware. Regarding further upgrades of GPU based clusters, scalability is an important factor. The scalability of the parallelization

Fig. 3. Scalability and METIS element distribution of a 4 GPU setup. 201 765 elements with 4th order basis functions.

as well as the METIS element distribution is presented in Fig. 3 resulting in 96.75% and 90.2% with and without the asynchronous file transfer feature, respectively. The benefits of the asynchronous file transfer result in better scalability, since the complete flux transfer could be hidden behind the execution of the volume kernel which took 11.56 ms on average, whereas the transfer process needed approximately 4.4 ms per timestep. The gap between these two times shows that further parallelization can be beneficial. Furthermore, since the work distribution of the METIS domain decomposition is not perfectly balanced, further improvement in scalability converging towards 100% is possible.

V. CONCLUSION

A multilevel parallelization strategy for solving DG-FEM discretized Maxwell's equations on a GPU cluster was presented. The suitability of DG-FEM for GPU computations using the CUDA programming model was described. With help of asynchronous file transfer, good scalability for up to four GPUs was demonstrated. Further improvements in scalability can be achieved by using work-balancing METIS functions, also on more than four GPUs, depending on the element distribution.

Abstract—This paper presents an adapted PEEC-based (Partial Element Equivalent Circuit) methodology applied to the modeling of interconnections of power electronics devices. Although this method is known, the originality of this work is its use to model a device presenting an industrial complexity. To make possible this modeling, two adapted integral methods, based on two different meshings are presented. They compute respectively parasitic inductances and capacitances and lead to an equivalent circuit of the system. From a time-domain simulation of this circuit, current and voltage sources can be extracted and used to compute the radiated near magnetic field. This approach has been applied to model a real industrial static converter, a variable speed drive.

I. INTRODUCTION AND STATE OF THE ART

Today power electronics devices are more and more compact and small and the working frequency range is rising. Consequently the compliance to EMC standards is not guarantee. That is why power interconnections need accurate modeling that takes into account some magnetic constraints (i.e., the skin and proximity effects) and the most important electric couplings between the conductors of the device. According to the sizes of the typical industrial application, the propagation phenomena can still be neglected because the frequency range is from 150kHz to 200MHz and the longest conductor size is around 10cm ($\lambda/10=15$ cm).

To model such industrial devices, constituted of complex conductors (multi-layer tracks close to each others), the finite element method would be few adapted regarding the difficulty of volume air region meshing and conductors discretization to properly take into account skin/proximity effects. On the contrary, the PEEC method (i.e. extraction of equivalent circuit components thanks to integral approach) is known to be well adapted to model complex geometries with an important surrounded air region [1]. However, the full-PEEC approach, based on dual inductive and capacitive meshings (and a 3D meshing of dielectrics), would be also very memory consuming and not adapted.

Thus, in the next part, we propose an adapted PEEC formulation where two integral methods lying on two separated meshes are combined to build a parasitic equivalent circuit of the power interconnections. In the last section, this approach is tested by modeling an industrial variable speed drive and comparisons between simulations and measurements are carried out: the behavior of the harmonic response and the emitted near magnetic field.

II. EXTRACTION OF (R-L-M-C) EQUIVALENT CIRCUIT

By considering the integral form of the Maxwell's equations and by assuming quasi-static conditions and surface location of the free-charges ρ in a medium of permittivity ϵ and permeability μ , the external applied electric field \mathbf{E} in a point \mathbf{r} of space can be rewritten as:

$$\begin{aligned}\mathbf{E}(\mathbf{r}) &= \frac{\mathbf{J}(\mathbf{r})}{\sigma} + j\omega\mathbf{A}(\mathbf{r}) + \nabla\phi(\mathbf{r}) \\ &= \frac{\mathbf{J}(\mathbf{r})}{\sigma} + j\omega\mu \iiint_V G(\mathbf{r}, \mathbf{r}') \mathbf{J}(\mathbf{r}') dV + \frac{1}{\epsilon} \nabla \iint_S G(\mathbf{r}, \mathbf{r}') \rho(r') dS\end{aligned}\quad (1)$$

where \mathbf{J} is current density, σ the conductivity of conductors, \mathbf{A} the magnetic vector potential, ϕ the electric potential and $G=1/(4\pi\|\mathbf{r}-\mathbf{r}'\|)$ the Green function. The three parts of (1) are respectively due to resistive, inductive and capacitive effects.

In our adapted PEEC approach, these effects are modeled by using two different meshings of conductors and dielectrics (Fig. 1). Parasitic resistances, inductances and mutual-inductances (R-L-M) are computed from a volume meshing of conductors, and capacitances (C), from a non-necessarily conformal surface meshing of conductors and dielectrics.

A. Extraction of resistive and inductive elements (R-L-M)

Each mesh element presents a resistance and a self inductance (analytical formulas). Mutual inductances between different elements are numerically computed thanks to a Galerkin method [1-2], which consists in integrating the magnetic vector potential created by one volume element on the other.

Depending on the directions of the flowing current, conductors can be either unidirectional (thin or long tracks) or bidirectional (large tracks and ground planes). The conductors belonging to the first type are meshed in the skin depth but not in their length (gain in number of elements), whereas the bidirectional ones are discretized in two directions. These meshes are adapted to model skin and proximity effects from which an inductive dense and square matrix and a resistive

Fig. 1. Resistive-inductive (left) and capacitive (right) meshings

diagonal matrix are extracted. The number of mesh elements is equal to the size of the (R-L-M) matrix.

B. Extraction of capacitive elements (C)

For the modeling of capacitive effects, an electrostatic formulation is used and consequently the meshing is adapted to the surface free-charge distribution (side effects). Thinner mesh elements than the inductive ones are required to take into account accurate spatial variation of surface charges which is due to the uniform surface distribution of electric potentials.

Unlike the use of a Galerkin method, a 0-order point matching method is sufficient to accurately compute the potential coefficients $P_{i,j}$ and the normal field coefficients $E_{i,j}$. These coefficients are respectively calculated between each conductor or dielectric elements and all (conductor and dielectric) elements of the meshing. Consequently, they compose the square and dense interaction matrix P/E [3].

The $N*N$ capacitance matrix ($N \ll$ number of elements) which models the electric couplings between the N conductors of the device (or part of conductors) is computed by properly adding free-charge sets. These ones (Q) are obtained by performing N resolutions of the linear system $V=[P/E]*Q$ with N different potential distributions V (0 or 1V on each mesh). The worst inconvenience of this method is the storage of the matrix and the integration time which increases in $O(n^2)$.

To overcome this issue of modeling large devices, the algorithm AMLFMM [4] is used: in fact, it accelerates the computation of interaction coefficients ($O(n.log(n))$) and is low-memory consuming thanks to the use of a truncated multipole decomposition of interactions. This method subdivides the geometry in cubes of different levels with an adaptive octree algorithm which controls the interaction computations and leads to a compact matrix-vector product. Finally, the problem is solved with an iterative solver, a left preconditioned GMRESR(m) algorithm [5].

III. APPLICATION TO AN INDUSTRIAL VARIABLE SPEED DRIVE

A. Extraction of the equivalent circuit

This methodology has been applied to obtain an equivalent circuit of an industrial static converter: a marketed variable speed drive. This complex device is composed of four copper-track layers. Figure 1 shows the two different meshings used to extract the lumped elements. The square resistive-inductive matrix (6,800*6,800 elements) is computed with InCa3D [6]. The capacitive matrix (27*27 elements) is computed with AMLFMM and 27 GMRESR(m) solvings of a linear system of 48,500 unknowns (the conductor charges).

The complete PEEC circuit of the interconnections of this device is built in a system-level software (Saber) and is composed of an (R-L-M) macroblock and all the capacitances which are manually linked themselves.

B. Harmonic response and near magnetic field studies

The supply chain, the load (a three-phase motor) and the command circuit are then added to the previous PEEC circuit. Thanks to time-domain simulations and Fourier transforms of the results, it is possible to analyse the parasitic equivalent circuit by means of a harmonic response study in the

conducted frequency range (150kHz-30MHz). This study has validated our method because the frequency resonances obtained by simulation and measurement are the same (detailed results of this analysis will be reported in the final version of the paper).

Then, a second analysis of the emitted near magnetic field, just over the static converter, has been led. The Fourier transform of currents and voltages of the circuit, which have been obtained by a time-domain simulation, have been introduced as sources in our model and the emitted magnetic field has been computed at a given frequency by means of the Biot and Savart law. Figure 2 shows the comparison between the vertical component of the magnetic field H_z at 32kHz simulated and measured and a good adequation between the two color shades can be appreciated. It means that the current loops are correctly modeled.

Fig. 2. Radiated near magnetic field H_z measured and simulated at 32kHz

IV. CONCLUSIONS

In this paper, it has been presented the coupling between two adapted integral methods from two adapted meshings allowing, respectively, the extraction of resistive-inductive and capacitive equivalent elements of power interconnections of industrial complexity.

It has also been highlighted that the complete (R-L-M-C) equivalent circuit can be exported into a SPICE-like tool where time-domain analysis can be performed. Then, the obtained Fourier transforms of the currents and voltages have been introduced as sources in the 3D geometric representation of the interconnections for analyzing the EMC performances of the system on a wide frequency range. The harmonic response and the emitted near magnetic field comparisons with measurements have validated this approach on a real industrial variable speed drive.

Abstract — A method for specifying the electrical parameters of a High-Frequency (HF) Radio-Frequency-Identification (RFID) transponder loop antenna is presented. It is based on a quasi-static or a full wave field analysis of the subjacent eddy-current problem. A comparison between two- and three-dimensional computations is given. Additionally, the results obtained by in-house software tools are compared with those from calculations using a commercial code. Finally, initial results of measurements carried out on a given HF-RFID transponder tag are presented.

I. INTRODUCTION

HF-RFID transponders, usually working at 13.56 MHz in the near field of the reader antenna are operating like resonant networks since the energy extraction from the emerging reader field can thereby be maximized [1]. Due to the resonance condition, it is of major importance that the electric parameters of the antenna structure and the analog input stage of the HF-RFID transponder chip are well specified [2].

In order to enhance the reading range the induced voltage has to be raised, this can be attained by increasing the number of windings of the loop antenna or the antenna area or the magnetic field strength \mathbf{H} of the reader at the given frequency. Since the reader field strength is limited by regulations, the only way to increase the induced voltage is to build efficient antennas considering the limitations given by the application. The loop antenna which is investigated in the present work is shown in Fig. 1 and a variation in terms of antenna size is not possible. Table I gives an overview of the structure of the transponder antenna.

Fig. 1. Geometry of the transponder antenna

In general, the input stage of an RFID transponder chip is a multi-stage charge pump structure with an effective input capacitance which mainly defines the silicon area of the chip [2], so the input capacitance is limited to a certain value in the small pF-domain. Hence, to enable the resonance condition of

the transponder, an additional capacitance C_{Res} as shown in Fig. 2 is necessary.

Fig. 2. Equivalent electrical circuit of the HF-RFID transponder

To determine the value of the resonance capacitor, the electrical parameters of the transponder chip as well as the electrical parameters of the given antenna structure have to be specified.

TABLE I
STRUCTURE OF THE TRANSPONDER LOOP

Number of windings n	1, 2, 14
Outer dimension a (mm)	6
Distance between turns d (μm)	90
Width of wire w (μm)	30
Relative permittivity of the substrate	4.1
Relative permittivity of the photoresist	3
Conductivity of the Nickel (Ni) trace (S/m)	$1.5625 \cdot 10^7$
Relative permeability of the Ni trace	1240

II. PROBLEM TYPE

Using the conditions for electrically small loop antennas in [3] valid for circular loop antennas and adapting them to a flat spiral loop of square shape leads to

$$k_0 \left(4 \cdot a + \sum_{i=1}^n 4 \cdot (a - 2i \cdot d) \right) \ll 1. \quad (1)$$

With the given dimensions of the loop and the phase constant for free space k_0 the condition (1) is certainly satisfied. Hence, one can assume a constant current along the circumference of the loop and, therefore, a quasi static approximation of the subjacent problem is allowed [4]. For the numerical simulation, the following equations in the time harmonic case applied in the eddy current region have to be solved [5]

$$\nabla \times \mathbf{E} = -j\omega \mathbf{B}, \quad \nabla \times \mathbf{H} = \mathbf{J} \quad \text{and} \quad \mathbf{J} = \sigma \mathbf{E}. \quad (2)$$

In the non-conducting domain

$$\nabla \times \mathbf{E} = -j\omega \mathbf{B} \quad \text{and} \quad \nabla \cdot \mathbf{B} = 0 \quad (3)$$

characterize the problem. The problem described in (2) and (3) is referred to as a quasi static magnetic field (QSMF) problem in the following. Note that in (2) the displacement

current is neglected. To get the stray capacitance of the loop one can either solve a full wave problem with

$$\nabla \times \mathbf{H} = \mathbf{J}_{tot} \text{ and } \mathbf{J}_{tot} = (\sigma + j\omega\epsilon)\mathbf{E} \quad (4)$$

or solve in addition to the QSMF problem a quasi static electric field (QSEF) problem and assuming a complex current flow:

$$\nabla \times \mathbf{E} = 0, \nabla \cdot (\mathbf{J} + j\omega\epsilon\mathbf{E}) = 0. \quad (5)$$

III. NUMERICAL MODELS

To get a reference point for the loop antenna's input impedance, a 2D analysis of the given antenna structure is considered first.

A. 2D simulations

The real 3D structure has been transformed to a rotationally symmetric arrangement by assuming an equal mean circumference of the innermost winding. Since a full wave simulation is not implemented in the 2D in-house code, the results given in Table II are limited to the resistance and inductance of the loop antenna.

B. 3D simulations

The equivalent circuit parameters according to Fig. 2 can be obtained from a field simulation by evaluating the mean power loss P_l , the magnetic energy W_m and the electric energy W_e . If the voltage, U , of the circuit is prescribed, the following relationships are valid for the resistance R_{Loop} , the inductance L_{Loop} and the capacitance C_{Loop} :

$$R_{Loop} + j\omega L_{Loop} = \frac{U^2}{P_l - j2\omega W_m}, \quad (6)$$

$$C_{Loop} = \frac{2 \cdot W_e}{U^2}. \quad (7)$$

If, on the other hand, the current, I , of the circuit is prescribed, R_{Loop} and L_{Loop} can be obtained as

$$R_{Loop} + j\omega L_{Loop} = \frac{P_l + j2\omega W_m}{I^2}. \quad (8)$$

1) Full wave simulations

The full wave simulations have been carried out with the voltage given and the circuit parameters have been obtained by (6) and (7). The results for full 3D models like the one shown in Fig. 3 are given in Table II. Since the convergence for the full wave simulation using an iterative solver is weak, only results for loops with one and two windings are available.

2) QSMF- and QSEF-simulations with full model

The QSMF simulations have been done with the current prescribed and the QSEF simulations with the voltage prescribed. QSMF simulations have yielded R_{Loop} and L_{Loop} from (8) and QSEF analyses C_{Loop} by (7). The results are presented in Table II, too.

3) QSMF-simulations with quarter model

An approximate way to determine the equivalent circuit is to assume two symmetry planes and analyze only a quarter of the problem. Influences of the contact areas on the ohmic part and the inductance of the loop antenna's input impedance are thereby neglected. The results are again shown in Table II.

The results obtained by the commercial code are also based on a QSMF simulation of the quarter problem to obtain R_{Loop} and L_{Loop} . These results are also given in Table II.

A detailed comparison of the efficiency and accuracy of the various approaches will be carried out in the full paper.

Fig. 3. Full 3D model of the transponder with two windings

C. Antenna measurement

As a first approach, a vector network analyzer measurement has been carried out [6]. Initial results for the resistance and the inductance are also given in Table II. Improvements in terms of more suitable test fixtures are matter of the running activities and the corresponding results will also be presented in the full paper.

alejandro.ospina@lgep.supelec.fr

Abstract — This paper deals with a original kind of planar coil model developed in the finite element method for non destructive testing applications. The model is constructed by the use of degenerated elements (shell elements). An example is implemented with two well known electromagnetic formulations in 2D. The accuracy of the model is established with analytical equations.

I. INTRODUCTION

Planar printed coils are increasingly used in eddy-current (EC) non-destructive testing (NDT) applications such as detection or material characterization [1-2]. The use of planar printed coils offers many advantages in NDT applications: capability to improve spatial resolution, sensitivity and if it is constructed on a flexible substrate, adaption to complex geometries.

Numerical methods are adapted for the study of electromagnetic problems in EC-NDT applications with complex geometries. Among the numerical methods for the study of planar coils in NDT the finite element method (FEM) is one of the most adapted. However, in the discretization stage, the FEM make a considerable increase in the number of unknowns and, in consequence, in the computation time. These difficulties are related to the meshing process, such as for example, a strong density of elements (increase in the unknown number) or deformed elements in the thin area and its vicinity (ill-conditioned system). In order to eliminate these problems a kind of degenerated elements (shell elements) is used in this paper [3-4].

In the meshing process, the planar coil is considered as a surface, since increase and deformation of elements are avoided. Then, in the stage problem formulation, the degenerated elements are introduced in order to model the planar coil. Finally, a linear equation system is solved and the fields are calculated in the “real” geometry.

II. PROBLEM DESCRIPTION

The basic geometric configuration is a classical problem in EC NDT: a coil placed above a metallic material (Fig. 1). The problem domain Ω is decomposed in three regions: the target material (conducting and/or ferromagnetic) Ω_c , the planar coil domain Ω_0 and the air region. The planar coil domain has a current density j_0 and a thickness denoted by d .

Fig. 1. a. Problem description. b. 2D cut plane

The planar coil is geometrically characterized by an aspect ratio L between its thickness d and a characteristic geometrical quantity L_g (in this case L_g is the inner radius):

$$L = \frac{d}{L_g} . \quad (1)$$

In the proposed example, the target material is conductive. Thus the field produced by the coil induces EC in the target. The thickness of the coil, d , vary between about 1 micron to 10 millimeters.

III. MAGNETODYNAMIC FORMULATIONS

The physical model of the EC problem is performed by the Maxwell reduced equations (without displacement currents: the capacitance effect is not significant). Among the models of EC problems, an approach based on dual formulations has been proposed by Ren and Razek [5]: the electric and the magnetic formulations.

In the electric formulation, the electric field \mathbf{e} is associated to a modified magnetic vector potential \mathbf{a}^* , in the form

$$\mathbf{a}^* = - \int_t \mathbf{e} dt . \quad (2)$$

The weak formulation is based on the Ampere's law, for $t > 0$ in the harmonic regime.

In the magnetic formulation, the magnetic field \mathbf{h} is decomposed in two potentials, the electric vector potential \mathbf{t} and the scalar magnetic potential ϕ , with

$$\mathbf{h} = \mathbf{t} - \mathbf{grad} \phi. \quad (3)$$

The weak form is based on the Faraday's law applied in the conducting regions and completed by $\text{div } \mathbf{b} = 0$ for all domains.

IV. SHELL ELEMENTS

The shell elements are a space degeneration of the finite elements. They are geometrical objects that have a $D-1$ geometrical dimensions, where D is the model geometrical dimension (usually $D=3$ or 2). In the first stage of the discretization process (meshing) since the shell elements are 1 dimensional geometrical objects (lines), the thin region is represented by a middle line (Γ_{sh}). Then, the edge and the nodes in Γ_{sh} are projected on two "virtual" lines (Γ_{sh}^+ and Γ_{sh}^-). The physical behavior inside the planar coil is represented by the shape functions in these lines. Additionally, these projections can be repeated many times in order to stratify the thin region. Using these approximations the formulations are transformed in linear systems in which, the unknowns are the vector circulation along the edges and the scalar quantities at the nodes.

In the first stage of the modeling process, a triangular mesh is constructed. This mesh is highly refined to reduce the error originated by triangular elements. After that, the shell elements are inserted in the thin region. In the example the thin region is stratified in four layers in order to obtain a better approximation of the fields. In this way the error is strongly dependent on the shell elements.

V. RESULTS

The spatial distribution of the real part of magnetic field lines is shown in Fig. 2. A good agreement is observed with the physical behavior: the magnetic field lines encircle the currents. The resistance and reactance of the coil are calculated in the dual formulations and compared with Dodd and Deeds model [6]. The results are shown in Fig. 3.

The field approximation which is made by the linear shape functions in the shell elements explain the different levels of

Fig. 2. Spatial distribution of the real part of magnetic flux density vectors and field lines obtained in the \mathbf{a}^* formulation.

accuracy in the results. The use of the \mathbf{a}^* formulation implies a linear variation of the electrical field. The magnetic field \mathbf{h} ,

calculated by the curl operator, is then constant and the error is quite important on the reactance (Fig 3b.). In the $\mathbf{t} - \phi$ formulation, the behavior of shell elements is analogue: the magnetic field \mathbf{h} has a linear variation across the thickness. The variation is more realistic, and the relative error on the

a.

b.

Fig. 3. a. Resistance vs aspect ratio (L). b. Reactance vs aspect ratio (L).

reactance is less important (Fig 3b.).

The example developed in this digest show that the application of the shell elements in the simulation of planar coils for EC-NDT applications represents an interesting solution when meshing with classical elements is impossible to realize or requires a high number of elements. In the extended paper more details will be provided about the 2D model and a 3D model of the planar coil will be presented.

Numerical Field Calculation in Support of the Hardware Commissioning of the LHC

Bernhard Auchmann*, Stephan Russenschuck*

*CERN/TE, Geneva, Switzerland, Email: bernhard.auchmann@cern.ch

Abstract—The hardware commissioning of the Large Hadron Collider (LHC) required the testing and qualification of the cryogenic and vacuum system, as well as the electrical systems for the powering of more than 10000 superconducting magnets. Non-conformities had to be resolved within a tight schedule. In this paper we focus on the role that electromagnetic field computation has played in the treatment of these non-conformities which have required analysis of magnet quench, electromagnetic force calculations in busbars and splices, as well as field-quality predictions for the optimization of powering cycles.

Index Terms—Superconductors, Quench Calculation, Persistent Currents

I. INTRODUCTION

WITH the Large Hadron Collider (LHC), the particle physics community aims at testing various grand unified theories by studying collisions of counter-rotating proton beams with a center-of-mass energy of 14 tera electron volts (TeV). Physicists hope to prove the popular Higgs mechanism for generating elementary particle masses of quarks, leptons, and the W and Z bosons. The LHC reuses civil engineering infrastructure at CERN with a tunnel of 3.8 m in diameter and a circumference of about 27 kilometers that straddles the Swiss French border near Geneva. With a given radius of the accelerator tunnel, the maximum achievable particle momentum is proportional to the operational field in the bending magnets. Superconducting dipole magnets cooled to 1.9 kelvin with a nominal field of 8.33 tesla, allow energies of up to 7 TeV per proton beam.

During the design and construction of the LHC, an undertaking of more than 20 years, various challenges had to be met in all domains of physics and engineering. They are, among others, material science for superconducting wires and cables, mechanical engineering challenges for the construction of magnets weighing up to 20 tons, the physics of superfluid helium, vacuum technology for insulation and beam vacuum, and electrical engineering challenges for power supplies, current leads using high- T_c superconductors, superconducting busbars, diodes operating at cryogenic temperatures, magnet protection systems, etc. The requirements of field uniformity in the superconducting magnets have also posed a challenge to numerical field computation and optimization techniques. Motivated by the magnet design, the CERN field computation program ROXIE [1] has been developed which was also used to trace manufacturing errors during magnet production.

After an ambitious hardware commissioning phase a first beam was circulated on September 10, 2009. In this paper we

review the role that numerical field computation plays during the hardware commissioning phase.

II. QUENCH SIMULATION

Above a certain limit on the temperature, current density or magnetic flux density, the superconductor shows a transition between the superconducting and normal conducting state which is known as resistive transition or quench.

Quench detection and magnet protection against overheating and voltages peaks during a quench is an important issue in the design of superconducting magnets. We will show that it is important to treat all involved phenomena (thermal, electrical, and magnetic) in a coupled way. The integrated numerical model allows to study the impact of different effects such as quench-back, normal zone propagation, quench heater performance, local field distribution, and iron saturation.

The simulation of thermal processes at cryogenic temperatures is an intricate problem. Material properties at cryogenic temperatures and under pressure are often difficult to know to adequate precision. The highly nonlinear behavior of these parameters lead to an ill-conditioned numerical problem in quench simulations. Moreover the problem generally is ill-posed, as there are more model parameters than validation criteria such as measurements of the current decay and signals at the voltage taps or quench antenna [2].

In the commissioning phase of the LHC a quench heater developed an open circuit after the cool-down of the magnet to the operation temperature. The aim of quench simulations was to determine the best powering scheme for the remaining quench heater circuits, while activating redundant heaters in the low field region of the coil. In another case a quench occurred in both apertures of a dipole magnet. The coincidence caused significant delays in the quench detection. Simulation efforts were directed at determining the worst-case scenario of heat deposition inside the magnet, under which the measured voltage signals could be reproduced.

III. 3-D FORCE- AND PEAK-FIELD-CALCULATIONS

Electromagnetic forces on interconnection busbars were identified during commissioning to be an important issue for the long-term reliability and the electro-mechanical integrity of the machine. While field-quality calculations for long accelerator magnets can be carried out to highest precision in 2-D calculations, the interconnect regions between magnet coils and neighbouring magnets require a 3-D approach. Applying the BEM-FEM technique, the finite-element modeling could

be restricted to the nonlinear ferromagnetic yoke. The involved layout of cosine-theta-type coilends and the busbar routing was captured in a Biot-Savart type model built from straight line-current segments.

The Biot-Savart model was generated from basic building blocks such as easy- and hardway bend and twists. The twist-pitch of the Rutherford-type cable is neglected. An automatic connection routine computes the transformations that are required for a continuous interconnection of individual components. The complete BEM-FEM model consists of about 600,000 line-current segments in the BEM domain, and only about 60,000 finite elements. The calculation of forces on the interconnection busbars takes approximately two hours on a 2.8 GHz Xeon processor machine.

Despite the relatively low number of finite elements in the model, the accuracy of peak-field calculations on the superconducting cable exceeds by far the precision that could be achieved in a pure finite-element model. The reason is that the local field distribution in the cables is determined by the current flow in individual strands, which cannot be adequately represented in a FEM approach. Among the results that will be presented in the full paper, we note that the forces pulling in longitudinal direction (along the magnet axis) on the so-called half-moon interconnects, see Fig. 1 (left) that connect individual coils in a magnet assembly are on average 240 N.

Fig. 1. Electromagnetic model of the interconnections at the end regions of the main-bending dipoles of the LHC.

IV. FIELD-QUALITY SIMULATION

The operation of the LHC requires that all field errors in the superconducting magnets are compensated for by dedicated corrector magnets, so that the integrated field error as seen by the particle beam remains below a tolerated limit. Beam-based measurements can serve as a feedback on the field quality and as an input for automated controls of the corrector magnets. Yet, for a large scale machine like the LHC, operators cannot rely solely on feedback systems. For this reason, the Field Description of the LHC (FiDeL) program collects measurement data of all components in the the LHC and extracts a fast online model, that yields the field quality at a given time, magnet operating current, magnet ramp rate, magnet temperature, and magnet powering history [3]. The modeling is especially critical at very low currents, where the persistent current magnetization of superconducting strands has a large influence on the field quality. The FiDeL model is based on measurements that were performed for quality assurance during the production of the LHC magnets. Simulation is performed if required for three reasons: 1) validation of the FiDeL mathematical model; 2) counter-check measurement data; 3) supply data where measurements are not available.

The FiDeL model is based on the identification and physical decomposition of the effects that contribute to the total field in the magnet aperture. Each effect is modeled by an appropriate mathematical model. The physical behavior of the models can be tested over the entire parameter space by means of simulation. At the exception of decay- and snap-back effects, the ROXIE software comprises all relevant effects. A database of electromagnetic models of all LHC superconducting magnets is used to compare model- and measurement results. Suspicious measurement data can be tested and validated by comparison. In the low-field region, where the persistent-current effects on field quality are dominant, the ROXIE model [4] can yield data for powering cycles that have not previously been measured. Most demanding in this respect are nested corrector magnets, where the persistent-current magnetization depends strongly on the powering cycle of each of the nested coil assemblies. In May 2009 the ROXIE vector-hysteresis model [4] for persistent currents will be validated for the first time by measurements of the MCBX corrector magnets, see Fig. 2. Results will be presented in the full paper.

Fig. 2. Left: Cross-section through the nested MCBX corrector magnet. Right: Persistent-current magnetization due to a rotating field in the magnet aperture.

V. CONCLUSION

Numerical field computation is indispensable in the design and manufacturing phase of accelerator magnets. Challenging computations, however, are carried out through the commissioning phase, in order to understand measured behaviour or to work out fall-back solutions. As a side-effect of an additional measurement campaign in 2009 we will be able to validate the ROXIE vector-hysteresis model for persistent currents.

Abstract — A non-invasive methodology to evaluate and classify the electrical system failures is presented in this work. It is based on the electrical system magnetic signature recognition using the wavelet signal decomposition and the resulting variance spectrum evaluation, respectively. The validation of the proposed methodology is carried out by comparison between theoretical and experimental results. The Finite Element Method is used in the numerical simulations of the magnetic flux density, and a post-processing approach is adopted in the signal decomposition and analyses. An experimental setup was built to obtain the magnetic signature regarding some pre-selected faults configurations.

I. INTRODUCTION

A methodology concerning the theoretical evaluation of fault detection in electrical systems was presented in the previous paper [1]. The proposed method is a non-invasive one based on the evaluation of the resulting magnetic signature of the electrical systems after applying the wavelet transform [2]-[3]. In this theoretical study, simulations were carried out, in order to obtain the fault current and the resulting magnetic field. In the present work, a new development is shown, including the fault classification approach and the validation based on an experimental setup.

II. METHODOLOGY

A brief description of the methodology used in this work is presented in this item. This methodology consists of two phases: The first is the experimental data acquisition (fault current and resulting magnetic flux density). Various kinds of faults were evaluated. Fig. 1 shows the experimental setup used. On the other hand, the fault waveforms are also introduced as current sources on corresponding electric circuit, and used to simulate the resulting magnetic flux density. The Finite Element Method is applied [4]. On the second phase, the decomposition of the magnetic flux signal through Wavelet Transform (WT), and the evaluation of the variance spectrum by the signals post-processing are carried out [5]-[7]. Critical analysis and discussion of the results are made, aiming to evaluate the suitability of the method for detecting and classifying the faults in electrical systems.

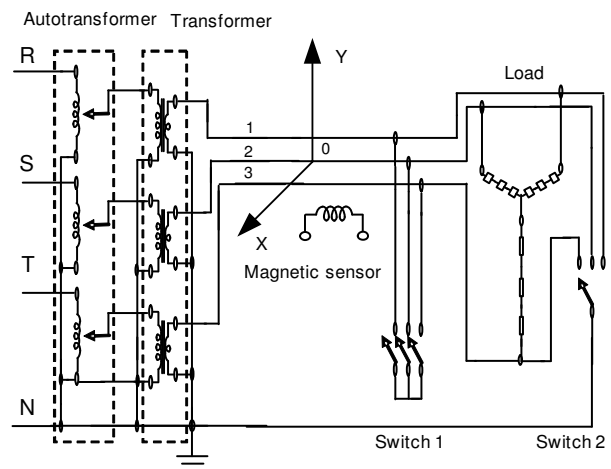

Fig. 1 – Sketch of the experimental setup

III. THEORETICAL ASPECTS

The information about both time and frequency domain can be obtained by applying the WT. This is an intrinsic and suitable WT characteristic concerning the signal decomposition accuracy. The details on the theoretical and practical aspects of WT are carefully described in the literature, e.g., [2], [3]. In general, the decomposed signal $x(t)$ can be expressed in a discrete form by:

$$x(t) = \sum_{k=-\infty}^{\infty} \sum_{j=-\infty}^{\infty} a_{jk} \psi_{jk} \quad (1)$$

In (1), j and k are integer numbers, and ψ are the Mother-Wavelet functions. The so-called *Daubechies Wavelet* was assumed as the base function in this work. This function was chosen, based on previous studies that support its robustness and suitability for fault detection evaluation. Concerning the signal decomposition process, Multiple Resolution Analysis (MRA) was applied [5]-[9]. The variance spectrum can be obtained based on Parseval's Theorem. It states that the distorted signal energy may be divided in terms of expansion coefficients [9]:

$$\int_{-\infty}^{\infty} |x(t)|^2 dt = \sum_{k=-\infty}^{\infty} |c(k)|^2 + \sum_{j=0}^{\infty} \sum_{k=-\infty}^{\infty} |d_j(k)|^2 \quad (2)$$

The variance can be considered as a measure of the average signal energy. Thus, the variance of the decomposed signal related to different resolution levels is proposed as merit index to the fault classification. The number of levels is selected according to the considered frequency range.

IV. APPLICATIONS AND RESULTS

In order to illustrate the proposed methodology, some theoretical and experimental results related to mono-phase faults are presented. The experimental setup (Fig.1) is a 220/1V (Y/Y) three-phase circuit, in which the secondary of the transformer was designed to obtain current peak values around 60 A (Fault conditions). The conductors (16 mm²) have a length equal to 4m, and are spaced by 0.50m. The clearance to the floor of the lab is 1.7m. The conductor phases are indicated by numbers 1, 2 and 3. By combining the switches 1 and 2, different sorts of faults can be reproduced. A specially designed coil probe was calibrated, and used as magnetic sensor. The Cartesian system adopted, regarding the evaluated points, is represented in Fig.1. As an example, Fig. 2 presents the results related to the magnetic flux density at P (-0.5, -0.25) m, for the Phase1-Ground faults. By inspecting the figure, besides the resulting peak values of the flux density, the fault durations can be noticed.

Fig.2 – Comparison between the simulated and measured magnetic flux densities Bx, at point P (-0.5;-0.25) m, for Phase 1-Ground fault (FIT).

Fig.3 – Experimental Results: Magnetic flux density variance spectrum for mono-phase faults - P (-0.50;-0.25) m.

Fig. 3 shows the wavelet variance spectrum of the magnetic flux density for the experimental mono-phase fault values at P(-0.5;-0.25) m.

It should be mentioned that the same variance spectrum profile can be observed when the theoretical approach is taken into account. Additional results will be presented in the full paper in order to illustrate and show the details of the method regarding fault detection and their classification.

Modeling the dynamic behavior of magnetostrictive actuators

Oriano Bottauscio, Paolo E. Roccatò, and Mauro Zucca
 Istituto Nazionale di Ricerca Metrologica
 Strada delle Cacce 91, 10135 Torino, Italy
o.bottauscio@inrim.it, p.roccato@inrim.it, m.zucca@inrim.it

Abstract — This paper deals with the modeling and design of magnetostrictive devices in dynamic regime. It starts from an approach which couples a physical model of magnetostriction with finite element electromagnetic field analysis of the entire device. A first study, developed under simplifying hypothesis of steady-state working conditions, is here extended to arbitrary supply conditions, including the mechanical coupling. A comparison between computed and measured results is presented.

I. INTRODUCTION

Magnetostrictive (MST) devices exhibit interesting electro-magneto-mechanical properties for applications like the micro positioning and the active control of mechanical vibrations. Compared with piezoelectric devices, they show higher forces and have significant advantages (e.g. higher dynamic), avoiding the need of heavy electrical insulations, required by high voltages, which reduce the cooling efficiency.

The prediction of the dynamical performances of MST devices is a fundamental step, both in the design phase and in the successive development of efficient algorithms for their real-time control [1-3]. To avoid a complex and wide experimental characterization, numerical tools are welcomed, allowing analysis under various working conditions (working frequency, excitation current, mechanical load, etc.). The modeling approach should be able to account for the electromagnetic phenomena arising in the device, as well as the complex magnetoelastic behavior of the active MST element.

First approaches to the modeling of MST devices have been proposed in [4, 5], where the magnetoelastic models of the MST rod have been coupled with finite element tools, enabling the analysis of the main phenomena affecting the macroscopic behavior of these devices. Anyway, the aforementioned works were developed under the simplifying hypothesis of steady-state working conditions, enabling the study and design of a new device, but making not possible their use as computational engine in real-time control. In the present work, the coupled finite element – magnetoelastic model has been extended to work under arbitrary supply conditions, also including the coupling with simplified mechanical equations. In the following, some aspects of the modeling approach are detailed, considering both the physical model for describing magnetostriction, as well as their

coupling with the finite element electromagnetic field analysis.

II. MODELING APPROACH

To accurately modeling the MST rod, both magnetic and mechanical hysteresis has to be properly taken into account. The mechanical effects are introduced in the magnetic properties through an effective field H_e , which depends on the applied stress σ [6]. Magnetic flux density B is expressed as:

$$B = \Psi(H) = \mu_0 H + J = \mu_0 H + \zeta(H_e) \quad (1)$$

where the magnetic polarisation J , including reversible and irreversible contributions, depends on H_e . Hysteretic function ζ is described through the classical Preisach model (CPM). The effective field H_e depends on the applied field H , tuned by a corrector term $\xi(J, \sigma)$, function of the mechanical stress σ :

$$H_e = H + \xi(J, \sigma) \quad (2)$$

At a given instant, the computation of magnetic flux density evolution by Eqn. (1) is performed by an iterative procedure based on Fixed Point (FP) technique. Assumed the applied stress σ and field H to be known, the effective field is written as:

$$H_e = H + \psi(H_e, \sigma) = \upsilon H_e + S(H_e, \sigma) \quad (3)$$

where function ψ is written as the sum of a linear term (with constant υ) plus a residual S . The constant υ is determined by the maximum and minimum slopes of ψ for the considered value of σ , and the nonlinear residual $S(H_e, \sigma)$ is updated during the iteration process, starting from a trial value. At the generic iteration ($m-1$), the sequence of operations is:

$$\begin{aligned} H_e^{(m)} &= \frac{H + S^{(m-1)}}{1 - \upsilon} \\ J^{(m)} &= \zeta(H_e^{(m)}) \\ S^{(m)} &= \xi(J^{(m)}, \sigma) - \upsilon H_e^{(m)} \end{aligned} \quad (4)$$

The magnetoelastic model of a MST rod is coupled with a step-by-step finite element computational scheme, accounting for the electromagnetic phenomena within all the device. Taking advantage of the geometrical structure of these kind of devices (Fig. 1), the computations are performed in an axial-symmetric domain with cylindrical coordinates $\{r, \theta, z\}$. By employing the FP iterative technique to handle the magnetic nonlinearities, the weak formulation becomes:

$$\int_{\Omega} \nabla \text{curl} \mathbf{A} \cdot \text{curl} w ds = - \int_{\Omega} \mathbf{R} \cdot \text{curl} w ds + \sum_k \left[\int_{\Omega_k} \frac{N_k \dot{A}_k}{S_k} w ds - \frac{1}{\rho_k} \int_{\Omega_k} \dot{A} w ds + \frac{1}{\rho_k} \int_{\Omega_k} \mathbf{M}_{\Omega_k}(\dot{A}) w ds \right] \quad (5)$$

where \mathbf{A} is the magnetic vector potential, w is the test function, and Ω is the full domain. In (4) k indicates a generic conductor of resistivity ρ_k having trace Ω_k , area S_k and turn number N_k , \mathbf{R} is the FP residual and $\mathbf{M}_{\Omega_k}(\dot{A})$ is the mean of \dot{A} over Ω_k . For the sake of simplicity, the dependency of the field quantities on time has been omitted.

Fig. 1. MST device structure and simulations of the magnetic field distribution inside the device for different configurations.

At each time step, nonlinear problem (5) is iteratively computed, starting from a trial value of the residual. At iteration j , the residual update is performed in two steps:

$$\begin{aligned} \tilde{\mathbf{H}}^{(j)} &= \nabla \mathbf{B}^{(j)} + \mathfrak{R}^{(j-1)} \\ \mathfrak{R}^{(j)} &= \tilde{\mathbf{H}}^{(j)} - \nabla \Psi(\tilde{\mathbf{H}}^{(j)}) \end{aligned} \quad (6)$$

where Ψ describes the relationship between magnetic field and magnetic flux density, here in bold type being vector quantities, and $\tilde{\mathbf{H}}^{(j)}$ represents a magnetic field estimate.

The Preisach distribution function, which defines CPM model described in (1) by ζ , and function ξ are identified starting from a set of static B - H cycles measured at different stresses, following the approach described in [4]. Known the time waveform of J , the local strain λ of the magnetostrictive rod is approximated by the function:

$$\lambda(J, \sigma) = \lambda_0 - \frac{\lambda_0}{e} \frac{|J| - J_0}{\Delta J} \quad (7)$$

where J_0 depends on stress σ and constants λ_0 , ΔJ , $J_{0,1}$, $J_{0,2}$, and $J_{0,3}$ are determined by a nonlinear minimisation algorithm.

The computation of the local value of strain λ within the rod by (7) enables the determination of the total rod elongation. The coupling with a simplified mass-spring mechanical model enables the determination at each time step of the new value of the mechanical stress σ .

III. ANALYSIS OF A MST DEVICE

The coupled FEM-MM approach has been applied to the simulation of a device equipped with a Terfenol-D rod. A prototype of actuator is available for laboratory

measurements, allowing the measurements of local and global electromagnetic and mechanical quantities. In the results reported in Fig. 2, the prediction of the total rod elongation, determined as average value of the local deformations over the entire rod, is plotted versus the excitation current and compared with experiments, showing discrepancies lower than 22%.

The dynamic response of the MST actuator is evidenced by the plots of Fig. 3, where the time evolution of the total rod elongation is plotted versus the supply current, for the rod with negligible preload and with a 13 MPa preload. Due to dynamic phenomena, simulations evidence how the area of the loop increases and the maximum elongation slightly decreases with frequency.

The modeling details and its complete validation by comparison with experiments will be presented at the Conference.

Fig. 2. Comparison between computed and measured total rod elongation.

Fig. 3. Dynamic response of the MST actuator. Plots of the total elongation versus supply current for the unloaded and preloaded rod.

Determination of d-q Axis Parameters of Interior Permanent Magnet Machines

P. Zhou, D. Lin, G. Wimmer and Z.J. Cendes
Ansoft LLC, 225 W. Station Square Dr, Pittsburgh 15219 USA
ping@ansoft.com

Abstract — In this paper, a new approach is presented for extracting saturated parameters L_d , L_q and permanent-magnet flux linkage λ_{md} for interior permanent magnet machines. The procedure starts with the parameter extraction in actual abc reference frame based on transient finite element analysis in time-domain. Then the parameters in abc reference frame are transformed to $d-q$ axis reference frame. This approach is able to provide better accuracy and allow easy implementation because the parameters are derived from a realistic physical representation and the effects of the slot leakage and phase-spread harmonic fields are included in the simulation.

I. INTRODUCTION

Interior permanent magnet (IPM) machines are widely used in various electrical devices due to their high torque-to-current and power-to-weight ratios, and their high efficiency. The transient finite element analysis (FEA) coupled with driven circuits can provide a powerful design tool to take geometric complexity, high local magnetic saturation, induced eddy currents, dynamic core loss and mechanical movement into account [1]-[2]. However, the extraction of saturated $d-q$ axis parameters is still highly desirable because in addition to providing good insight into the feasibility of a design [3], $d-q$ axis parameters are also fundamental parameters to many vector control algorithms in the $d-q$ reference frame for fast and accurate response with quick recovery from a disturbance [4].

For computation of saturated $d-q$ axis parameters, the conventional method considers neither the change of winding induced voltage with load nor the cross effects on field saturation between the d -axis and q -axis [5]-[6]. A method called the loading method was developed in [7] to consider the cross effects of d - and q -axis load currents on field saturation with improved accuracy. This method computes the $d-q$ axis parameters based on the fundamental air-gap fluxes from two field solutions in terms of a specific load current and a small current increment at a fixed rotor position. However, this procedure may cause some uncertainty due to the arbitrary choice of a small displacement from the operating point, or the arbitrary alignment of the rotor pole center with the stator slot center, the tooth center, or in between. In addition, the effects of stator slot leakage and phase-spread harmonic leakage are not directly taken into account in the field simulation.

In this paper, the saturated parameters and the flux linkage produced by permanent magnet (PM) at various load conditions are first directly extracted in actual (natural) abc reference frame based on the frozen method from the transient FEA solution. Then they are transformed to $d-q$ axis reference in terms of the average values over one steady-state cycle. Thus, the extracted $d-q$ parameters have taken into account the

effects of the slot leakage and phase-spread harmonic field. This approach is able to provide better accuracy.

II. PARAMETER EXTRACTION IN ABC REFERENCE FRAME

The saturated parameters in the abc reference frame vary with the load conditions. When the three-phase windings are excited with constant three-phase AC voltages, these parameters can be extracted and expressed as a function of torque angle δ . Because the torque angle is the displacement by which the induced voltage phasor lags the applied voltage phasor, this modeling request can be easily realized in transient FE analysis by the following steps: 1) rotate the rotor to the initial position θ_0 at which the negative d -axis aligns with the positive phase-A axis as shown in Fig. 1; 2) apply three-phase voltages in terms of a specific torque angle as

$$\begin{cases} v_a = \sqrt{2}V_1 \sin(\omega t + \delta) \\ v_b = \sqrt{2}V_1 \sin(\omega t + \delta - 2\pi/3) \\ v_c = \sqrt{2}V_1 \sin(\omega t + \delta - 4\pi/3) \end{cases} \quad (1)$$

where ω is the angular frequency. With such scheme, phase-A will have the negative maximum flux linkage produced by PM at the initial position, which corresponds to zero crossing from negative to positive of the induced voltage in phase-A.

Fig. 1 Initial rotor position where d -axis oppositely aligns with phase-A axis

After solving transient FEA under a specific load condition at each time step, the FEA system's coefficient matrix is frozen, which is equal to freezing the permeability of each element. Then the field is resolved with the frozen coefficient matrix together with different right-hand sides corresponding to the excitation of 1A current in turn in each winding with the exclusion of magnets and all other winding excitations. As a result, the calculated flux linkages provide the self and mutual inductances for all windings. Similarly, by enabling the excitation of magnets alone with zero currents in all windings, the flux linkage due to magnets for each winding is obtained.

III. PARAMETERS IN DQ REFERENCE FRAME

The transformation matrix from abc reference frame to $d-q$ reference frame is

$$[C] = \sqrt{\frac{2}{3}} \begin{bmatrix} \cos\theta & \cos(\theta - 2\pi/3) & \cos(\theta - 4\pi/3) \\ \sin\theta & \sin(\theta - 2\pi/3) & \sin(\theta - 4\pi/3) \\ 1/\sqrt{2} & 1/\sqrt{2} & 1/\sqrt{2} \end{bmatrix} \quad (2)$$

where θ , which is equal to $\omega t + \pi$ at the synchronous speed, is the angle from the phase-A axis to the d -axis in electrical radians. It can be verified that this transformation is able to keep the power and torque invariant, as well as to have identical transformation for both current and voltage. Therefore, the transformation of impedance is

$$\begin{bmatrix} L_d & 0 & 0 \\ 0 & L_q & 0 \\ 0 & 0 & L_0 \end{bmatrix} = [C] \cdot \begin{bmatrix} L_{aa} & L_{ab} & L_{ac} \\ L_{ab} & L_{bb} & L_{bc} \\ L_{ac} & L_{bc} & L_{cc} \end{bmatrix} \cdot [C]^T \quad (3)$$

where superscript T denotes the transpose of $[C]$. The transformation of flux linkage produced by PM alone is

$$\begin{bmatrix} \lambda_{md} \\ \lambda_{mq} \\ \lambda_{m0} \end{bmatrix} = [C] \cdot \begin{bmatrix} \lambda_{ma} \\ \lambda_{mb} \\ \lambda_{mc} \end{bmatrix} \quad (4)$$

The $d-q$ axis inductances L_d and L_q , and flux linkages λ_{md} and λ_{mq} are computed for each time step. Figs. 2 and 3 show the variations of average values of these parameters over one steady-state cycle with the torque angle δ for the application example to be discussed in the next section.

Fig. 2 L_d and L_q profiles with torque angle

Fig. 3 λ_{md} and λ_{mq} profiles with torque angle

IV. NUMERICAL VALIDATION

As an application example, the proposed approach is applied to simulate the performance of 8-pole, 48-slot Toyota Prius IPM motor [8]. The rating of the prototype is 50kW at 200V phase peak voltage and 3000 rpm.

In order to validate the effectiveness of the proposed approach, let us to compare the torque value between two cases: the first one is that the torque value is obtained directly from transient FEA simulation; the other one is that the torque

value is derived in terms of the above extracted parameters shown in Figs. 2 and 3 based on the lumped parameter model. From (1) and (2), the $d-q$ voltage at the synchronous speed is

$$\begin{bmatrix} v_d \\ v_q \\ v_0 \end{bmatrix} = [C] \cdot \begin{bmatrix} v_a \\ v_b \\ v_c \end{bmatrix} = \begin{bmatrix} -\sqrt{3}V_1 \sin\delta \\ -\sqrt{3}V_1 \cos\delta \\ 0 \end{bmatrix} \quad (5)$$

The voltage equation in the $d-q$ reference frame is

$$\begin{bmatrix} v_d \\ v_q \end{bmatrix} = \begin{bmatrix} 0 \\ -\dot{\theta}\lambda_{md} \end{bmatrix} + \begin{bmatrix} R_1 & \dot{\theta}L_q \\ -\dot{\theta}L_d & R_1 \end{bmatrix} \cdot \begin{bmatrix} i_d \\ i_q \end{bmatrix} \quad (6)$$

where $\dot{\theta}$ is the synchronous speed in electrical radians per second, and R_1 is the resistance of the phase winding. Thus

$$\begin{bmatrix} i_d \\ i_q \end{bmatrix} = \frac{1}{R_1^2 + \dot{\theta}^2 L_d L_q} \begin{bmatrix} R_1 v_d - \dot{\theta} L_q (v_q + \dot{\theta} \lambda_{md}) \\ \dot{\theta} L_d v_d + R_1 (v_q + \dot{\theta} \lambda_{md}) \end{bmatrix} \quad (7)$$

and the torque is

$$T_e = p \left[-(L_d - L_q) i_d i_q - \lambda_{md} i_q \right] \quad (8)$$

where p is the number of pole pairs. Fig. 4 shows the torque characteristics computed by (8) using the extracted lumped parameters, compared with the results directly from FEA transient simulation. It can be seen they match very well.

Fig. 4 Torque characteristics from the lumped parameter model, compared with the FEA transient simulation results

Abstract — The stator winding overhangs of two permanent magnet (PM) synchronous machines are simulated using a 3D simulation program dedicated for calculation of special end effects in electrical machines. The main issues with simulation of the stator winding ends and the adopted solutions are presented in this paper. Two models with different type of winding overhangs are calculated to demonstrate the program functionality.

I. INTRODUCTION

Numerical simulation of electrical machines is widely used especially by the calculation and optimization of PM machines. Often in the daily use, specialized 2D programs [1], which allow fast deploying of the model and offer the necessary results in a convenient manner, are preferred to a multipurpose general program, which may not be so time efficient. In order to expand the capabilities of an established 2D FEM code, a special 3D program is developed for considering only 3D end effects in electrical machines. The program uses as the base for the mesh generation the established 2D mesh, which is extruded to create the three dimensional meshes. For solving the 3D numerical problems an open source software [2] is used.

Fig. 1. a) Tooth wound coil b) Two layers distributed coil (Source a) TU Darmstadt, b) VA Tech Andritz)

Simulation of electrical machines with 3D models is usually avoided due to the complicated model construction and increased calculation time. For many cases a 2D calculation is considered sufficient. However, if the simulated machine is relatively short like the disc type machines, or if the stator and rotor have big differences in length in the axial direction or the effects of the winding overhang are important, a 2D solution is not sufficient. In this paper the generation of the winding overhang as a special example of a 3D problem is discussed. The winding overhang can be complicated to implement, depending on the machine type. The tooth wound coils (Fig. 1 a)) are easy to implement, but the high voltage two layer distributed winding (Fig. 1 b)) features a complicated 3D structure, which must be considered by a special mesh generation. The developed 3D FEM code provides the user with an automatic generation of the winding

overhangs in order to reduce the time, needed to prepare the simulation.

II. WINDING OVERHANG MESH GENERATION

For the treatment of end effects the mesh is generated mostly by extrusion from the original 2D mesh of the previously investigated machine. The same procedure is applied also for the winding overhangs, where the extrusion path is chosen to be found in the center of the coil cross section. Thus the extrusion path is a 3D curve that needs to follow the winding overhang shape. One problem that arises during extrusion is that the coil can get skewed and the lateral cross section areas are not planar anymore. That requires the use of second order elements which are not supported by the used open source software. For this reason the winding overhangs mesh is not done with hexahedral or triangular based prisms, but with first order tetrahedral elements, which due to their triangular faces have always plane faces. A small geometrical discretization error (Fig. 2) appears for strong twisting, which can be reduced by an increase of the mesh density.

Fig. 2. Skewed geometry with the non-planar quadrilateral surface A approximated by two planar triangular surfaces A_1 and A_2

The extrusion path contains straight segments and circle arcs. In order to avoid unnatural deformation of the mesh during extrusion, straight segments are not usually connected directly, if they are forming an angle different of 180° . A procedure that connects two neighboring segments with an arc of a given radius is used to maintain a valid mesh. A simple application is a tooth wound coil, which only contains two straight segments and an arc, all found in the same plane. The example is an outer rotor PM machine, used as a fan motor (Fig. 3 a)). For this example the simulation of a 3D model is interesting, because the outer rotor is longer than the stator.

III. TWO LAYER DISTRIBUTED WINDING

Distributed windings are used instead of tooth wound coils, because they are decreasing the harmonic content of the

stator field and so decrease the losses in the machine. The complicated manufacturing increases the manufacturing costs. Two layers distributed winding with a constant coil span are used as form wound coils in large machines. The coils are connected between the upper and the lower layer coil side without intersecting each other in the overhang region and having a regular arrangement of the end connections (Fig. 3 b)). The presented example is a linear machine. In the case of rotating machines an additional bending is necessary to follow the machine cylindrical shape.

Fig. 3. a) One pole pair of the tooth wound coil outer rotor PM synchronous machine b) One pole of the two layers distributed winding linear PM machine

TABLE I
MAIN MOTOR PARAMETERS FOR SIMULATION

Parameter\Motor	Tooth-coil	Distributed winding
Phase number	3	3
Turns / Phase	100	5
Iron stack length	5 mm	60 mm
Magnet length	15 mm	60 mm
Overhang length	12 mm	67 mm
Iron relative permeability	1000 (rotor) 10000 (stator)	1000

The modeling of this type of machine is difficult, when the symmetry is exploited and periodical boundary conditions are used to limit the calculation domain. For example, in Fig. 3 b) the mesh for only one pole of the motor is used and the winding must pass through the boundary. That can happen at an arbitrary angle and so care must be taken that the elements remain valid. Furthermore, the periodical boundary conditions require that the mesh on both sides (left and right in Fig. 3 b)) is identical. The solution adopted was to generate the entire preformed coil and to cut the part that surpasses the model boundary. The parameters used for the simulations are given in Table I.

IV. CALCULATION RESULTS AND COMPARISON WITH 2D RESULTS

For validation of the results the calculations were done using the 2D software [1]. The model for the 3D software was based on an extruded mesh similar to the 2D model (a). For this purpose the end windings and end region were not simulated, and at the two boundaries in longitudinal direction (minimum and maximum z) a parallel flux *Dirichlet* boundary condition was used. The results of the 2D and 3D model are directly comparable in this case (Table II). All presented simulations are no-load calculations without excitation current in the stator winding only the PM field of the rotor is considered. Due to yet limited post processing capabilities the only integral value available is the flux linkage Ψ integrated according to (1), where \mathbf{A} is the magnetic vector potential, N

is the number of turns per phase and C is the curve on which the coil is extruded.

$$\Psi = N \int_C \mathbf{A} \cdot d\mathbf{s} \tag{1}$$

The full 3D simulation (b) considers also the winding overhang (Fig. 4). For the tooth wound coil PM machine the flux linkage increases about three times due to the longer magnets on the rotor. The length of the magnets is about 3 times bigger than the stator iron stack. Also due to the linear calculation, which neglects the iron saturation. For the distributed winding machine the full 3D model uses the same magnet volume. The flux linkage decreases due to the fact that a part of the magnetic flux lines closes in the air at the motor end without contributing to the winding flux.

Fig. 4. Vector plot of magnetic flux density of: a) Tooth coil PM machine b) The distributed winding PM linear machine

TABLE II
COMPARISON OF CALCULATED FLUX LINKAGE IN WINDINGS FOR 2D AND 3D SIMULATION (IN $10^{-3} \cdot \text{V} \cdot \text{s}$)

Program\Motor	Tooth-coil			Distributed winding		
	U	V	W	U	V	W
2D	0.181	0.181	0.362	29.2	-43.0	9.8
a) 3D as 2D	0.183	0.183	0.365	29.0	-42.8	9.8
b) 3D	0.494	0.493	0.986	23.7	-34.6	7.8

The results of the 2D model and the first 3D model are in good concordance and so the results of the 3D program are validated.

V. CONCLUSIONS

The first results obtained with a 3D electrical machines oriented program were presented in this paper. The generation of the winding overhangs model is done using the extrusion of the 2D mesh of the coil along an arbitrary path. Periodical boundary conditions require a special treatment of the mesh generation to ensure identical mesh on the master and slave sides of the boundary condition.

Abstract— This paper proposes a dynamic analysis method for a novel spiral resonant actuator with two-degree-of-freedom employing the 3-D finite element method (FEM). The effects of the slit structure on the performance of the actuator are quantitatively clarified using this method.

I. INTRODUCTION

We have been developing a novel spiral resonant actuator with two-degree-of-freedom based on the linear resonant actuator with active vibration absorber [1][2].

In this paper, we propose a dynamic analysis method for the actuator, in which motion equations of linear and rotation are simultaneously solved employing the 3-D finite element method (FEM). Consequently, the effects of the slit structure on the performance of the actuator are quantitatively clarified using this method.

II. BASIC STRUCTURE AND PRINCIPLE OF OPERATION

Fig. 1 shows the proposed spiral resonant actuator. It mainly consists of an armature (yoke A and shaft) and a stator (coil, permanent magnet, yoke B and case). The armature is connected to the resonance spring. The active vibration absorber, which decreases the vibration of case, is connected to the armature.

Fig. 2 shows the magnetic circuit at the x-z section. The thrust is not generated on the armature when the coil is not excited because the magnetic flux by the magnet is balanced in two gaps. On the other hand, when the coil is excited, the thrust is generated on the armature because the total magnetic flux by the magnet and current becomes unbalanced.

Fig. 3 shows the magnetic circuit at the x-y section. In order to achieve the spiral motion, both of the armature and the stator have slits (pitch θ_p , width w , depth d), and the upper and lower slits of the armature are shifted with θ_s and $-\theta_s$ against the stator slit. The clockwise torque is generated on the armature when the armature moves in the positive direction of

Fig. 1. Spiral resonant actuator.

z-axis because the torque generated on the upper part of the armature is dominant. On the other hand, the counterclockwise torque is generated on the armature when the armature moves in the negative direction of z-axis because the torque generated on the lower part of the armature is dominant.

III. ANALYSIS METHOD

A. Magnetic Field Analysis

The equations of the magnetic field and the electric circuit are coupled using the 3-D FEM, which are given by the magnetic vector potential \mathbf{A} and the exciting current I_0 as follows [3]:

$$\text{rot}(\nu \text{rot } \mathbf{A}) = \mathbf{J}_0 + \nu_0 \text{rot } \mathbf{M} \quad (1)$$

$$E = V_0 - RI_0 - \frac{d\Psi}{dt} = 0 \quad (2)$$

$$\mathbf{J}_0 = \frac{n_c}{S_c} I_0 \mathbf{n}_s \quad (3)$$

where ν is the reluctivity, \mathbf{J}_0 is the exciting current density, ν_0

Fig. 2. Magnetic circuit (x-z section).

Fig. 3. Magnetic circuit (x-y section).

is the reluctivity of the vacuum, \mathbf{M} is the magnetization of permanent magnet, V_0 is the applied voltage, R is the effective resistance, Ψ is the interlinkage flux of exciting coil, n_c and S_c are the number of turns and the cross-sectional area of the coil respectively and \mathbf{n}_s is the unit vector along with the direction of exciting current.

The kinetic model of this actuator is shown in Fig. 4.

The linear motions of the armature, the active vibration absorber and the case are described as follows [3]:

$$m_1 \frac{d^2 z_1}{dt^2} = F + k_1(z_3 - z_1) + k_2(z_2 - z_1) + c_1 \left(\frac{dz_3}{dt} - \frac{dz_1}{dt} \right) + c_2 \left(\frac{dz_2}{dt} - \frac{dz_1}{dt} \right) \quad (\text{armature}) \quad (4)$$

$$m_2 \frac{d^2 z_2}{dt^2} = k_3(z_3 - z_2) + k_2(z_1 - z_2) + c_3 \left(\frac{dz_3}{dt} - \frac{dz_2}{dt} \right) + c_2 \left(\frac{dz_1}{dt} - \frac{dz_2}{dt} \right) \quad (\text{active vibration absorber}) \quad (5)$$

$$m_3 \frac{d^2 z_3}{dt^2} = -F + k_1(z_1 - z_3) + k_3(z_2 - z_3) + c_1 \left(\frac{dz_1}{dt} - \frac{dz_3}{dt} \right) + c_3 \left(\frac{dz_2}{dt} - \frac{dz_3}{dt} \right) \quad (\text{case}) \quad (6)$$

where m_i , z_i , k_i and c_i ($i=1,2,3$) are the mass, displacement, spring constant and viscous damping coefficient of the armature, active vibration absorber and case, respectively. F is the electromagnetic force acting on the armature.

The rotation of the armature is described as follows [3]:

$$I \frac{d^2 \theta}{dt^2} = T_m + k' \theta + c' \frac{d\theta}{dt} \quad (\text{armature}) \quad (7)$$

where I is the moment of inertia of the armature, θ is the rotation angle, T_m is the torque acting on the armature, k' is the spring constant for rotation and c' is the viscous damping coefficient for rotation.

B. Dynamic Analysis Method

In order to simulate the dynamic behavior of the actuator, it is necessary to solve the motion equations of linear and rotation simultaneously.

The detail of the procedure is shown as follows:

- (i) The meshes are modified according to the displacement of the armature for linear motion analysis.
- (ii) The meshes are modified according to the rotation angle of the armature for rotation analysis.
- (iii) The 3-D magnetic field analysis is conducted.
- (iv) The displacement of the armature, the active vibration absorber and the case are calculated by solving (4)-(6).

Fig. 4. Kinetic model of spiral resonant actuator.

- (v) The rotation angle of the armature is calculated by solving (7).

IV. ANALYZED MODEL AND ANALYSIS CONDITIONS

The magnetic circuit of the actuator is analyzed using the 3-D FEM (Ref. Figs. 2 and 3). The analyzed region is 1/12 of the whole region because of the symmetry. The slit pitch θ_p , the slit depth d and the slit shift θ_s are 30.0° , 0.3mm and 7.5° , respectively.

V. RESULTS AND DISCUSSION

Fig. 5 shows the waveforms of current, thrust and torque in steady state. From this figure, the maximum thrust and the maximum torque are 2.9N and $1.8\text{mN}\cdot\text{m}$, respectively. Fig. 6 shows the amplitude and rotation of the armature in resonance. From this figure, the resonance is synchronized with the rotation. The maximum amplitude and the maximum rotation angle are 0.36mm and 6.6° , respectively. The effectiveness of the calculated results will be confirmed through the comparison with the measured ones in the full paper.

Abstract—Doubly fed induction generator is attracting attention among options in distributed wind energy harvest. Traditional design and analysis of Doubly Fed Induction Generator (DFIG) dominantly rely on lump-parameters and Finite Element models. Although Finite Element Analysis (FEA) method is available, the computational time limits its application in iterative optimal design practices of DFIG. This paper is based on the use of Field Reconstruction Method (FRM) which can greatly reduce the computation cost while maintaining acceptable accuracy. In order to conduct efficiency optimization the procedure to calculate flux density and core losses are described. Finally, an optimal design method of DFIG towards maximum annual energy production in a given area with available wind speed information is presented.

I. FIELD RECONSTRUCTION METHOD IN DFIG

A. Field reconstruction model of machine

FEA is the mainstream tool in the design and analysis of electric machines. However, an optimal and iterative design of an electrical machine, using FEA, typically requires much more computation cost than lump-parameter model. In the absence of magnetic saturation, Field Reconstruction (FR) method [1] can offer the distribution of the flux density with acceptable accuracy using superposition of two pre-existing magneto-static FE field solutions. It is understood that distributed wind generators that are grid connected should not operate under saturated conditions to avoid emission of undesirable harmonics. Therefore, with the linearity assumption, the normal and tangential flux density in the airgap of DFIG can be viewed as the superposition of the stator and rotor contributions

$$B_n = B_{ns} + B_{nr} \quad (1)$$

$$B_t = B_{ts} + B_{tr} \quad (2)$$

In (1) and (2), B_{ns} , B_{nr} , B_{ts} , B_{tr} denote the normal and tangential components of flux density generated by stator and rotor excitations respectively. In particular, B_{ns} , B_{ts} can be obtained by adding the flux components created by 3 phases stator current I_{as} , I_{bs} and I_{cs} . This can be expressed as

$$B_{ns} = B_{nas} + B_{nbs} + B_{ncs} \quad (3)$$

$$B_{ts} = B_{tas} + B_{tbs} + B_{tcs} \quad (4)$$

Where B_{nas} , B_{tas} can be defined as

$$B_{nas} = I_{as} f_{ns}(\phi_{sm}) \quad (5)$$

$$B_{tas} = I_{as} f_{ts}(\phi_{sm}) \quad (6)$$

In which, $f_{ns}(\phi_{sm})$, $f_{ts}(\phi_{sm})$ are the basis functions only related with the geometry parameters of DFIG. The angle ϕ_{sm} refers to angular position relative to stator axis. Due to the symmetry of stator, the flux component of stator can be expressed as

$$B_{ns} = I_{as} f_{ns}(\phi_{sm}) + I_{bs} f_{ns}(\phi_{sm} - \theta) + I_{cs} f_{ns}(\phi_{sm} - 2\theta) \quad (7)$$

$$B_{ts} = I_{as} f_{ts}(\phi_{sm}) + I_{bs} f_{ts}(\phi_{sm} - \theta) + I_{cs} f_{ts}(\phi_{sm} - 2\theta) \quad (8)$$

Where θ is equal to 120 degree divided by number of pole pairs. Since the structure of rotor is similar to stator in DFIG, B_{nr} , B_{tr} can be defined as

$$B_{nr} = I_{ar} f_{nr}(\phi_{rm}) + I_{br} f_{nr}(\phi_{rm} - \theta) + I_{cr} f_{nr}(\phi_{rm} - 2\theta) \quad (9)$$

$$B_{tr} = I_{ar} f_{tr}(\phi_{rm}) + I_{br} f_{tr}(\phi_{rm} - \theta) + I_{cr} f_{tr}(\phi_{rm} - 2\theta) \quad (10)$$

B. Basis functions

Magneto static Finite Element Analysis of DFIG Model in commercial Maxwell is used to compute the basis functions $f_{ns}(\phi_{sm})$, $f_{ts}(\phi_{sm})$, $f_{nr}(\phi_{rm})$, $f_{tr}(\phi_{rm})$. By setting the $I_{as} = 1A$ while other phases of stator and rotor are kept open, basis functions $f_{ns}(\phi_{sm})$ and $f_{ts}(\phi_{sm})$ can be obtained using a single FE field solution. Similarly, the basis functions of rotor flux density can be calculated. Fig. 1 and Fig. 2 show the normal and tangential flux density of one 4 poles, 3 phases DFIG calculated by FR and FEA methods when the excitation is 30AT, -15AT, -15AT at stator phase a, b, c respectively. The rotor excitation is the same with stator. Our results show that FRM is typically two orders of magnitude faster than FEA and can have a high impact on computational time and resources.

Fig. 1. Normal flux density in the airgap calculated by FR method and FEA

Fig. 2. Tangential flux density in airgap calculated by FR method and FEA

II. FLUX AND CORE LOSS CALCULATION

Starting from the knowledge of flux distribution in the middle of the airgap the flux at various parts of the DFIG is calculated by integration of flux density over the area of various stator teeth. Once the flux distribution is known, the core loss model of the ferromagnetic materials is applied to calculate the core loss. Since the normal and tangential component of magnetic field is already computed by FR method, the calculation of core loss distribution is straight forward according to (11).

$$P_v = K_h f B_m^2 + K_c (f B_m)^2 + K_e (f B_m)^{1.5} \quad (11)$$

In which, K_h , K_c , K_e refer to the hysteresis loss, eddy current loss and excess loss coefficients respectively, which only related with material properties and B_m is the magnitude of flux density. Fig. 3 shows core loss of the DFIG model used in this paper when fed by 5A current at both stator and rotor.

Fig. 3. Core Loss of the DFIG

III. OPTIMAL DESIGN OF DFIG ACCORDING TO WIND SPEED DISTRIBUTION

A. Wind Speed Distribution

One drawback of the wind energy is that the available power relies heavily on the weather condition. There would be large fluctuation in wind energy due to the uncertainty of wind speed. To facilitate the optimal design, the Rayleigh distribution showed in Fig. 4, which has reasonable approximation of real wind speed condition, is applied in this paper. The probability density function is given by

$$f(v) = (\pi v / 2u_a) \exp(-\pi v^2 / 4u_a^2) \quad (12)$$

In which, v is the wind speed, u_a is average wind speed.

However, in the practical design, it is better to take advantage of specific site wind speed distribution data if it is accessible.

Fig. 4. Rayleigh wind speed distribution under different average wind speeds

B. Optimal design

Typically, the electric machines are designed to have the maximum efficiency at the rated operation condition. Nevertheless, DFIG always works at points apart from the rated condition due to the uncertain wind condition. The total output power of DFIG based on such design may not be the maximum in unit period. Actually, it is more straightforward if the optimal design aims at highest overall efficiency or total annual power output. However, accurate simulation based on FEA is time consuming. Fig. 5 shows the proposed optimal design procedure of DFIG which only requires one single magneto statistic FEA evaluation in one optimization circle when new geometry parameters generated. This can be much less time consuming than optimal design based on FEA.

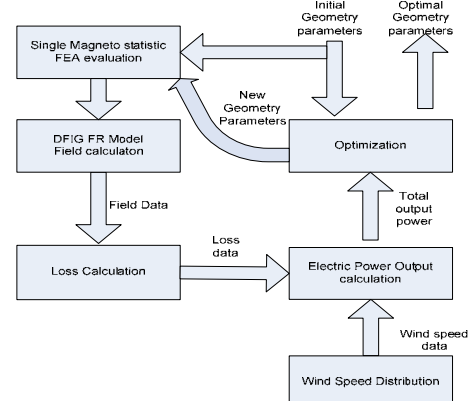

Fig. 5. Magnetization as a function of applied field

IV. CONCLUSION

An optimal design method of DFIG based on FR and FEA, aimed at maximum annual energy production, is proposed in this paper. Using the proposed method, optimal design can be achieved while the computation cost would be significantly reduced with reasonable accuracy compared to FEA. An optimal design case will be presented in the full version of the paper.

Analysis of Harmonic Iron Losses for IPMSM Considering the Rotating Field

Jang-Ho Seo and Hyun-Kyo Jung

School of Electrical Engineering, Seoul National University, Shillim-dong, Kwanak-gu, Seoul, 151-742, Korea
jangoho78@elecmech.snu.ac.kr.

Abstract— In this paper, we investigated the iron loss of interior permanent magnet machines for high-speed operation. In the analysis, to consider the harmonic magnetic field and the rotational variation of flux vectors in the core of the machine effectively, we proposed a new harmonic iron loss calculation method based on variable loss coefficients due to their flux density and frequency. In order to verify the performance of the proposed method, we calculated the iron loss in interior-permanent magnet synchronous machine (IPMSM) with conventional methods. Then, the estimated iron losses were compared with the experimental data. It was clarified that the proposed method is more effective than conventional methods at high-speed operation.

I. INTRODUCTION

With the increasing demand on high efficiency and high power density for energy saving, it is important to estimate iron loss of electrical machines accurately [1]-[5]. Until now, several models for harmonic iron loss in rotating machines using both Fourier transform and Epstein test have been developed [1]-[2].

In [1] the authors showed an iron loss evaluation method (*Conv. Method-1*) considering elliptically rotating field and harmonic flux density distribution. The method used the constant loss coefficient which is acceptable for line-fed machines with magnetic circuit loaded at 1.5-1.8T. However, such strategy based on constant loss coefficients is not suitable for the machine using field-weakening control in which the frequency and the flux density of flux waveform are varied remarkably according to its driving condition [3]-[5].

In [2] the authors showed a simple iron loss calculation method (*Conv. Method-2*) without using loss coefficients. However, the method needs experimental data curves very much because the model can't define the arbitrary loss curve used to calculate harmonic iron losses.

In this study, we proposed a new iron loss model adopting the variable loss coefficients concept [3], [4]. In order to verify the performance of the proposed method, we calculated the iron loss in IPMSM with conventional methods. Then, the estimated iron losses were compared with the experimental data.

II. PROPOSED MODEL

A. Adaptive Loss Coefficients

The conventional iron loss model with constant coefficients give rise to substantial error in specific frequency range and flux density, we adopt the concept of variable coefficients [3]-[5]. The iron loss model using the variable coefficients can be expressed as follows:

$$w_i = K_e(f, B)f^2 B^2 + K_h(f, B)f B^2. \quad (1)$$

The coefficients of K_e and K_h are variables with f and B . To attain the variable coefficients (K_e and K_h) with small relative error, we divided overall frequency range into two parts. One is low frequency (50-1000 Hz), the other is high frequency (1000-10000 Hz). And the determination of loss coefficients is shown in Fig. 3.

The following fifth-order polynomials were employed for curve fitting of K_e and K_h :

$$K_e = k_{e0} + k_{e1}B + k_{e2}B^2 + k_{e3}B^3 + k_{e4}B^4 + k_{e5}B^5, \quad (2)$$

$$K_h = k_{h0} + k_{h1}B + k_{h2}B^2 + k_{h3}B^3 + k_{h4}B^4 + k_{h5}B^5. \quad (3)$$

B. Rotational Iron Loss Evaluation

Generally, the loss data obtained from Epstein test has been widely used to calculate iron loss [1]-[5]. The Epstein test is performed in alternating field conditions and the method give good precision in predicting iron loss in transformers where the alternating field is dominant. However, in case of the rotating machines, there exist rotational flux density variations with different degrees of polarization. In addition, it has been reported that the iron loss occurring in the rotational field is much larger than that of the alternating one [1].

The additional iron loss caused by the rotational field is assumed to be proportional to the circular degree of flux vector loci expressed by the short-axis-to-long-axis rate c ($0 \leq c \leq 1$). The evaluation of this additional iron loss can be expressed as follows [1]:

$$W_i = \begin{aligned} &= P_{hys-rot} + P_{eddy-rot} \\ &= P_{hys-alt} + P_{eddy-alt} + P_{add_rot} \end{aligned}, \quad (4)$$

$$P_{add-rot} = \gamma \frac{L_{short}}{L_{long}} (P_{hys-alt} + P_{eddy-alt}), \quad (5)$$

$$= \gamma c (P_{hys-alt} + P_{eddy-alt})$$

where $P_{hys-rot}$ and $P_{eddy-rot}$ is hysteresis and eddy-current loss respectively when rotational field considered, P_{add_rot} is the additional iron loss caused by rotational field, L_{short} and L_{long} is the short and long axis of the flux vector trajectory ellipse, γ is the rate of iron loss increment under the circular rotational field to the loss in alternating field. The constant ' γ ' varies with flux density and the kind of core material. For simplicity, γ is fixed to 1.

Using FEM analysis, the flux density waveform at each element can be obtained. And then, Fourier transform is

performed to get fundamental and harmonics components. According to (4), total iron loss considering rotating field can be estimated as follows [1]:

$$W_i = \int_{iron} \sum_n \left(K_e D \cdot (nf)^2 B_{m,n}^2 + K_h D \cdot (nf) B_{m,n}^a \right) \cdot (1 + \gamma C_n) dv, \quad (6)$$

where C_n is the short-axis-to-long-axis rate of the flux vector locus at harmonic order n .

Since using the constant coefficients may induce the large computational error, (6) is not suitable for the machine using field-weakening control in which the frequency and the flux density of flux waveform are varied dramatically according to its driving condition.

Based on the equation (1), (2), and (3), we proposed a new iron loss model that employs the variable loss coefficients. The proposed model, based on (6), can be formulated as follows:

$$W_i = \int_{iron} \sum_n \left(K_e(nf, B_{m,n}) D \cdot (nf)^2 B_{m,n}^2 + K_h(nf, B_{m,n}) D \cdot (nf) B_{m,n}^a \right) \cdot (1 + \gamma C_n) dv \quad (7)$$

III. SIMULATION RESULTS AND DISCUSSION

To verify our proposed method, an IPMSM having 3[kW] power rating prototype machine was selected. For validation of our proposed method, the estimated iron loss was compared with the measurements. In the experiment, the open-circuit iron losses were measured with an input-output test. Fig. 2 shows the experimental equipments for measuring of iron loss. Fig. 3 shows the FE model and iron loss distribution of the machine at open-circuit operation.

The comparison of computational results is presented in Fig. 4. From the figure, we can see that our method agree well with the experimental ones compared with the conventional methods.

Characteristic Analysis & Optimum Design of Permanent Magnet Assisted Synchronous Reluctance Motor for Premium Efficiency Performance

Jung Ho Lee, *Member, IEEE*, Tae Won Yun, Sung Ju Mun
 Dept. of Electrical Engineering, Hanbat National University
 Dukmyung-Dong Yuseong-Gu, Daejeon, 305-719, KOREA
 komosin@nate.com

Abstract — This study deals with the characteristics analysis and optimum design of Permanent Magnet Assisted Synchronous Reluctance Motor (PMASynRM) using Finite Element Method (FEM) and Response Surface Methodology (RSM). The focus of this paper is finding of optimum design solutions due to the characteristics analysis of d, q axis inductance according to the size and magnetizing quantity of interior permanent magnet for PMASynRM. Investigation on nonlinear characteristic of machine is performed by Preisach's theory application. The proposed optimum design procedure (RSM) & characteristics analysis allow to define the rotor geometric dimensions performed premium efficiency starting from an existing motor or a preliminary design.

I. INTRODUCTION

The performance of a synchronous reluctance motor (SynRM) in terms of torque and power factor depends on the two-axis inductance L_d and L_q of the machine. The large difference of $(L_d - L_q)$ and L_d / L_q ratio are good for the machine's properties. Unless the high saliency ratio L_d / L_q is reached, the torque density, power factor and efficiency remain well below those of induction motors with an identical stator. Considerable attention has been paid in the past to improve rotor design of SynRM [1]-[3].

By adding a proper quantity of permanent magnets the torque density and power factor of SynRM can be greatly increased. It is called Permanent Magnet Assisted mSynchronous Reluctance motor (PMASynRM).

However, when a proper quantity of P.M. is chosen to counteract the quadrature mmf as shown in Fig. 1, 2 rotor ribs must be saturated by means of an additional magnet quantity. The effects of saturation and iron losses are often important issues in the performance of PMASynRMs. The saturation effect in the daxis of the rotor is very different from that of the q-axis because the nature of the magnetic paths is different. In the case of d-axis excitation, the saturation is the combined effect of saturation in the stator yoke, stator teeth, and rotor ribs, and can reduce the L_d inductance by as much as 50%. [4],[5]

In high speed applications, iron losses can become the major cause of power dissipation. Therefore, whereas in other kind of machines a rough estimation of iron losses is acceptable, their importance in PMASynRM justifies a greater effort in calculating them more precisely.

Finite element methods have the abilities to model the

complicated internal structure within PMASynRM and to model magnetic saturation to a high degree of accuracy.

This study deals with the characteristics analysis and optimum design of Permanent Magnet Assisted Synchronous Reluctance Motor (PMASynRM) using Finite Element Method (FEM) and Response Surface Methodology (RSM). The focus of this paper is finding of optimum design solutions due to the characteristics analysis of d, q axis inductance according to the size and magnetizing quantity of interior permanent magnet for PMASynRM.

Investigation on nonlinear characteristic of machine is performed by Preisach's theory application.

The proposed optimum design procedure (RSM) & characteristics analysis allow to define the rotor geometric dimensions performed premium efficiency starting from an existing motor or a preliminary design.

Fig.1 Rotor cross-section of PMASynRM

Fig.2 Phasor diagram corresponding to PMASynRM

II. CONCEPT OF RESPONSE SURFACE METHODOLOGY

The RSM seeks to find the relationship between design variable and response through statistical fitting methods, which are based on the observed data from system.

The response is generally obtained from real experiments or computer simulations. Therefore finite element analysis (FEA) is performed to obtain the data of SynRM in this paper.

There are many experimental designs for creation of response surface. In this paper the central composite design (CCD) is chosen to estimate interactions of design variables and curvature properties of response surface in a few times of experiments. The CCD has been widely used for fitting a second-order response surface. [6]

TABLE I
ANALYSIS OF VARIANCE

Source of Variation	Degree of Freedom	Sum of Squares	Mean Square	F_0
Regression	k	SS_R	$SS_R / k = MS_R$	MS_R / MS_E
Residual	$n-k-1$	SS_E	$SS_E / (n-k-1) = MS_E$	
Total	$n-1$	S_{yy}		

It is always necessary to examine the fitted model to ensure that it provides an adequate approximation to the true response and verify that none of the least squares regression assumptions are violated. In order to confirm adequacy of the fitted model, analysis-of-variance (ANOVA), shown in Table I is used in this paper. In Table I, n is the total number of experiments and k is the number of parameters in the fitted model.

III. OPTIMIZATION PROCEDURE

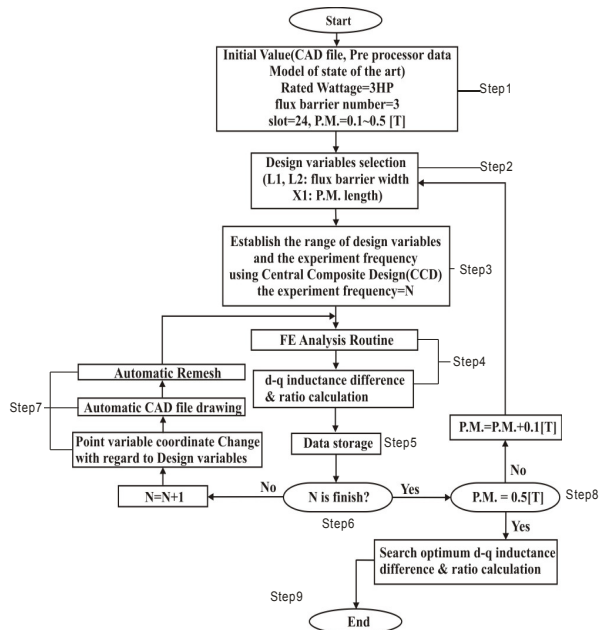

Fig. 3 the flow chart of optimum design procedure

Fig3. shows the flow chart of total design strategy.

Design procedure according to the flow chart is as follows;
Step1 : Set the initial value (CAD file, Pre-processor data). And the initial model is assigned to Rated Wattage=3HP, flux barrier=3, slot=24, P.M.=0.1~0.5[T]

Step2 : flux barrier width (L1,L2) in rotor are adopted the design variables related to torque density in the SynRM.

However, the ribs have a fixed value due to inherent manufacturing limitations.

Step3 : The range of design variables and experiment frequency is established by using the central composite design (CCD). The experiment frequency is N.

Step4 : Finite element analysis (FEA) is performed and Ld-Lq is calculated.

Step5 : The Ld-Lq obtained from FEA, are stored.

Step6 : The experiment frequency (N) is finish?

► Yes:P.M.=0.5[T]. ► No: N=N+1

Step7 : When the rotor shape according to variables (L1,L2) is varied, they have a difficulty in performing a lot of the pre-processor for FEA. For this reason, the new CAD file is redrawn with regard to the change of the design variables automatically. Next the process of automatic mesh generation follows. In mesh generation, mesh data doesn't change the node number, element number, region, boundary condition, etc., but only x, y coordinate data of the design variables. In this way, the proposed pre-processor procedure can be performed in a short period of time.

Step8 : P.M.=0.5[T]

► Yes: Finite element analysis (FEA) is performed and Ld-Lq is calculated.

► No: P.M.=P.M.+0.1[T]

Step9 : The response surface model is created by data obtained from FEA according to an established range.

Therefore, it is possible to get optimum torque density

More detailed results and discussion will be given in final paper. And the mathematical expressions for response surface methodology and optimum design procedures will be also given in extended version.

Abstract—This paper presents the effective analysis method of irreversible demagnetization for line-start permanent magnet (LSPM) motor considering magnetic field produced by secondary conductor bars. By using Finite Element Analysis (FEA) in transient magnetic field, currents in primary and secondary conductors are estimated and used for demagnetization analysis in magneto-static field. Therefore closer condition to actual situation can be achieved. General demagnetization analysis using primary currents only and presented analysis methods are compared and verified by experiments.

I. INTRODUCTION

LSPM motors have both conductor bars and permanent magnet (PM) in the rotor. Accordingly, line-start of induction motor (IM) is possible and operation in synchronous speed is possible at steady state by magnetic torque and reluctance torque. Therefore position sensor of general permanent magnet motor for starting and operation is not necessary, and conductor loss of general induction motor is small since LSPM motor operates at synchronous speed in steady state. Consequently, LSPM motor provides lower production cost than general permanent magnet motors and higher efficiency than general induction motors. The application of LSPM motor is suitable for home appliances which require low cost and high efficiency [1]. However, the large current at starting causes irreversible demagnetization of PM [2]. Generally the irreversible demagnetization of PM is decided by the operating point in B - H or M - H curve of PM when only primary part is excited. However, LSPM motor is operated as IM at starting and magnetic field by secondary conductors produced. This results in the reduced magnetic field acting on PM to be reduced. Therefore general demagnetization analysis leads to the over estimation of magnetic field acting on PM, and results in excessive PM usage.

This paper deals with demagnetization of LSPM motor by considering magnetic field by secondary conductor bars. By using FEA in transient magnetic field, currents in primary and secondary conductors are estimated and used for demagnetization analysis in magneto-static field. Therefore closer condition to actual situation can be achieved. General demagnetization analysis using primary currents only and presented analysis methods are compared and verified by experiments.

II. STRUCTURE OF SINGLE-PHASE LSPM MOTOR

The configuration and winding connection of a single-phase LSPM motor with rare-earth PM are shown in Fig. 1(a) and

(b) respectively. As shown in Fig. 1, both consist of main and subsidiary windings in the stator and conductor bars to produce the starting torque in the rotor. Starting capacitance C_s , running capacitance C_r , and positive temperature coefficient (PTC) are connected with the subsidiary windings to increase the starting torque and power factor. Accordingly, it could be considered as a two-phase motor. The motor has 2-pole rotor with 28-slot stator for household appliance.

Fig. 1. Single-phase LSPM motor and their stator winding connection

Fig. 2. Characteristic curve of permanent magnet

III. DEMAGNETIZATION OF PM

A. Nonlinear analysis of PM

The demagnetization analysis considers not only nonlinear characteristics of the core but also that of the PM on the B - H curve. Fig.2 shows an irreversible demagnetization curve of rare earth PM magnet each temperature. The equation (1) is approximate equation for Magnetization M [3].

$$M = B - \mu_0 f(B) = h(B). \quad (1)$$

Where H is $f(B)$ and μ_0 is permeability.

B. Calculation of demagnetizing current

On designing the thickness of PM, demagnetizing current is calculated in equation (2).

$$I \leq h_m \frac{2}{m} \cdot \frac{\pi}{4} \cdot \frac{2pH_c}{\sqrt{2}Nk_w}. \quad (2)$$

Where H_c is coercive force, m is phase number, h_m is PM thickness, p is pole-pair, k_w is a winding factor and N is turn number.

C. Analysis process

General demagnetization analysis method (Method1) using primary currents only and presented analysis method (Method2) for LSPM motor are compared. Initially, irreversible demagnetization current of Method1 is calculated using equation (2) at the TABLE I, and then identical current is used to Method2 in order to consider the effect of secondary conductor bars current on the irreversible demagnetization of PM.

As shown in fig. 3, the analysis process of demagnetization for LSPM motor is as following. Firstly, using transient analysis, currents in primary and secondary conductor bars are estimated. Then calculated currents by transient analysis are applied to irreversible demagnetization analysis in every rotor position considering not only nonlinear characteristic of the core but also that of the PM on the *B-H* curve. When the operating point of PM is below its knee point, the residual flux density of the PM is renewed. Finally, with renewed flux density of the PM elements, no-load back-EMF is calculated. By comparing no-load back-EMF before and after demagnetization field, irreversible demagnetization of PM is determined.

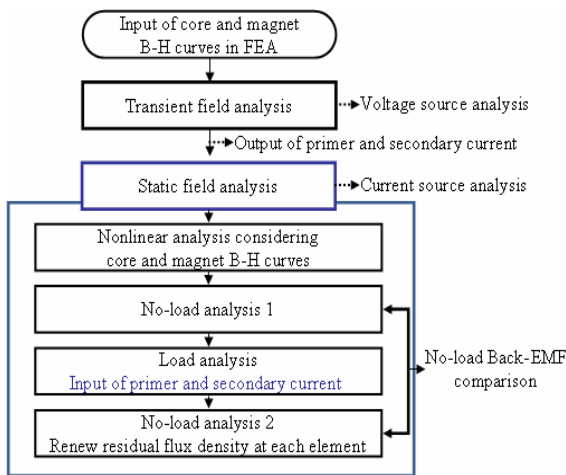

Fig. 3. The process of Method 2

TABLE I
INPUT CURRENT AT THE ROCKED-ROTOR STATE

Temperature [°C]	Magnetizing current [A]	Magnetization ratio [%]
120	60	8.20
150	28	12
165	15	8.81

IV. RESULT AND DISCUSSION

Fig. 4 shows comparison of magnetic flux density from Method1 and Method2 when external demagnetization field is applied. Using Method2, magnetic field by primary current reduced by secondary conductor current can be observed. Experiments are conducted under identical current and temperature conditions. To verify results according to analysis method by the test, DC current is excited in Method1 and AC current is excited in Method 2. Fig. 5 shows the input current and temperature of conductor bars and PM at experiments. As seen in Fig. 6 and TABLE II, using Method1, 8.8% of PM is

irreversibly demagnetized from analysis and experimental results. Meanwhile, no irreversible demagnetization occurs with Method2.

The effect of reduced primary field by secondary conductor field is clearly shown, therefore Method2 is closer to actual situation. Using presented analysis method 2, effective estimation of irreversible demagnetization of PM and cost reduction of LSPM motor reasonably can be achieved.

cougo@laplace.univ-tlse.fr

Abstract— This paper presents a method to speed up an accurate optimization of intercell transformers (ICTs). ICT design strongly relies on its associated leakage inductance, which is usually calculated by 3D or 2D FEM simulation. In an optimization procedure, introducing 3D or even 2D FEM simulation in the main loop considerably slows down the process. In order to speed up an accurate ICT optimization process, we use intensive 2D FEM simulation to generate an N-dimensional matrix containing the values of the leakage inductance related to N parameters which define the ICT geometry. In this way, the optimization loop simply performs an N-dimensional interpolation of the N-dimensional matrix to find the leakage inductance required in the design development.

I. INTRODUCTION

Intercell Transformers (ICTs) are used mainly in interleaved converters to reduce conduction losses in the switches and copper losses in the inductors [1]. Depending on the application, the design of such transformers specially relies on the calculation of the leakage inductance. Analytical formulation of the field distribution inside the window is easily obtained under the assumption that the window is rectangular and its depth is infinite. However, some real components are far from this assumption, and the field outside the window (which cannot be easily modeled) has a very significant contribution to the overall leakage inductance. Consequently, the use of 3D FEM simulation is necessary to precisely predict the leakage inductance.

The use of 3D FEM simulation may result on accurate calculation of the leakage inductance, but it is very time consuming. 2D FEM simulation can be considered [2] if the procedure used in the simulation takes into account 3D effects.

Even though 2D FEM simulations are much faster than 3D, it is sometimes impractical to make use of them inside an optimization process. The time necessary to the main optimization algorithm to call the FEM software, draw the 2D model, simulate it and acquire the resulting inductance values is enormous when comparing to a simple equation resolution or table reading.

The idea is to speed up the process of obtaining the desired leakage inductance by simply interpolating pre-simulated values of such inductances. These values are stored in an N-dimensional matrix where N is the number of geometrical parameters of the magnetic device which may modify the leakage inductance.

II. SIMULATION OF SIMPLE INTERCELL TRANSFORMERS

Let's analyze the proposed method by taking as an example the transformer on Fig. 1a. The leakage inductance is due to the energy stored in the air inside the core window and also outside it. The energy outside the core may be simulated using 2D FEM simulation. On the other hand, the energy inside the core window may be easily analytically calculated by making some assumptions which are acceptable for most of industrial transformers. In our analysis we will just deal with the energy outside the core and we will assume that the calculation inside the core is possible. When the calculation of the energy inside the core window cannot be done analytically, the proposed method may be used.

Fig. 1. Simple model for the simulation of the energy outside the window of an intercell transformer

Concerning the leakage inductance related to the energy outside the core window, we may simulate it by using the model represented in Fig. 1b [3]. Note that both windings are represented only outside the core window and that, independently of the number of turns and conductor cross-section shape, it is represented by a rectangular conductor with P turns.

In Fig. 2 all the parameters which may change the leakage inductance are represented. By simulation, 3 conclusions could be stated:

1. If we shrink or expand the transformer, maintaining the ratios between all parameters shown in Fig. 2, the leakage inductance per unit length remains the same.
2. Parameter F (core leg width) has a negligible influence on the leakage inductance if it is greater than 8% of A (core width). This is usually the case for regular transformers and cores available on the market.
3. Leakage inductance is proportional to the square of the number of turns in the winding, independently of the shape of the core and winding.

By conclusions 2 and 3, we assume that parameters F and P are not essential parameters when creating the N-dimensional matrix containing the pre-calculated leakage inductance values. By conclusion 1, we observe that we just

need to simulate a transformer normalized in geometry. We did it by fixing parameter A as the reference parameter. The other parameters (B , C , D , E) should be related to A , which lead us to a matrix with 4 dimensions (B/A , C/A , D/A , E/A).

Fig. 2. Transformer parameters

A. Number of Points

The number of points needed in each dimension must be wisely chosen in order to minimize the interpolation error and the size of the 4-dimensional matrix. For this purpose, simulations were performed by varying each parameter at once (starting from a standard shape) and using small steps. The result is shown in Fig. 3. Note that in fact parameter F does not significantly modify the leakage inductance. Also, since the other curves have a soft shape, a small number of points is needed to reliably represent the leakage inductance behavior related to the transformer geometry.

Fig. 3. Variation of the normalized linear inductance

The number of points in each dimension was chosen to be equal to 10, which makes a 4-dimensional matrix with 10000 values. The number of simulations needed is the same as the number of values in the matrix, and so the simulation mesh must be carefully chosen. A study about the mesh generation in this case will be shown in the full paper.

III. SIMULATION RESULTS

The 4-dimensional matrix was created and it took about 16 hours to be completed with 10000 values. In order to compare the advantages of using this matrix in an optimization process instead of inserting the FEM simulation inside the optimization loop, the time consumed by the FEM simulation (using the software FEMM) and the multidimensional interpolation must be compared. This comparison is shown in Table I, where there is also an evaluation of the maximum error observed for each type of interpolation used in software MATLAB. The computer used has Windows Vista operational system and Pentium dual-core (1.46GHz) processor.

TABLE I
TIME AND ERROR COMPARISON

	Direct FEM Simulation	Interpolation Method		
		linear	cubic	spline
Time (ms)	12527	7.57	570	604
Max Error (%)	0	1.07	1.24	1.24

Note that the greatest maximum error exists when using cubic and spline interpolations and this error is only 1.24%. By this table we can see the great advantage of the proposed method. The fastest interpolation method (which is the most accurate) is 1655 times faster than direct FEM simulation.

IV. CONCLUSION

Accurate prediction of leakage inductance is necessary in ICT design since its current ripple strongly depends on the inductance. The lack of analytical formulas to describe leakage inductance due to the energy outside the core makes necessary the use of 2D or 3D FEM simulation. The use of this type of simulation in an optimization process is impractical given that it very time-consuming task.

In this paper, a method was proposed to speed up this process. It is based on the pre-processing of the desired leakage inductances and the storage of the essential values in an N-dimensional matrix. By multidimensional interpolation of this matrix, the desired leakage inductance value is found in few milliseconds. We showed that the slowest and the fastest interpolation methods are, respectively, 20.74 and 1655 times faster than 2D FEM simulation and they are both accurate.

The proposed method can also be used to predict leakage inductance inside the core window when 2D and 3D effects are predominant and when the use of well-known 1D analytical formulas is not possible.

Abstract — This paper presents the hysteresis torque analysis method for the permanent magnet rotary motor using hysteresis loss separated from the measured core loss data. Principally, hysteresis torque is defined by hysteresis loss. In this paper, hysteresis loss to get the torque is computed flux density of each element of FEM which is used of the initial magnetizing curve. And the core-loss is calculated considering hysteresis model and tested material core loss. In this case, core-loss data is provided by manufacturing companies. And this method is tested in electric motor with lower cogging. The calculated hysteresis torque is compared to the experimental result.

I. INTRODUCTION

Hysteresis phenomenon is become important in many areas of science and technology, such as magnetic recording, permanent magnets, hysteresis motor and so forth. Many models are known in literatures about hysteresis modeling [1]-[2]. The Preisach model is general and provides precise prediction of magnetization in the various models for scalar hysteresis models [3]-[4]. Hysteresis phenomenon is inevitable in general electric machines and occurs even without electrical input in permanent magnet motor. Hysteresis loss produces loss torque and called hysteresis torque, and hysteresis torque is assumed to be maintained constant force like a mechanical friction. In order to analyze the hysteresis torque, the use of measured hysteresis loop using the Preisach model is reasonable and efficient, however, the method and process are complicate. Therefore, a simple calculation method of hysteresis loss torque is presented using hysteresis loss data separated from measured core loss data. The hysteresis torque causes the breaking torque in electric motor. In order to compute the hysteresis torque, FEM is used. After calculation of $B(t)$ (magnetic flux density) in each element of core, hysteresis loss is calculated. The hysteresis loss data is separated from core loss by using Steinmetz Equation. At the result, analysis results are compared to experimental results.

This method is more convenient than the method using Preisach model and easy to understand the theoretical background. A surface permanent magnet motor for electric power steering system (EPS) is used for the hysteresis torque analysis and measurement of cogging torque.

For the EPS motor, the effect of cogging torque is very important due to driving comforts, therefore, the cogging torque and hysteresis are important factors in EPS system[4].

In order to verify the accuracy of simulation result, hysteresis torque is tested.

The experimental method of electric motor hysteresis torque is similar with cogging torque test. From the cogging torque test result, the offset of dc-bias component is defined hysteresis torque and friction torque. As a result, hysteresis torque is measurable considering cogging and friction in shaft torque.

II. MODEL AND ANALYSIS METHOD

A. B-H curve and Hysteresis Loss

In this paper, FEM simulation is used with initial b-h curve, also hysteresis curve are used for computation hysteresis loss.

Fig. 1 shows the b-h model and Fig. 2 shows the process of hysteresis torque analysis. This method can include some errors of magnetizing curve, but it is much simpler than Preisach model.

Fig. 1. Initial B-H curve and hysteresis curve

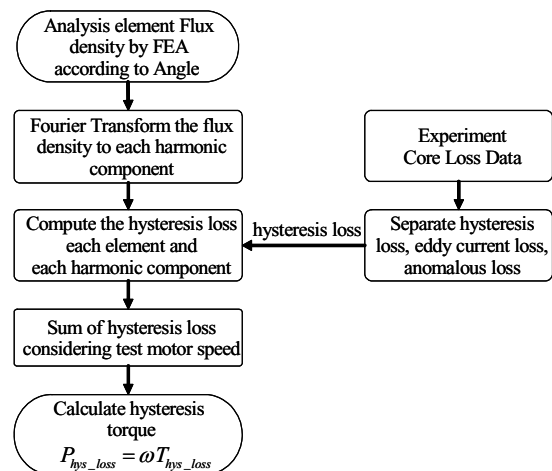

Fig. 2. Process of hysteresis torque analysis

B. Magnetic Field Analysis

The static field FEM is used for the analysis of the magnetic field. The governing equation for 2-D FE analysis is given by (1).

$$\frac{\partial}{\partial x} \left(\frac{1}{\mu} \frac{\partial A}{\partial x} \right) + \frac{\partial}{\partial y} \left(\frac{1}{\mu} \frac{\partial A}{\partial y} \right) = -J_0 - J_m \quad (1)$$

where, A is the z-component of magnetic vector potential, μ is the permeability, J_0 is electrical input current density and J_m is magnetizing current density. The input current J_0 is not exists in hysteresis torque analysis. Therefore, J_0 is equal to zero.

C. Hysteresis loss data

Core loss data is provided by manufacturer. The data are measured with sinusoidal input source. But the magnetic field \mathbf{H} is not sinusoidal in each element. Therefore, hysteresis loss is calculated by each harmonic component of each element. And hysteresis loss data is separated from the tested core loss data using Steinmetz equation as in (2). In this paper,

$$P_{core} = k_h f B^2 + k_e f^2 B^2 + k_a f^{1.5} B^{1.5} \quad [\text{W/kg}] \quad (2)$$

where k_h , k_e , k_a is coefficient of hysteresis loss, eddy current loss, anomalous loss respectively.

D. Analysis Model

Fig. 1 and Table I shows the cross-section and brief specifications of the analysis model.

Fig. 3. Cross-section view of 3-phase brushless motor

TABLE I
BRIEF SPECIFICATIONS OF 3-PHASE BRUSHLESS MOTOR

Item	Value	Item	Value
Pole number	6	Magnet Br (T)	1.2
Slot number	27	Recoil Perm.	1.05
Stator outer dia. (mm)	85	Core-Material	S60 (0.5t)
Airgap (mm)	0.8	PM direction	Radial
Stack length (mm)	26	Voltage (Vdc)	12

III. RESULT AND DISCUSSIONS

Fig. 4 shows the FEM result and FFT result of flux density in P1. Hysteresis loss distribution is shown in Fig. 5. High density hysteresis losses exist in tooth. And hysteresis loss of rotor is almost zero because there is few flux variation. Fig. 6 shows comparison between the experimental result and simulation result. In the test result, cogging torque is very small about 2.5mNm and the offset of torque is 13.8mNm, the mechanical friction is included in the offset. The simulated hysteresis torque is 13.4 mNm. The difference between simulation result and tested result are expected to the friction torque.

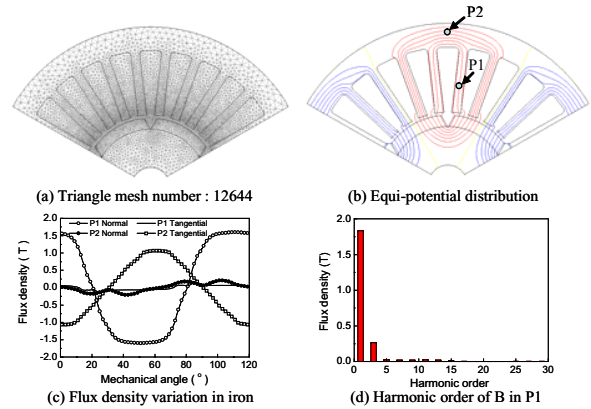

Fig. 4. FEM Result and Hysteresis loss distribution

Fig. 5. Hysteresis loss distribution of permanent magnet motor

Fig. 6. Comparison experiment and analysis result

IV. CONCLUSION

In this work, hysteresis torque is obtained from hysteresis loss which is separated from the core-loss experiment. This method is much simple than Preisach model and the result is similar experiment and analysis result. The proposed analysis method and experimental results will be reported in extend paper in detail.

Abstract— A progressive type of contactless torque transmission is effectuated by the innovation of a magnetic gear. The torque is purely transmitted by a selectable gear ratio via the magnetic fields inside the magnetic gear. Therefore, the assembly, the operating mode, the generation of the torque, and numerical field analyses by means of a FEM are presented, discussed and proven.

I. INTRODUCTION

An efficient design of the several components to obtain high torque and avoid harmonics in the torque is the main challenge. For lower rotational frequencies, the magnetic gear possesses a significantly higher efficiency than a mechanical gear due to no friction losses at all. The only occurring losses in the magnetic gear are caused by eddy currents that are only increasing by the frequency.

The magnetic gear is above all a very good alternative to mechanical gears. Also the weight and treatment of the magnetic gear are advantageous as no attendance is needed. The magnetic gear holds an overload protection by the physical effects. For overloading forces it acts like a slipping clutch and no teeth can ever blockate or even never break.

II. COMPOSITION OF THE MAGNETIC GEAR

The magnetic gear consists of three major parts, a rotor, a modulator, and a stator, that are separated by air gaps. The rotor and the stator possess a specific number of magnetic poles (p_R and p_S respectively) while the modulator consists of a specific number of modulator segments (p_M) that are composed of a magnetizable material e.g. iron. The rotor contains a ferrous core.

Fig. 1. Setup of the magnetic gear

Figure 1 shows the schematical setup of the magnetic gear with its rotor, modulator and stator.

The gear ratio is fixed and depends on the number of modulator segments and the number of magnetic poles in the rotor and the stator.

III. THEORY OF THE OCCURING FIELDS AND WAVES INSIDE THE GEAR AND GENERATION OF THE TORQUE

A torque is generated if the occurring waves in the magnetic gear are reacting with each other. One wave is effected by the permanent magnets of the rotor and another one by the magnets of the stator. The modulator's ferrous segments are modulating the frequencies of the existing waves.

A. Magnetomotive Force of the Stator

The magnetomotive force Θ_S of the stator is calculated via Ampere's Law. It leads to a $2\pi/p_S$ -periodic rectangular function with the amplitude Θ_S' as shown in Fig 2.

Fig. 2. Magnetomotive Force of the Stator

The Fourier analysis of this rectangular function leads to

$$\Theta_S = \hat{\Theta}_S \left[\cos(p_S \gamma) + \frac{1}{3} \cos(3p_S \gamma) + \frac{1}{5} \cos(5p_S \gamma) + \dots \right] \quad (1)$$

with the fundamental wave

$$\Theta_S = \hat{\Theta}_S \cdot \cos(p_S \gamma) \quad (2)$$

and the amplitude $\hat{\Theta}_S$ [1].

B. Magnetic Permeance of the Modulator

For the modulator the modus operandi is similar, however instead of the magnetomotive force the magnetic permeance of the modulator segments is examined. Figure 3 shows that also the magnetic permeance in the modulator follows a rectangular function; hence the period is $2\pi/p_M$ now.

The Fourier analysis of this rectangular function leads to

$$\Lambda = \Lambda_0 + \Lambda_{p_M} \cos(p_M(\gamma + \omega_M t)) + \Lambda_{2p_M} \cos(2p_M(\gamma + \omega_M t)) + \dots \quad (3)$$

where ω_M is the angular speed of the modulator.

Fig. 3. Magnetic permeance of the modulator segments

C. Magnetomotive Force of the Rotor

Similar to the computation of the magnetomotive force of the stator the fundamental wave of the magnetomotive force of the rotor can be specified as

$$\Theta_R = \hat{\Theta}_R \cdot \cos(p_R(\gamma + \omega_R t)) \quad (4)$$

where ω_R is the angular speed of the modulator.

D. Magnetic Air Gap Induction, Stator's Part

The magnetic poles of the stator are causing a part of the total air gap induction, calculated via

$$B_S = \Theta_S \cdot \Lambda. \quad (5)$$

As this is only a consideration of how the torque is generated, the harmonics can be neglected and the formula is simplified to

$$B_S = \hat{\Theta}_S \cdot \Lambda_0 \cdot \cos(p_S \gamma) + \frac{1}{2} \cdot \hat{\Theta}_S \cdot \Lambda_{p_M} \cdot \cos(\gamma(p_S + p_M) + p_M \omega_M t) + \frac{1}{2} \cdot \hat{\Theta}_S \cdot \Lambda_{p_M} \cdot \cos(\gamma(p_S - p_M) - p_M \omega_M t) \quad (6)$$

E. Generation of the Torque

For generating the torque, the magnetic air gap induction of the stator is reacting with the magnetomotive force of the rotor. The comparison of the relevant waves leads to the following interrelationships between the number of poles or segments respectively of stator, modulator and, rotor:

$$p_L = p_S - p_M. \quad (7)$$

the gear ratio is simply calculated via

$$gr = \frac{\omega_M}{\omega_R} = \frac{p_M}{p_L}. \quad (8)$$

The torque can be calculated via the transverse strain $\tau(\gamma)$ [1] but therefore it is important to take into account that the magnetic induction B is only in rough approximation the sum of B_S and B_R as the whole system is not linear.

IV. OPTIMIZATION

For optimizing the magnetic gear, that means maximizing the transmittable torque, the harmonics of the torque waves have to be minimized. For erasing the seventh harmonic for example, the pole coverage of the rotor of 6/7 is used [2]. The geometric dimensions of the gear like radii, dimensions of magnets, air gaps and segments can be adjusted to ameliorate the performance of the magnetic gear.

V. SIMULATION

The development of the magnetic gear is based on numerical simulations. Therefore, the FEM software Ansys is used. A quasi-static analysis is performed while eddy currents are not considered.

Fig. 4. Magnetic field

Fig. 5: Magnetic fluxlines

VI. CONCLUSION

A prototype of the magnetic gear has been manufactured and is in use in a machine tool. It is in an endurance test and performs satisfying results. Another illustrative model prototype is available and will be presented in an augmented reality session with a camera-notebook setup.

Tests and simulation results of the static torque characteristics of a brushless DC permanent magnet motor

P. P. de Paula and P. S. Ulian

Technological Centre of the Brazilian Navy
Av. Prof. Lineu Prestes, 2468, São Paulo, SP, 05598-000, Brazil
pedro.pereira@ctmsp.mar.mil.br

Abstract — This paper shows the simulation and tests activities developed to study some design aspects of a brushless permanent magnet motor regarding the torque production using the finite-element method and static torque tests.

I. INTRODUCTION

This paper regards a prototype of a converter fed brushless permanent magnet motor designed and manufactured at the Technological Centre of the Brazilian Navy. This prototype has similar characteristics to the drives presented in [1], [2] and [3]. An analytical method to get the main dimensions of the machine was used at the design stage. Several tests and simulations were already done with the prototype showed in [4], [5], and [6]. The full paper will show the simulations and tests results of the static torque characteristics which are very important to improve the efficiency and to minimize the noise and vibrations due to the cogging torque. The skewing of the stator slots are also taken into account in the simulations. The comparisons of the simulations and tests results have a good agreement, which assures the improvement of the design methods of this kind of drive.

II. THE MOTOR PROTOTYPE

This variable speed drive prototype consists of a brushless permanent magnet motor with electronic commutation. The motor is fed by a DC lin by 6 PWM inverters and each phase has its own converter and the main characteristics are showed in Table 1.

TABLE I
MAIN CHARACTERISTICS OF THE PROTOTYPE

Rated power	75 kW
Maximum speed	600 rpm
Number of phases	6 phases
Number of poles	12 poles
Rated voltage – DC link	600 volts
Maximum current	29 A (peak per phase)
Permanent magnets	Sm2Co17
Power converter type	H bridge

The prototype is an interior rotor motor with surface mounted permanent magnets and radially oriented magnetic field in the air gap. The magnetic induction waveform in the air gap is trapezoidal due to the configuration of assembling the permanent magnets.

The stator stack laminations are of the silicon steel type and has 72 slots. The winding is distributed on the stator slots as a lap winding, single layer and full-pitch, with 6 slots/pole. The signals to switch the phases is generated by an incremental encoder attached to the machine axis. Fig. 1

shows the cross section of the machine. This figure was depicted through the software FLUX2D [7], which is used in the simulations of this work, and shows also the flux distribution on the machine due to the permanent magnets. One can notice in this figure that the rotor of the machine has some pieces to guide the flux.

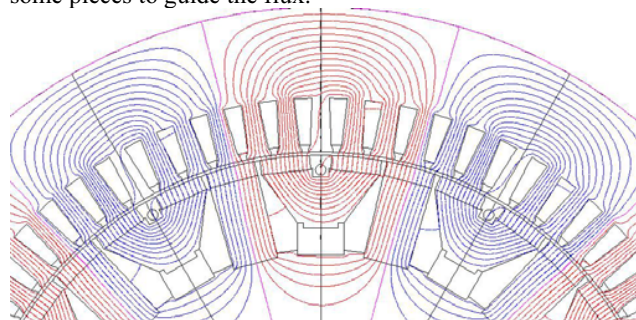

Fig. 1. Machine cross-section

III. STATIC TORQUE SIMULATIONS

The FLUX2D software solves complex electromagnetic field problems by using the finite-elements method. In this paper the problem is a bi-dimensional magnetostatic problem. The domain of study comprehends 30 degrees of the motor cross section, which corresponds to one pole of the motor. A 2D n-slice model, with $n=10$, was used to take into account the skewed slots of the stator. The axial length of the stator laminations is 160 mm and the simulations were done with a model of 16 mm length. The total torque is then calculated taking into account the angular displacements of the several slices of the model. The slots are skewed by the equivalent of one slot pitch, which means a skewing of 5 degrees regarding the longitudinal axis of the machine.

The static torque characteristic of the machine is the torque obtained from the machine for one or a set of phases energized with constant DC current as a function of the rotor position. The simulations were done for one phase energized and for a set of 5 phases energized. The details will be discussed in the full paper.

IV. STATIC TORQUE TESTS

The torque transducer and a special device designed and manufactured for these tests are showed in Fig. 2. The details of the equipments, devices and test methods will be presented in the full paper.

The static torque tests were developed with one phase energized by the following values of constant DC currents: 5,

11. Electric Machines and Drives

10, 15 and 20 ampères. Another set of tests were done with 5 phases connected in series for the same current values.

Fig. 2 – Torque transducer and special device

V. RESULTS

Fig. 3 shows the tests results for one phase fed with the currents values of 5, 10, 15 and 20 ampères. The lower curve corresponds to the test results with no current in the phase. The other curves corresponds to the torques obtained to increasing values of the currents, the maximum torque regards the maximum current. One may notice that the waveform of the torque characteristic is the same of the magnetic induction in the air gap.

Fig. 3 – Tests results for one phase energized

Fig. 4 shows the test and simulation results of the static torque characteristic for one phase energized with a current value of 10 A and the good agreement between these results. The skewing was taken into account as explained before which assures the good agreement of the results. The full paper will show the details of these achievements.

Fig. 5 shows the test and simulation results of the static torque characteristic for five phases energized with a current value of 10 A and the good agreement between these results. The skewing was taken into account as explained before which assures the good agreement of the results. The full paper will show the details of these achievements.

Fig. 6 shows the simulation results for five phases energized for three different skewing values, which shows the importance of this feature on the performance. The full paper will discuss these achievements.

Fig. 4 – Tests and simulation results for one phase energized

Fig. 5 – Tests and simulation results for five phases energized

Fig. 6 – Simulation results for some different skewing values

huangyunkai@gmail.com, joe@eng.uts.edu.au, youguang@eng.uts.edu.au

Abstract—The soft magnetic composite (SMC) is a new type of soft magnetic material made of insulated iron powders. Core loss is very important to SMC motor design. For accurate prediction, the rotational core losses model should be used. But rotational core loss coefficients derived from rotational loss data are difficult to get for most designers, because two dimensional core loss tester isn't popular as 25cm Epstein frame. This paper presents an improved calculation model for core losses of SMC motors, which only uses alternating core loss coefficients. Compared under different standard loci, such as alternating, circular, and elliptical ones, the new model shows the sufficiently accuracy. Finally, the model is testified by experiments on a high speed motor with SMC material.

I. INTRODUCTION

Made of insulated iron powders, the SMC is both magnetically and mechanically isotropic, and therefore is suitable for making electrical machines of 3D flux, such as the claw pole and transverse flux machines, which introduces many new design flexibilities in machine topologies and performance. To make the best use of the material for design, it's important to calculate core loss accurately.

There is an increasing need to develop high efficiency electrical machine nowadays for energy saving and the protection of the environment, which requires a more accurate prediction of core losses in the stage of design. Epstein test or single sheet test is performed with alternating fields where the core loss versus flux density is obtained. Designers use these data to calculate core loss of each part of the machine. This method has been proved to have a good consistence in the calculation of core loss in transformers, where the alternating field is dominant. In rotating machines, this method has a relative worse accuracy because the flux variation pattern is more complicated than in transformers. There exists a rotational flux component with different degrees of polarization besides the alternating components of flux observed in transformers. The loci of the flux in rotating machines may be line, circle, ellipse or other complicated pattern depending on location. It has been reported that core loss under a rotational field has a much larger value than that in an alternating field. In calculation of core loss in rotating machines, ignoring such additional loss caused by the rotational field will result in an excessively large value of error [1, 2].

Experience coefficients derived from a long-term production were used to modify the calculation of core loss. It is commonly used in the design of asynchronous machines, and gets good effects. But, for machines which have new materials or new structures, especially SMC motors, the

experience coefficient is very difficult to get. Many researchers [3-5] used the three term model for alternating core losses and time-stepped finite element method. There is about 20% difference because the rotational core loss is neglected. As the occurring of two-dimensional core loss tester, more and more researches have been conducted in the area of rotational core loss in electrical machines. Zhu et al. [1, 6, 7] studied core losses of core materials under 2-D and 3-D magnetic excitations, and proposed the rotational core loss model in electrical machines by combing FEA results with physical models of core loss. Stranges and Findlay[2] described direct approaches for coupling rotational core loss measurements with FEA results that yield the distribution of rotational flux in induction motor cores. Because the two-dimensional core loss tester exists only several research institute, and the international standard is in draft, it makes the rotational core loss model is difficult to use widely. Nowadays, although it has been realized that a considerable amount of the total core loss of a rotating electrical machine is caused by the rotating magnetic field, alternating core loss models were generally employed due to the lack of rotational core loss data.

This paper presents an improved calculation model for core losses, which only uses alternating core loss coefficients. Through theoretic calculation and experiments on high speed SMC motor, it shows good accuracy.

II. CORE LOSS MODE

A. Rotational core loss model

Corresponding to various types of magnetizations and soft magnetic materials, a core loss model was developed[6]. In a soft magnetic material, the core loss with various typical magnetic flux patterns can be calculated by:

Alternating flux:

$$P_{alt} = K_{ah} f B_m^h + K_{ae} (f B_m)^2 + K_{aa} (f B_m)^{3/2} \quad (1)$$

Circular rotating flux:

$$P_{rot} = P_{rh} + K_{re} (f B_m)^2 + K_{ra} (f B_m)^{3/2} \quad (2)$$

Elliptical rotating flux:

$$P_{fe} = R_B P_{rot} + (1 - R_B)^2 P_{alt} \quad (\text{W/kg}) \quad (3)$$

where $R_B = B_{min}/B_{maj}$ is the axis ratio; B_{maj} and B_{min} are the major and minor axes of the elliptical \mathbf{B} locus.

B. Improved model

The elliptical \mathbf{B} locus can be expressed as:

$$\mathbf{B} = e_{maj} B_{maj} \cos(\omega t) + e_{min} B_{min} \sin(\omega t) \quad (4)$$

where, e_{maj} and e_{min} are unit vector along the major and minor axes of the elliptical locus.

Eddy current loss under the elliptical B locus:

$$\begin{aligned} P_{e_ell} &= K_{ae} \int_0^T \left(\frac{d\mathbf{B}}{dt} \right)^2 dt \\ &= K_{ae} (fB_{maj})^2 + K_{ae} (fB_{min})^2 \end{aligned} \quad (5)$$

Anomalous loss under the elliptical B locus:

$$\begin{aligned} P_{a_ell} &= K_{aa} \int_0^T \left| \frac{d\mathbf{B}}{dt} \right|^{3/2} dt \\ &= K_{aa} \int_0^T \left[\left(\frac{dB_{maj}(t)}{dt} \right)^2 + \left(\frac{dB_{min}(t)}{dt} \right)^2 \right]^{3/4} dt \end{aligned} \quad (6)$$

Hysteresis loss under the elliptical B locus:

$$P_{h_ell} = K_h f (B_{maj})^h + \alpha_h K_h f (B_{min})^h \quad (7)$$

where, when $B_{maj} < B_s$, $\alpha_h = 1 \sim 1.2$, and $B_{maj} > B_s$, $\alpha_h = -1$

The total core loss under the elliptical B locus:

$$P_{fe} = P_{h_ell} + P_{e_ell} + P_{a_ell} \quad (\text{W/kg}) \quad (8)$$

The detail will be presented in the full paper.

The calculation flow can be seen form fig. 1.

Compared under different loci ($f=50\text{Hz}$, $B_{maj}=0.7\text{T}$), such as alternating ($R_B=0$), circular ($R_B=1$), and elliptical ones, as shown in Table 1, the improved model shows the sufficiently accuracy.

TABLE I
COMPARED RESULT UNDER DIFFERENT LOCI

R_B	Rotational model	Improved model	Error (%)
0	3.68	3.68	0
0.2	3.89	4.01	3.12
0.4	4.39	4.66	5.7
0.6	5.19	5.51	5.8
0.8	6.28	6.54	3.9
1	7.67	7.72	0.7

III. EXPERIMENT

Fig.2 compares the calculated and measured core losses of the high speed claw pole PM motor. As shown the maximum error is about 20%. This can be attributed to that the core loss coefficients were deduced from the core loss data of SMC measured up to 100 Hz while the operation frequency of this machine is 666.67 Hz, and the eddy current loss is under estimated. More results will be presented in the full paper.

IV. CONCLUSION

In this paper, an improved model is proposed to calculate core losses of SMC motor, which only uses alternating core loss coefficients. Compared with the rotational core loss model and experiment results on a high speed SMC motor, it shows the sufficiently accuracy, and it can be also used to calculate core losses of motors which have special structure or materials.

Abstract — This paper investigates the influences of the two-dimensional (2D) magnetic properties of silicon steel sheet on the performance of a very large-scale permanent magnet brushless DC motor. The 2D magnetic properties of a non-oriented silicon steel (50A1300) are measured by using 2D single sheet tester and modeled by using an extended B - H curve method to be applied to finite element method. Through the finite element analysis the influences of the two-dimensional magnetic properties of silicon steel on the motor performance are investigated.

I. INTRODUCTION

Recently, very-large scale permanent magnet brushless DC (BLDC) motors of which rating power is few MW have been employed for the propulsion system of electric trains, vessels [1]. The performances such as iron loss, back-emf and torque characteristics of the large scale motors are a lot affected by the magnetic properties of silicon steel sheets employed. A non-oriented silicon steel sheet for motor, conventionally, has been assumed to have independent magnetic characteristics on the direction of the applied magnetic flux density (B), i.e. the magnitude of magnetic field intensity (H) has been modeled as a function of only that of B , and the direction of H has been assumed to be exactly same with that of B without regard to the direction of B . With the development of two-dimensional (2D) single sheet tester (SST), however, it is found that even a non-oriented silicon steel has different magnetic properties according to the direction of B [2]. Fig. 1 compares the measured H -waveforms when constant magnitude (1.3T) of alternating magnetic flux density is applied in the directions of 0° , 15° , and 75° . The H -waveforms are measured at 50Hz by using 2D single sheet tester (SST) having waveform control function with the specimen of non-oriented silicon steel 50A1300. It can be seen that both the magnitude and direction of H strongly depend on the direction of B . The 2D magnetic properties of silicon steel sheet, therefore, should be considered in finite element analysis (FEA) for more precise performance analysis such as iron loss and cogging torque.

In this paper, the 2D magnetic properties of non-oriented silicon steel sheet (50A1300) are measured by using 2D SST and numerically modeled with independent variables of the magnitude and direction of magnetic flux density to be applied to FEA of a large-scale permanent magnet BLDC motor.

II. MAGNETIC RELUCTIVITY MODEL

In this paper, the hysteretic H -waveform corresponding to an alternating B -waveform of which maximum magnitude and

direction are B_m and θ_B , respectively, is measured by using 2D SST with B -waveform control, and the relationship between B and H is represented, as shown in Fig. 2, as (B_m, θ_B) - (H_m, θ_H) where H_m and θ_H are magnitude and direction of H corresponding to (B_m, θ_B) [3]. For various B_m and θ_B , by repeating this procedure, the relationships between (B_m, θ_B) and (H_m, θ_H) are obtained as shown in Fig. 3. It is observed that the silicon steel has the smallest magnetic permeability around 50° - 55° , and the biggest phase difference between B and H around 30° from its rolling direction. Since the B -waveform is represented as (B_m, θ_B) , this approximation is referred to, hereinafter in this paper, (B_m, θ_B) model, and this is a natural extension of the conventional B - H curve method.

Through the measured 2D magnetic properties shown in Fig. 1 and Fig. 3, it can be seen that the catalog data which is measured along rolling direction ($\theta_B=0$) and provided by manufacturer is not enough for precise modeling of the 2D magnetic properties even in non-oriented silicon steels. The 2D magnetic properties should, therefore, be considered for accurate performance analysis of the motors.

The magnetic reluctivity tensor for describing the relationship between B and H considering the modeled 2D magnetic

Fig. 1. Measured H -waveforms for different directions of the applied magnetic flux density when $B_m=1.3$ (T).

Fig. 2. B - H relationships approximated from measured H -waveforms corresponding to alternating B -waveforms when $\theta_B=60^\circ$.

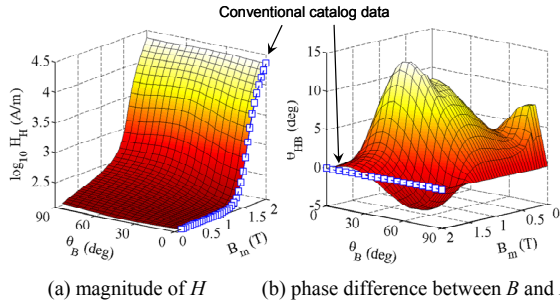

Fig. 3. Measured 2D magnetic properties for non-oriented silicon steel sheet 50A1300, where line marked by empty rectangular is catalog data.

Fig. 4. Specifications of 6MW PM BLDC motor (1/32 model).

properties is derived based on the effective anisotropic reluctivity as follows [3], [4]:

$$[v] = \begin{bmatrix} v_x & 0 \\ 0 & v_y \end{bmatrix} = \begin{bmatrix} H_x(B_m, \theta_B)/B_x & 0 \\ 0 & H_y(B_m, \theta_B)/B_y \end{bmatrix} \quad (1)$$

During the non-linear finite element analysis, in an element, if (B_m, θ_B) is found, then the corresponding reluctivities can be obtained using (1) and Fig. 3.

Using (1), the weighted residual and its derivative required in Newton-Raphson formulation for non-linear analysis is derived as follows:

$$R_i^{(e)} = v_x B_x d_i / 2 - v_y B_y c_i / 2 - J_0 \Delta / 3 \quad (2)$$

$$\frac{\partial R_i^{(e)}}{\partial A_j} = (v_x d_i d_j + v_y c_i c_j) / 4 \Delta + 0.5 B_x d_i \frac{\partial v_x}{\partial A_j} - 0.5 B_y c_i \frac{\partial v_y}{\partial A_j} \quad (3)$$

where Δ is the area of an element (e), c_i and d_i are the functions of coordinates of nodal points, and A and J_0 are magnetic vector potential and applied current density, respectively. The derivatives of the magnetic reluctivities in (3) are function of B_m , θ_B , H_m and θ_H , and expressed as follows:

$$\frac{\partial v_k}{\partial A_j} = c_1^k \frac{\partial H_m}{\partial B_m} + c_2^k \frac{\partial H_m}{\partial \theta_B} + c_3^k \frac{\partial \theta_H}{\partial B_m} + c_4^k \frac{\partial \theta_H}{\partial \theta_B}, \quad k = x, y \quad (4)$$

where c^k is calculated from B_m , θ_B , H_m and θ_H , and the derivatives are calculated by using Bezier surface spline of the measured data [5].

III. ANALYSIS RESULTS OF 6MW BLDC MOTOR

Fig. 4 shows a 6MW permanent magnet BLDC motor of which rating voltage is 720(V). The rolling direction of the stator and rotor is coincident with x -axis initially, and that of rotor rotates. Fig. 5 compares the distributions of the magnetic flux density obtained from the conventional and proposed

Fig. 5. Comparison of magnetic flux density distributions.

Fig. 6. Comparison of B -waveforms at the points P1 and P2 shown in Fig 4.

Fig. 7. Comparison of iron loss distributions.

analyses. It is observed that the proposed analysis distributes the magnetic flux more extensively with smaller maximum magnetic flux density than the conventional one. Fig. 6 shows the B -waveforms at the points P1 and P2 shown in Fig. 4. It is found that the two analyses give a lot different B -waveforms. Fig. 7 shows quite different distributions of iron loss between conventional B - H curve method and proposed method.

In the version of full paper, the influences on the other characteristics such as cogging torque and Back-emf waveforms will be investigated.

E-mail: huyansy@163.com

Abstract—A finite element method, coupled field-circuit, is applied to compute on electromagnetic torque of a solid rotor induction motor in this paper. And a field-circuit coupled model has been set up for considering the velocity effect, eddy current effect and non-linear property. A new end-region coefficient is presented to correct the effect of end region. It makes performance calculation more accurate. The method makes the period of design short and saves hardware from computing three-dimensional non-linear model. The comparison between tested and computed results proves that the method has higher accuracy and validity.

I. INTRODUCTION

Since having high starting torque and small starting current, solid rotor induction motor is suitable for starting with heavy load. Its quality factor of starting is better than that of common squirrel-cage induction motor. But the low efficiency and power factor has limited its development. For a long term, in order to solve this problem, many scholars have been working on it. Due to so many hypotheses and approximate treatments, analytical methods are incapable of calculating rotor parameters accurately. So the analytical methods will result in huge error in design of solid rotor induction motor.

In recent years, with the development of numerical arithmetic, finite element method has been used to compute the electromagnetic field in motor. Since the electromagnetic field in solid rotor is typically three-dimensional non-linear eddy field, there too many unknown quantities to be solved. And this will be restricted by the capability of computers. Actually, in the case of having no huge differences in structure and field distribution in axial direction, computing a two-dimensional model will get satisfied results. So a two-dimensional coupled-circuit method is adopted to design and analyze solid rotor induction motor. Because of taking voltage source directly as the known quantity and it is unnecessary to calculate rotor parameters separately, the error caused by calculating rotor parameters has been avoided. But the effect of end region still exists and being ignored in this method, so a new end-region coefficient is presented to consider the effect caused by end region in this paper. The level of designing has been improved greatly.

II. MATHEMATICAL MODEL

Considering saturation, the mathematical model of two-dimensional non-linear sinusoidal eddy field can be written as

$$\begin{cases} \nabla \times (\nu \nabla \times \dot{A}_z) = js\omega_1 \sigma \dot{A}_z - J_s \\ \dot{A}_z|_{\Gamma_1} = 0 \end{cases} \quad (1)$$

where ν is magnetic resistivity, Γ_1 is the boundary of model, s is slip ratio, ω_1 is angular velocity of stator current, σ is conductivity, J_s is current density of stator windings, $js\omega_1 \sigma \dot{A}_z$ is eddy current density of rotor. And the unknown quantity J_s , which varies with different loads, can be obtained by the expression^[1] as follows.

$$J_s = K \frac{N_{s1} \dot{I}_1}{S_a} \quad (2)$$

where N_{s1} is number of conductors in one slot, \dot{I}_1 is stator phase current, S_a is effective area of conductors in one slot, K is coefficient represented the direction of current, it is 1 along positive z-direction and -1 along negative z-direction.

Voltage equation for one phase can be expressed as

$$U_1 = -\dot{E}_1 + \dot{I}_1 R_1 + j\omega_1 L_1 \dot{I}_1 \quad (3)$$

where U_1 is voltage of one phase, R_1 is resistance of one phase, L_1 is leakage inductance of end region, \dot{E}_1 is back electromotive force and can be obtained by \dot{A}_z ^[2].

There is no need to solve \dot{I}_1 directly, the first step is to solve electromagnetic field by finite element method to get z-component magnetic potential \dot{A}_z , and then \dot{E}_1 will be obtained by \dot{A}_z . At last, \dot{I}_1 can be obtained by equation (3). So all we have to do is to apply actual sinusoidal voltage source to the finite model^[2].

III. ELECTROMAGNETIC TORQUE AND END-REGION EFFECT

A. Electromagnetic Torque

Z-component magnetic potential has been solved, and electromagnetic force and torque can be computed by Virtual work. The basal expression to calculate electromagnetic torque can be written as

$$F = -\frac{\partial W_m}{\partial s} \quad (4)$$

where W_m is stored energy of magnetic field. The air elements adjacent to rotor surface are effective in this method^[3]. In order to calculate the total magnetic force, it is

necessary to summarize the force acting on each element by the expression as follows.

$$F_e = \int_{V_e} (\mathbf{B}^T \frac{\partial \mathbf{B}}{\partial s} - \frac{\partial}{\partial s} \int_0^H \mathbf{B}^T d\mathbf{H}) dV \quad (5)$$

where F_e is s-component force acting on element e , s is displacement at x, y and z direction respectively^[4], V_e is the volume of each element. For two-dimensional analysis, electromagnetic torque can be written as

$$T_{em} = \sum_{e=1}^{E_a} F_t r = \sum_{e=1}^{E_a} (F_x \sin \theta_e - F_y \cos \theta_e) r \quad (6)$$

where F_t is tangential magnetic force acting on element e , F_x is x-component magnetic force, F_y is y-component magnetic force, E_a is the number of air elements selected, θ_e and r are the angle and radius location in coordinate system respectively.

B. End-Region Effect

By the rotor field analysis, it can be seen that as slip increases, rotor eddy current increases correspondingly. But the axial length of rotor is finite, and the direction of eddy current gradually changes from axial to tangential in end region. As a result, tangential current in end region increases greatly, skin effect becomes more intense and heat generation caused by power loss increases enormously. All these changes will have significant influence on performances of solid rotor induction motor. Therefore, the influence of slip should be included in the computation of end-region coefficient.

All kinds of end-region coefficients^[5] are given in Fig.1.

Fig.1 All kinds of end-region coefficients versus slip

None of them but K_{eK} and K_{eF} varies with slip, moreover, K_{ey} , K_{em} , K_{eG} and K_{eu} are constant and have nothing to do with slip.

As a matter of fact, none of them is suitable for the method used in this paper. So based on lucubrating of all kinds of end-region coefficient and the variation with slip, a new end-region coefficient is proposed. And it can be written in terms of slip:

$$K_{FE} = \left(\frac{K_T}{2} \right)^s \quad (7)$$

where

$$K_T = K_{eG} + K_{eF} \quad (8)$$

It is used to correct the performances of solid rotor induction motor influenced by end region. The curve of K_{FE} versus slip is shown in Fig.1.

IV. COMPUTED RESULTS

By the proposed method, a solid rotor induction motor, rated power is 7.5kW, has been designed. Rated data are given in table I. Computed values and tested results are given in table II. Comparison between the computed values and tested results shows that the computed values have very high accuracy.

TABLE I
DATA OF SOLID ROTOR INDUCTION MOTOR

Rated voltage	connection	pole	stator slot	Core length	rotor steel	rotor radius	air gap
380V	Δ	4	36	145 mm	10#	210 mm	0.6 mm

TABLE II
COMPARISON BETWEEN TESTED AND COMPUTED RESULTS

slip	performances	tested	computed	error
s=1	I_{st}/A	31.5	30.78	2.28 %
	$T_{st}/N \cdot m$	74	75.02	1.37 %
s=0.0067 (no-load)	I_0/A	5	5.084	1.68 %

V. CONCLUSION

Field-circuit coupled method based on finite element theory is applied to design solid rotor induction motor. This method can not only consider velocity effect, but also the non-linear property. Since there's no need to calculate parameters of rotor separately, the errors caused by calculating parameters of rotor are avoided. At the same time, a new end-region coefficient is proposed to correct the influence of end region in this paper. It makes the performances computation more accurate and improves the level of designing. And the tested results prove the accuracy and validity of the proposed method.

Dynamic Characteristics Analysis in A Pole Changing Memory Motor Using Coupled FEM & Preisach Modeling

Jung Ho Lee, *Member, IEEE*, Yong Hyun Cho, Il Kyo Lee
 Dept. of Electrical Engineering, Hanbat National University
 Dukmyung-Dong Yuseong-Gu, Daejeon, 305-719, KOREA
 E-mail: legend213@hanmail.net

Abstract — This paper deals with the PM performance evaluations in a pole changing memory motor (PCMM) using a coupled transient finite element method (FEM) and Preisach modeling, which is presented to analyze the magnetic characteristics of permanent magnets. The focus of this paper is the dynamic characteristics evaluation relative to magnetizing direction and the pole number of machine on re-, demagnetization condition in a pole changing memory motor.

I. INTRODUCTION

Electric drives in which discrete speed control is required are today equipped exclusively with squirrel-cage induction motors, due to the property of the squirrel cage to always have the same number of poles as the stator winding. Conventional permanent-magnet (PM) machines have a constant number of poles and can be operated from a constant frequency source only at one speed. If a PM machine is built after the principles of memory motors, one can change its number of poles as simply as in a squirrel-cage machine.

The operation of a memory motor is based on its ability to change the magnetization of its magnets with a low amount of stator current. It is illustrated how the magnetization of rotor magnets can be continually varied by applying a short pulse of stator current [1], [2].

If the rotor of a memory motor is built following the same sandwich principle shown in [1], but with more than one magnet per pole one can group equally magnetized magnets in various manners. As a consequence, the number of rotor poles changes. This is the basic principle of operation of a pole-changing memory motor, as illustrated in Figs. 1 and 2.

In Fig. 1, the cross-sectional view of a pole-changing memory motor with 32 tangentially magnetized magnets is shown. On the rotor side there are four magnets per pole, all of them being magnetized in the same direction. PMs along with iron segments build the rotor wreath which is mechanically fixed to a nonmagnetic shaft. After the stator winding is reconnected into six-pole configuration, a short pulse of stator current changes the rotor eight-pole magnetization into a six-pole one, as shown in Fig. 2. Since the number of magnets per pole is not any more an integer ($32/6=5.333\dots$), some magnets can remain demagnetized.

Issues such as magnetizing direction and quantity are important in evaluating the performance of the memory motor.

Such characteristics depend upon the characteristic of material and, therefore, require a numerical evaluation.

Whereas in other kinds of machines a rough estimation of hysteresis and magnetizing characteristics can be accepted, their importance in a memory motor justifies a greater effort in calculating them more precisely. The Preisach model is now generally accepted to be a powerful hysteresis model, and is therefore intensively studied [3], [4].

In this paper, a coupled finite element analysis and Preisach modeling for a PCMM are presented and dynamic characteristics analysis are performed under the situations of pole changing due to short pulse current.

II. COUPLED FEM AND PREISACH'S MODELING

A. Governing Equation of PCMM

Maxwell's equations can be written as

$$\nabla \times \vec{H} = \vec{J}_0 \quad (1)$$

$$\nabla \cdot \vec{B} = 0 \quad (2)$$

$$\vec{B} = \frac{1}{\nu_0} \vec{H} + \vec{M} \quad (3)$$

where, \vec{M} is the magnetization of magnetic material with

respect to the magnetic intensity \vec{H} . The magnetic vector potential \vec{A} and the equivalent magnetizing current \vec{J}_m are expressed as follows:

$$\vec{B} = \nabla \times \vec{A} \quad (4)$$

$$\vec{J}_m = \nu_0 (\nabla \times \vec{M}) \quad (5)$$

The governing equation derived from (1)-(5), is given by

$$\nu_0 (\nabla \times \nabla \times \vec{A}) = \vec{J}_0 + \vec{J}_m \quad (6)$$

When the moving coordinate system is used, the governing equation in 2D is given as follows:

$$\frac{\partial}{\partial x} \nu_0 \left(\frac{\partial A_z}{\partial x} \right) + \frac{\partial}{\partial y} \nu_0 \left(\frac{\partial A_z}{\partial y} \right) = -J_z - J_m \quad (7)$$

$$J_m = \nu_0 \left(\frac{\partial M_y}{\partial x} - \frac{\partial M_x}{\partial y} \right) \quad (8)$$

Where, A_z : z component of magnetic vector potential

J_z : current density

ν_0 : magnetic resistivity

M_x, M_y : Magnetization of magnetic material

with respect to the magnetic intensity H_x, H_y

B. System Matrix

The circuit equation is written as:

$$\{V\} = [R]\{I\} + [L_0] \frac{d}{dt} \{I\} + \{E\} \quad (9)$$

Where, $\{E\}$: E.M.F. vector in the winding

$\{V\}$: supplying voltage vector

$\{I\}$: phase current vector

$[L_0]$: leakage inductance

To solve (7), we used the Galerkin finite element method. For the time differentiation in (9), a time stepping method is used with backward difference formula. Coupling (7), (8) and (9), the system matrix is given as follows:

$$\left[\begin{array}{cc} \nu_0 [S] & -[N] \\ [0] & [R] \end{array} \right] + \frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \left\{ \begin{array}{c} \{A\} \\ \{I\} \end{array} \right\}_t = \frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \left\{ \begin{array}{c} \{A\} \\ \{I\} \end{array} \right\}_{t-\Delta t} + \left\{ \begin{array}{c} \{M\} \\ \{V\} \end{array} \right\}_t \quad (10)$$

Where, $[LG]$ is coefficient matrix related to emf, the magnetization $\{M\}$ is calculated by preisach modeling

C. Application of Preisach's Model

The magnetization M can be expressed as a scalar model, because the rotor rotates according to the input current angle θ synchronously. Therefore, it can be supposed that the domain in stator is an alternating field with reference to x axis and y axis. B and H of the domain in rotor is constant and is a rotating field, but it is an alternating field with reference to x axis and y axis, also [5]-[7]. It is natural that M, H which is calculated on the same axis has a same vector direction.

$$M(t) = \iint_{\alpha\beta} \mu(\alpha, \beta) \gamma_{\alpha\beta}(H(t)) d\alpha d\beta \quad (11)$$

$$= \iint_{S^+(t)} \mu(\alpha, \beta) d\alpha d\beta - \iint_{S^-(t)} \mu(\alpha, \beta) d\alpha d\beta$$

A more convenient treatment of this model is also to substitute the Everett plane for Preisach's one as shown in (12).

$$E(\alpha, \beta) = \iint_{\alpha\beta} \mu(\alpha, \beta) \gamma_{\alpha\beta}(H(t)) d\alpha d\beta \quad (12)$$

In the Everett plane, the distributions of M , which is accepted from experimental data of material S40 and ferrite magnet, are Gaussian ones.

III. ALGORITHM OF COMPUTING

Fig. 3 shows the block diagram of whole analysis mechanism.

The field-oriented control algorithm with PWM fed inverter is applied to the proposed analysis model for the example of dynamic characteristics and magnet characteristic due to PWM input source, as shown in Fig. 3.

Through the more detailed analysis, the variable performance of the pole changing memory motor will be represented in next extended version.

Abstract— this paper describes thermal analysis of eddy currents phenomena in a switchgear partition wall and determination of input parameters of numerical FEM model with particle swarm optimization (PSO) algorithm. The main intension of presented procedure is to fully calibrate numerical model, respectively calculate all necessary input parameters for analysis of eddy currents and thermal analysis. The goal of the optimization procedure is to achieve even better agreement between results of the numerical analysis and measured results (with thermovision camera). Numerical analysis presents a coupled problem of eddy currents phenomena through a thermal field observation. Both analyses are based on finite element method.

I. INTRODUCTION TO THE NUMERICAL MODEL

Partition wall is located between two medium voltage switchgear cells, where conductors (bus bars) go through. Partition wall consists of a metal plate and three bushing elements that go through it (model is shown in Fig. 3, which presents results). Beside insulation, the bushing elements contain cylindrical brass mesh (brass is any alloy of copper and zinc). Conductive areas, such as cylindrical brass meshes and metal plate, have an affinity towards eddy currents occurrence that cause Joule losses and affect temperature increase.

Constants that present some material properties (for example, conductivity, permeability, heat transfer coefficient) are obtained from tables and are given under certain boundaries. For the exact calculation of the temperature values it is necessary to calibrate the numerical model. The calibration is carried out with an optimization algorithm, which estimates the correct input parameters of numerical model for the thermal calculation.

Since the calculation is based on finite element method, it is crucial to define a proper numerical model. The numerical model consists of two components. First component considers eddy current density and magnetic field [1], meanwhile the other one takes into consideration thermal properties [2]. Finite element method is separately applied to eddy currents and thermal analysis, which means that the model is coupled [3].

Eddy currents are not uniformly distributed since the origin of the phenomena is based on proximity effect. Due to

the non-uniform eddy currents distribution, a numerical postprocessor is designed to calculate the average eddy current density value in each finite element, which belongs to the metal plate or cylindrical meshes. Joule losses are obtained from previous calculations, and are applied further on in the second part of the process (thermal analysis) [4].

II. DETERMINATION OF FEM MODEL PARAMETERS WITH PARTICLE SWARM OPTIMIZATION ALGORITHM

The complete procedure of calibration of the numerical model with measured parameter values is based on particle swarm optimization (PSO) algorithm [5]. Detailed analysis of the process is shown as a pseudo-code in Fig. 1. Numerical calculations evolve inside the optimization algorithm and compose the objective function. The objective function f_t of the optimization algorithm is a sum of square differences (Euclidian norm) between calculated and measured temperature values in different points of interest:

$$f_t = \mathbf{e}_t^T \mathbf{e}_t, \quad (1)$$

where the difference \mathbf{e}_t in n points between measured and calculated results is given by

$$\mathbf{e}_t = \mathbf{t}_m - \mathbf{t}_c \quad [n \times 1] \quad (2)$$

Temperature field distribution was firstly calculated by using initial parameters presented in Table 1.

TABLE I
Initial FEM model parameters

Parameter	index	value
Conductivity of metal partition wall	σ	$6 \cdot 10^6$ S/m
permeability	μ	300
heat transfer coefficient (in air)	h_a	0.024 W/(m ² K)
heat transfer coefficient (in metal partition wall)	h_{pv}	64 W/(m ² K)
heat transfer coefficient (in cylindrical brass mesh)	h_m	80 W/(m ² K)

The complete numerical model is built with two parametric preprocessors, numerical postprocessor and a graphic postprocessor. The preprocessors are written in Matlab and FEM calculations are carried out with EleFAnT3D

solver [6]. The numerical model consists of 45,100 finite elements, which are 20-nodal isoparametric hexahedrals.

III. RESULTS

This digest describes results of the numerical analysis. Fully described results will be presented in the full paper.

Eddy currents are caused when a moving or changing magnetic field intersects conductive areas, or when conductive areas move throughout magnetic field. The relative motion causes a circulating flow of particles or current. These circulating eddies of current create electromagnets with magnetic fields that is opposite to the main magnetic field. The stronger the applied magnetic field, or greater the electrical conductivity of the conductor, or greater the relative velocity of motion, the greater the currents developed and the greater the opposite field is.

Eddy currents indirectly affect warming of medium voltage cell. They occur in metal plate and cylindrical brass meshes, because of the proximity of source conductors, which are placed in the middle of the bushing elements and carry 630 A of effective current. Depending on conductivities and permeabilities of the metal plate and cylindrical meshes, eddy current density varies. The whole physical process could be explained with proximity effect. The source conductors generate time-harmonic magnetic field, which is assessed with Biot-Savart law. Variable magnetic field has an amount of influence on conductive materials. According to Faraday's Law time-harmonic magnetic field that crosses materials induces voltage and consequently the current. The closer the source conductors are, the greater is the influence on the rest of the conductive materials. Effective current value of conductors is the second significant parameter that determines magnetic field impact on the conductive areas located near the source (bus bars). Values of eddy current density calculated on axis that go through all three conductors are shown on Fig. 2a.

Power losses in every finite element are a direct input in the numerical preprocessor for thermal analysis. Distribution (histogram) of the power losses magnitudes inside the finite element model is shown in figure 2b.

Fig. 2. a) Distribution of the eddy currents effective values in the metal plate, b) Histogram of the average power loss values in finite elements.

Temperature distribution, which occurs because of the eddy currents, is shown in Fig. 3. For the fully presented problem, it is important to take into consideration effective conductors' current of 630 A, which contributes to the total temperature increase. The temperature increases in the metal plate for 0.3 °C extra.

Fig. 3. Temperature of the metal partition wall as a consequence of eddy currents.

IV. CONCLUSION

The aim of this research is to improve parameters of the numerical thermal model. Numerical model is calibrated when calculated and measured results achieve good agreement. Determined parameters (conductivity, permeability, heat transfer coefficients) can be used in further analysis and other calculations for medium voltage cell.

Abstract— This paper presents the field computation and the operating characteristics of a series-connected self-excited synchronous generator. Modeling for time-stepping coupled field–circuit analysis is explained. The proposed method is vigorously tested on a three-phase, 1.8-kW induction generator for various operating conditions. The computed results obtained by the FEA are found to be in good agreement with experimental results.

I. INTRODUCTION

Series-connected self-excited synchronous generator (SCSESG) is a wound-rotor induction machine in which the stator and rotor windings are connected in series, the phase sequences of the stator being opposite to that of the rotor. When driven by an external prime mover and a suitable capacitance is connected across the stator terminals, the machine will self-excite and deliver electrical power at a frequency equal to half of the rotor angular frequency. Steady-state and transient D-Q theory have been used for analyzing the performance [1]–[3]. Performance of this type of machine based on field analysis, however, has not been attempted before. In this paper, we briefly address the field computation aspects with reference to the SCSESG and then, we present a comparison between the experimental results and the computed results based on FEA in order to verify the feasibility of the proposed approach.

II. COMPUTATION METHOD

In order to simulate the operating conditions of this generator the computation method presents the following features:

- Due to the existence of magnetic circuits with saturated magnetic materials a nonlinear FEA was adopted.
- The anti-periodic boundary condition was applied to the field analysis to decrease computation time.
- Time-stepping FEM was employed in order to correctly evaluate the transient characteristic of the generator's voltage and current changes due to its rotation.

A. Governing Equations

The governing system of equations for 2-D FEA is derived from the Maxwell equations

$$\nabla \times (\mathbf{v} \nabla \times \mathbf{A}) - \nabla \mathbf{v}_e \nabla \cdot \mathbf{A} = -\sigma \frac{\partial \mathbf{A}}{\partial t} - \sigma \nabla V \quad (1)$$

where \mathbf{A} is the magnetic vector potential, \mathbf{v} is the reluctivity tensor, σ is the conductivity tensor, and \mathbf{v}_e is defined as one third of the trace of reluctivity tensor. In the analysis, the winding is assumed to be composed of stranded coils, each

having many fine turns in series and with eddy current effect ignored. For a stranded coil, (1) becomes:

$$\nabla \times (\mathbf{v} \nabla \times \mathbf{A}) - \nabla \mathbf{v}_e \nabla \cdot \mathbf{A} = \mathbf{J} \quad (2)$$

with the current density given by

$$\mathbf{J} = i_n \frac{n}{s} i(t) \mathbf{z} \quad (3)$$

where S_c is the coil cross sectional area, n is the number of turns and $i(t)$ is the current per turn. i_n is a unit to stand for the coil current in the z (axial) direction.

B. Field Coupling to External Circuit with Periodic Boundary Condition

Modeling of the external electric circuit was achieved by using the connectivity patterns between various circuit elements such as resistors, capacitor and inductors. Such elements consist of nodes having voltage potential DOF (degree of freedom). The stranded coil nodes possess magnetic potential A_z , EMF and current DOFs in field region. The stranded coil represents a current source in the circuit loop, and it has three nodes. Two nodes carry the voltage potential DOF and these are used for connection with other circuit elements; the third node is any node in the field region for the stranded coil, and so this node carries current and EMF information. Since anti-periodic boundary condition is applied to the field region, the current source for the conductor regions in the remaining $\frac{3}{4}$ of the machine cross-section can be coupled to the modeling conductors' nodes directly.

Fig. 1. Computed flux line distribution at a rotor position of 60 electrical degrees under no load condition ($C=120 \mu\text{F}$, speed = 1143 rpm)

C. Initial Conditions for Field Computation

Modeling of the residual flux in the FEA computation presents some difficulties as the residual flux cannot be easily incorporated into the material properties in the machine model. To overcome this problem the initial current is specified instead. Computations showed that the initial current DOF value for the conductor region is important for successful simulation of voltage build up. It was found that the residual current magnitude should be about 1 A and its electrical angle should be approximately the phase difference between the stator and rotor current vector directions.

III. RESULTS

A. Field Computation Results

The stator end-winding leakage inductance L_{es} of the prototype SCSESG is 0.154mH, and the rotor end-winding leakage inductance L_{er} is 0.025mH, determined using an analytical method [4].

Fig. 1 shows the computed no-load flux line distribution for a rotor position of 60 electrical degrees when $C=120 \mu\text{F}$ and the rotor speed is 1143 rpm. Fig. 2 shows the computed radial flux density distribution for the same rotor position when the generator is under no load and when supplying a resistance load of 131.7Ω per phase. It can be seen that the air gap flux density decreases when the generator is loaded.

Fig. 2. Computed radial flux density distribution at a rotor position of 60 electrical degrees under no load and loaded conditions ($C=120 \mu\text{F}$, speed = 1143 rpm)

B. Performance Characteristics

The experimental slip-ring induction machine has the following ratings: 1.8 kW, 380/220V, Y/ Δ , four-pole 50Hz. TABLE I shows the number of unknowns and total computation time for a computation task. The computed and measured no load voltage versus speed is given in Fig. 3 when the excitation capacitance is $120 \mu\text{F}$, $200 \mu\text{F}$ and $280 \mu\text{F}$. It can be observed that the voltage increases with generator speed, and higher voltages are produced by a larger capacitance. For a given capacitance, the SCSESG cannot maintain the excitation below a certain cutoff speed. The load characteristic of the SCSESG is shown in Fig. 4. A fair agreement between computed and experimental results is observed.

Fig. 3. Variation of no-load voltage of SCSESG with speed with different excitation capacitances

TABLE I
COMPUTATIONAL COST PER ANALYSIS

Abstract — The use of finite element analysis (FEA) to design electrical motors increased significantly last years due the better performance of modern computers. Even though the analytical software remains the most used tool, the FEA is widely used to refine the analysis and gives the final design to be prototyped. The power factor, a standard data of motor manufactures data sheet is important because it shows how much reactive power is consumed by the motor. This data became important when the motor is connected to network. However, the calculation of power factor is not an easy task. Due the saturation phenomena the input motor current has a high level of harmonics that cannot be neglected. In this work the FEA is used to evaluate the power factor of a small single-phase induction motor.

I. INTRODUCTION

The analytical methodology remains as the most important daily work tool of motor designers at industry. The use of analytical tools is important to reduce calculation time especially during optimization. However some important phenomena cannot be evaluated in these methodology and then numerical methods are used. The use of finite element analysis is very important because it provides detailed simulation and it is more accurate regarding saturation and field distribution. Even though demanding more calculation time the use of FEA to simulate electromagnetic devices increased significantly last years due the better performance of modern computers. The literature is full of valuable works that finite element analysis to evaluate the performance of electrical motors [2][3]. Some of these works use software developed at academy and others use the available commercial software. No matter the software used the understanding of basic phenomena are required to make a good work. If motor designers do not know very well the theory of electrical motor they cannot evaluate correctly the results and may take wrong decisions.

Induction motors consume alternative power and then consume both real power (P) and reactive power (Q). The vector sum of real and reactive power is the apparent power (S). The power factor of an electric motor is defined as the ratio of its real power P in Watts to the apparent power S in VA. The presence of reactive power causes the real power (or useful power) to be less than apparent power, consequently induction motors have power factor less than 1. Motors with low power factor are undesirable load in the network [1]. Even though the power factor of an induction motor can be easily obtained by tests, this is not true for simulations carried by the finite element method because it is not obtained directly at the end of calculation. The level of saturation can also

distort the current curve and leads to false values of power factor.

In this work the finite element method is used to evaluate the performance of a small industrial capacitor run, single-phase induction motor. A method to extract the input power of a motor calculated from post-treatment of a finite element model, including consideration of saturation and harmonics, is proposed hereafter. The power factor is then deducted and calculated, but might be considered as an indicative value due observed distortion.

Results of simulation are compared to experimental ones and the problem of power factor calculation discussed is. The analysis presented in this paper may be not new for skilled engineers that are used to run the finite element method in motor design. However, it is useful for the fresh ones that look for information normally not available in the literature.

II. POWER FACTOR ANALYSIS

To analyze the problem of calculation of power factor by the finite element method the single-phase run capacitor motor of 100W, 60 Hz, 2 poles of Fig.1 is used. The coupled electric circuit is shown in Fig.2.

Fig.1. Design of analyzed single-phase motor

The basic theory of single-phase induction motor shows that, the mean input power P_{IN} of a run capacitor single-phase induction motor can be obtained by the equation (1). The V_{source} , I_{main} , I_{aux} are the applied voltage, the current of main winding and the current of auxiliary winding, taken in one period of the time T respectively. The time T of calculation corresponds to one cycle (1/f) of input power where f is the frequency of applied voltage.

Fig. 2. Coupled electric circuit

$$P_{IN} = \frac{1}{T} \int_t^{t+T} (V_{source} \times (I_{main} + I_{aux})) dt \quad (1)$$

It is known that the input power of induction motors has several harmonics and they are more pronounced in saturated motors where the input current is strongly distorted as shown in Fig. 3. The high level of harmonics in the total current affects the correct calculation of power factor.

Fig. 3. Curves of V_{source} and I_{total} at steady state

In the finite element method two ways are normally used to calculate the power factor $\cos\phi$. The first way is the direct one where the values of V_{source} and I_{total} ($I_{main} + I_{aux}$) are taken at each time of one analyzed cycle at steady state. This methodology requires a calculation with a very small time step. The time where the V_{source} and I_{total} became positive (or negative) is taken. The difference between them gives the angle of displacement and consequently the value of power factor $\cos\phi$. Even though this academic method is easy and fast it may be avoided in analysis of saturated motors because the current curves are distorted. Additionally, as the time step increases the real time where the curves change the direction is lost as shown in Table I. This easy method is useful only in non-saturated motors and simulated with a very small time step ($\Delta t < T/180$).

TABLE I
POWER FACTOR FOR DIFFERENT TIME STEP CALCULATION

Time step (ms)	Cos ϕ
0.092	1
0.185	1.
0.277	0.994

The second way to calculate the power factor is by the use of equation (2). In this equation the power factor is deduced from the input power mean value P_{IN} and the rms total current and rms V_{source} . To have the input mean value P_{IN} at first we calculate the $P_{IN}(t)$ by use of equation (3). Here the V_{source} , I_{main} and I_{aux} versus time are exported from Flux2D. Next, the main value of P_{IN} is obtained directly at Flux2D with $Mean_{value}(P_{IN}(t)) = P_{IN}$.

As shown in Fig. 3 the harmonic content of total current is high. From a Fourier point of view, the result obtained with equation (2) is not correct because P_{IN} it is not limited to first harmonic. The value of power factor is then only an approximated value.

$$\cos\phi = \frac{P_{IN}}{V_{SOURCE} \text{eff} \times (I_{main} + I_{aux}) \text{eff}} \quad (2)$$

$$P_{IN}(t) = V_{source}(t) \times (I_{main}(t) + I_{aux}(t)) \quad (3)$$

As the power factor is only an approximated value the motor efficiency is calculated directly with equation (4). The output power is deduced from the shaft torque mean value T_N (N.m) and speed mean value ω_R (rad/s), that is $P_{OUT} = \omega_R \times T_N$.

$$\text{eff} = \frac{P_{OUT}}{P_{IN}} \quad (4)$$

In the full paper results of simulations with a capacitor run single-phase motor will be presented. The complete analysis will show the power factor value obtained by the different methods discussed above. The final paper will also discuss more deeply the effect of time step in power factor calculation and compare the calculated and measured motor efficiency.

Abstract—The vibrations of electric motors are mainly determined radial force excitation and stiffness of stator and frame. Stator shapes have a large influence on vibration performance. In this paper four different stator shapes were analyzed by using transient magnetic and thermal analysis and it was found that the “V” shape has the best thermal effect. Modal analysis was carried out on precise mechanical models of prototype motor in three dimensional finite element method (3D FEM) software to study the structure borne transfer function.

the motor to environment, whereas the square shape has the worst one.

I. INTRODUCTION

The switched reluctance motor (SRM) has raised significant interest among the industry for several reasons, including a mechanically and thermally robust rotor, simple stator windings and ease of manufacture. The study of acoustic noise in SRM has attracted much attention due to the ever-increasing consciousness of environmental noise pollution.

II. STUDY ON STATOR SHAPES

Based on the same inner structure of stator (inner side stator yoke diameter, pole and winding) and utilization of lamination, four shapes as proposed in [1] were used to design stators. The stator outer diameter is largest diameter of stator in ‘V’ ‘T’ shape model and the side in square shape. Modal analysis was also carried out. Comparing the modal frequency and modal shape, same conclusion could be obtained as [1], so it is skipped here. Dynamic finite element analysis of the motors with different stator shapes were carried out. The flux density distributions are shown in Fig. 1. With the same turn on angle 1°, turn off angle 16° and rotating speed 3600rpm, the square shape and ‘V’ shape model have a lower efficiency whereas ‘T’ shape has highest efficiency.

For a simple comparison of thermal effect of stators, a transient thermal analysis was carried out. During simulation, the environmental temperature and initial stator temperature was assigned to be 22°C. At t=0, the inside surface was assigned with a temperature of 80°C and the temperature of outside surface was checked after 5s. The temperature distributions are shown in Fig. 2. Performances were summarized in Table II. Comparing the heat exchange rate of four models, it could be concluded that ‘V’ shape stator has the best thermal effect which dissipate the heat generated in

Fig. 1. Flux density distribution of different stators: (a) circle shape; (b) ‘T’ shape; (c) ‘V’ shape; (d) square shape.

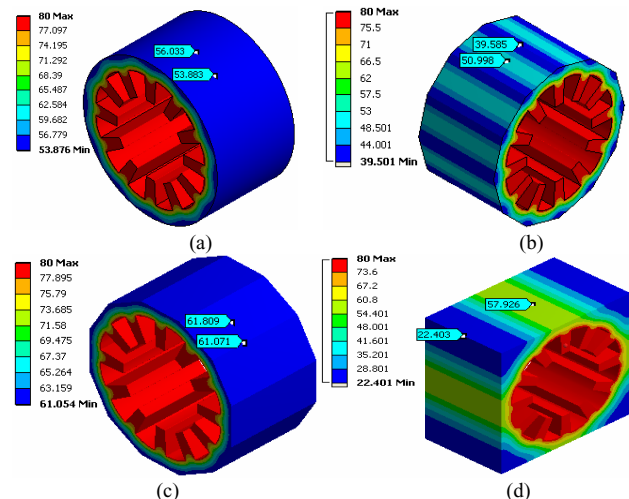

Fig. 2. Temperature distribution of different stators: (a) circle; (b) ‘T’; (c) ‘V’; (d) square shape.

TABLE II
MOTOR'S PERFORMANCE ACCORDING TO STATOR SHAPE

Stator shape	Circle	'T'	'V'	Square
RMS current (A)	6.16	6.30	6.24	6.18
Copper loss (W)	141.4	143.2	140.2	137.4
Iron loss (W)	166	163	170	178
Power (W)	1748	1763	1733	1763
Efficiency	85.0%	85.2%	84.8%	84.8%

III. MODAL ANALYSIS OF FRAMES

A modal analysis, or a free vibration analysis, is performed to obtain the natural frequencies and mode shapes of a structure. For a modal analysis, the natural circular frequencies ω_i and mode shapes ϕ_i are obtained from the matrix equation:

$$([\mathbf{K}] - \omega_i^2 [\mathbf{M}])\{\phi\} = \{0\} \tag{1}$$

where the structure stiffness matrix $[\mathbf{K}]$ and the inertia matrix $[\mathbf{M}]$ are formed from elementary stiffness inertia matrix stiffness inertia matrix, respectively [6]. Equation (8) has a nontrivial solution when the determinant of the coefficients vanishes, i.e.

$$\det([\mathbf{K}] - \omega_i^2 [\mathbf{M}]) = 0 \tag{2}$$

The polynomial equation has n eigenvalues, which corresponds to n natural frequencies.

After the stator core was studied, five frames with different structure and material to study the structure borne transfer function. The five models with same stator are shown in Fig. 3. The traditional circle shape stator is still used since the emphasis is frame in this part. Model I has an axial ribbed aluminum frame with 2.5mm thickness. In Model II, the thickness of frame increases to 5 mm. Model III has the same shape with Model II but uses gray iron cast. Model IV has a radial ribbed aluminum frame, 5 mm thickness. The material of frame in Model V is changed to structural steel and there are no ribs on frame because manufacture of ribbed steel frame is a big problem. The end bells in these models are made of aluminum and have the same dimensions. The in-plane flexural modes play important roles in electromagnetic vibrations while the bending, tensional, and out-of-plane flexural modes contribute to vibrations under unbalanced or fault situations [2], so only the in-plane flexural mode shapes are presented graphically in Fig. 4(a)-(e), which shows the 2nd mode shapes and their associated frequencies.

IV. CONCLUSION

This paper investigated the influence of stator shapes and frames to motor's performance. Modal analysis of stator shapes was described in literature, electromagnetic and thermal analysis of stator shapes are the new contribution of this paper. Comprehensive study of frames with different shapes and materials using modal analysis is firstly proposed in this paper. Since the paragraph limitation, more results and experimental verification will be reported in full paper.

 laplace_sun@hotmail.com, hongjp@hanyang.ac.kr

Abstract — This paper studies the influence of permanent magnet (PM) on the total motor system efficiency. Two PM synchronous motors with Nd-Fe-B and ferrite magnets which have the same Back electromotive force and output power have been designed. An indirect coupled field-circuit analysis is used in this paper to calculate motor losses and inverter losses. First, the electric circuit domain simulation is performed with the parameters of the semiconductor devices and these two motors. The current waveforms, copper losses and inverter losses can be evaluated in this process. And then, by means of the current waveforms, numerical methods and Epstein Frame, the iron losses of these two motors will be calculated. Finally, the sum of the inverter losses, copper losses and iron losses can be used to reflect the influence of the magnet on the total system efficiency. The analysis results will be verified by the experiment to show the validation of this analysis method.

I. INTRODUCTION

Ferrite magnet has been widely used in permanent magnet synchronous motors (PMSM) for a few decades. Recently, due to the superior remanent flux density and coercively force, the Nd-Fe-B magnet is gradually replacing the application of ferrite magnet. By using Nd-Fe-B magnet, the high efficiency and size reduction can be easily achieved. Considering the cost difference between the Ferrite magnet and Nd-Fe-B magnet, however, it is necessary to investigate the influence of magnet on the total motor system performance. As the same back electromotive force (Back-EMF) and output power, the motor with ferrite magnet may have higher inductance and resistance than the motor with the Nd-Fe-B magnet because of its larger number of winding turns and dimension. The different inductance and resistance may lead to the different time constant, which seriously affects the switching efficiency of the motor drive and current waveforms. Furthermore, the different current waveforms will produce different copper losses and iron losses in motors.

In order to solve this coupled field-circuit problem, [1]-[3] proposed several methods. These methods can be classified into direct coupled field-circuit method and indirect coupled field-circuit method. In the direct coupled field-circuit method, the field governing equations are combined with the circuit state space equations, and solved simultaneously [1]. To obtain the accurate current waveforms, the computation step of this method should be small enough. Although [3] proposed a computation step optimization method, the convergence of each step still is in both field and circuit equations. The indirect coupled field-circuit method solved the time consuming problem of the direct coupled

field-circuit method [2]. In the circuit domain calculation, the steady state could be achieved more quickly. Therefore, it does not need to spend much time into the transient process.

Based on the mentioned above, an indirect coupled field-circuit method is used to evaluate the motor and inverter losses in this paper. Two PMSMs have been designed with the same Back-EMF and output power using the ferrite magnet and Nd-Fe-B magnet, respectively. First, the parameters of these two motors including magnet flux linkage, phase resistance and nonlinear inductance profiles are calculated by the magneto-static field finite element method (FEM). Then, using the parameters of the inverter and motors, the losses of the switching devices, current waveforms, and the copper losses of motors are calculated by an electric circuit domain simulation program considering pulse width modulated (PWM) current regulation. Next, a magneto-static FE model is computed with the current waveforms obtained from the circuit domain simulation. The obtained flux densities of all elements are decoupled into the temporal and spatial components by the Discrete Fourier transforms (DFT), and used to index the iron losses with the Epstein frame. Finally, the iron losses of motor can be calculated by summing the losses of all elements in the all harmonics. An experiment will be done to verify the validation of this method. The analysis results will give more suggestions to the application of ferrite and Nd-Fe-B magnets.

II. MODELING IN CIRCUIT DOMAIN

A. Modeling of PMSM

According to the Park's transformation, the state space equations of the PMSM can be described as (1)-(3). And the corresponding d- and q-axis equivalent circuits are shown in Fig. 1 (a) and (b), respectively. [4]

$$\begin{bmatrix} v_d \\ v_q \end{bmatrix} = R_a \begin{bmatrix} i_{od} \\ i_{oq} \end{bmatrix} + \left(1 + \frac{R_a}{R_c}\right) \begin{bmatrix} v_{od} \\ v_{oq} \end{bmatrix} + P \begin{bmatrix} L_d & 0 \\ 0 & L_q \end{bmatrix} \begin{bmatrix} i_{od} \\ i_{oq} \end{bmatrix} \quad (1)$$

$$\begin{bmatrix} v_{od} \\ v_{oq} \end{bmatrix} = \begin{bmatrix} 0 & -\omega L_q \\ \omega L_d & 0 \end{bmatrix} \begin{bmatrix} i_{od} \\ i_{oq} \end{bmatrix} + \begin{bmatrix} 0 \\ \omega \psi_a \end{bmatrix} \quad (2)$$

$$T = P_n \left[\psi_a i_{od} + (L_d - L_q) i_{od} i_{oq} \right] \quad (3)$$

The parameters required in PMSM state space equations could be calculated in the numerical methods which have been introduced in [4].

Fig. 1. Equivalent circuits of PMSM: (a) d-axis equivalent circuit, (b) q-axis equivalent circuit

B. Modeling of Inverter

The voltage source inverter is modeled by using of the switch function concept which is introduced in [5]. As the transistors switching-on or switching-off, four kinds of losses are produced [6]. They are current flowing losses and switching losses in transistors and freewheeling diodes, respectively. The calculation equations of these four losses are shown in (4)-(7).

$$P_{IO} = I_{MP} V_{CES} \left(\frac{1}{8} + \frac{M}{3\pi} \cos \theta \right) \quad (4)$$

$$P_{DO} = I_{MP} V_F \left(\frac{1}{8} - \frac{M}{3\pi} \cos \theta \right) \quad (5)$$

$$P_{IS} = (E_{on} + E_{off}) f_{sw} \frac{1}{\pi} \quad (6)$$

$$P_{DS} = \frac{1}{4} f_{sw} Q_{rr} V_{DC} \quad (7)$$

where all variables will be explained in the extended paper.

III. MODELING IN MAGNETIC FIELD DOMAIN

A. Magneto-static Field FEM

The 2D magneto-static field FEM is used to calculate the magnetic field distribution with the known current waveforms and time steps. Its governing equation, i.e. the nonlinear Poisson equation, is described in (8).

$$\nabla \times \nu (\nabla \times \mathbf{A}) = \mathbf{J} + \nabla \times (\nu \mu_0 \mathbf{M}) \quad (8)$$

where all variable will be explained in the extended paper.

B. Iron Losses Calculation

The iron losses calculation is consisted of three processes, which is simplified in Fig. 2. The detail introduction of this method is presented in [4].

IV. ANALYSIS MODEL AND RESULTS

Two PMSMs with ferrite and Nd-Fe-B magnets have been designed to have the same Back-EMF and output power. Their d- and q-axis inductances are shown in Fig. 3 (a) and (b), respectively. Additionally, at 25°C the motor with ferrite magnet has 1.16Ω phase resistance and 32.13V_{rms}/krpm line-to-line Back-EMF, while the motor with Nd-Fe-B magnet has 1.09Ω phase resistance and 30.475V_{rms}/krpm line-to-line Back-EMF.

The circuit domain calculation has been processed to both motors. And the current waveforms at 2000rpm and 0.35Nm operation condition are shown in Fig. 4. It is obvious that the current of the motor with Nd-Fe-B magnet is regulated more frequently, while the current of the other motor has more sm-

Minimizing Torque Ripple of a BLDC Motor by Offsetting Cogging Torque with Voltage Control

Jin-seok Jang and Byung-taek Kim
 Dept. of Electrical Eng., Kunsan National University
 San68, Myrongsong, 573-701, Korea
 sadimy@kunsan.ac.kr

Abstract — This paper deals with reduction of torque ripple in a brushless DC motor with input voltage control. The commutation torque ripple can be controlled with varying input voltage, although cogging torque is independent on it. So, in this paper a strategy for minimizing torque ripple is proposed by offsetting the cogging torque with deliberate voltage control. The optimal condition is determined with various voltage levels and lead angles. As results, it is shown that the method causes 71% decrease of torque ripple.

I. INTRODUCTION

Torque ripple of a brushless DC (BLDC) motor consists of one produced by a voltage commutation and the other due to magnetic cogging. Numerous studies have been proposed for reduction of the torque ripple [1]~[3]. Of these studies, a method reducing the ripple by a various voltage instead of DC voltage was presented [3]. It focused on eliminating the current ripple, however, strangely the method was not applied to a BLDC motor but to a sinusoidal wave motor, so it was not possible to look into the effect of cogging torque ripple.

In this paper, reduction of a net ripple including cogging torque is focused. Since a cogging torque is inherent and unavoidable, we propose a method offsetting it with an input voltage control. For a given BLDC motor, equations to achieve a certain commutation ripple are analytically induced, and cogging torque is obtained with FE-analysis. With variance of voltage lead angle and commutation ripple, the net torque ripples are calculated in order to find the best voltage condition.

II. PROPOSED METHOD FOR TORQUE RIPPLE MINIMIZATION

A. Components of Torque Ripple in a BLDC motor

A 3-phase, concentrated wounded, surface PM BLDC motor is shown in Fig. 1. When it is driven with a DC voltage, the phase currents are obtained by using circuit analysis as shown in Fig. 2. The phase currents produce a commutation torque through interaction with a back EMF as given by

$$T_{com} = \frac{I_a E_a + I_b E_b + I_c E_c}{\omega_m} \quad (1)$$

, where ω_m is mechanical angular velocity and E is back-EMF. Using (1) the commutation torque can be calculated as shown in Fig. 2. Both Fig. 1 and Fig. 2 show that the commutation torque ripple is due to current ripples and it is deeply related with falling time t_f of each phase current.

Fig.1. Circuit of BLDC motor

Fig. 2. Current, voltage and back-EMF waveforms

Fig. 3. Commutation torque (equivalent circuit analysis)

The actual net torque is obtained through FE-analysis as shown in Fig. 4. Since it includes both commutation and cogging torque ripples simultaneously, only a cogging torque is again analyzed by using FEM as shown in Fig. 4. The commutation torque is obtained by subtracting cogging torque from a net torque and represented in Fig. 5. It shows that the simulation results in Fig. 3 are very similar to the actual commutation ripples therefore, the analytic approach is valid.

Fig. 4. Magnetic flux lines in BLDC motor (FE-analysis)

Fig. 5. Torque waveforms (FE-analysis)

Fig. 6. Commutation torque (FE-analysis)

B. Cogging Torque Offset with Commutation Ripple

The commutation ripples in current and torque can be controlled by adjusting the input voltage V_1 and V_2 as shown in Fig. 7. Especially the falling time of a phase current t_f is expressed in terms of V_1 and V_2 , given by

$$t_f = \frac{(1 - 2e^{-\tau t_0/2})V_1 + \frac{3}{2}V_2 - E(1 - 2e^{-\tau t_0/2})}{(1 - 2e^{-\tau t_0/2})V_1 + \frac{3}{2}e^{-\tau t_0/2}V_2 + E(2 - e^{-\tau t_0/2})} \quad (2)$$

, where τ is the time constant of a circuit, that is R/L

Fig. 7. Waveforms in voltage control

As previously shown in Fig. 2 and Fig. 3, the falling time t_f of each phase fairly affects the torque ripple. Therefore, the V_1 and V_2 are obtained by using (2) for various t_f , and the commutation torques are calculated and depicted in Fig. 8. It shows that comparing with the cogging torque, the magnitude of commutation ripple changes so abruptly that it is very difficult to offset the cogging torque. Thus we select a lead angle of voltage as well as a falling time t_f for control variables. From -30° to 30° for lead angle, the magnitudes of ripple in net torque are calculated according to variation of falling time, and the calculated results are plotted in Fig. 9. It shows that the best lead angle is 9.5° at which V_1 and V_2 are

respectively 434.2[V] and 170.4[V]. The net torque produced by the determined voltage conditions is shown in Fig. 10 which is reduced by 71% of that of a conventional DC input voltage.

Abstract— This paper describes the development of a novel transverse flux linear motor (TFLM) excited by permanent magnets. It produces high thrust force with reduced normal force by combining the advantages of two different kinds of TFLMs. Magnetic field is analyzed by combining three-dimensional equivalent magnetic circuit network (EMCN) method with two-dimensional finite element analysis. The experimental results of prototyped motors are in good agreements with the analysis ones, and show the possibility of the new suggested motor as a direct drive requiring relatively long displacement of a mover.

I. INTRODUCTION

In direct drive applications, the main issue is to increase the force and power density of the machine by improving constructional design of stator and mover constituents. This normally requires careful considerations in the designing of the magnetic topologies, which promotes significant weight reduction in the magnetic mass as well as improvement in the form factor of the magnetic design [1]. A number of novel forms of permanent magnet machines have been developed for such applications and transverse flux machines are considered as one of the candidates to achieve the highest force densities among them, especially at a low speed. In this research, two different kinds of TFLMs with PM excitation are compared, and a novel transverse flux machine is suggested by combining the advantage of the two structures.

Fig. 1 shows the one phase of two different kinds of TFLM with PM excitation [2]. In each mover, the permanent magnets are fitted between the iron cores and magnetized with alternating polarity facing to each other. These arrangements produce a high air gap flux density in the air gap region compared to other permanent magnet motor types. The ends of the mover are skewed by one pole pitch each other, and form the path for three-dimensional flux flow with the adjacent teeth of the stator. With these features, it can produce unidirectional thrust force at the entire region by reversing the polarity of the applied current. The major differences between models are the positions of the armature windings and the presence of normal force. The first model has armature windings in the stator and the mover is inserted between the poles of the stator. In this case, normal force does not exist and lateral forces existing in the two air gaps between the teeth of stator and mover are cancelled out each other. However, some applications require long stroke of mover, and it is not practical to mount armature windings in the long stator considering the effective utilization

Fig. 1. Conventional design of TFLMs (a) I-shaped mover core type (b) U-shaped mover core type

of windings and significant loss of flux linkage. The second model has U-shaped mover cores and the armature windings are inserted into the poles of the mover. This feature seems to be suitable for the applications requiring relatively long displacement of the mover comparing I-shaped mover core type. However, this type of motor produces much bigger normal force than the thrust force. This can limit the use of it due to the friction loss caused by the normal force.

In the stocker system, which is used for transferring glasses in the LCD industry, there are great demands for linear direct drives to avoid drawbacks of traditional drives having rotary motor and mechanical motion conversion devices. In this application, the stator is installed up to 100 m and system requires thrust force of 10,000N. Thus, it is difficult to apply the I-shaped mover core type alone due to the leakage flux caused by long stator. Of course, U-shaped mover core type can be applied to this application, but it has also drawbacks of huge normal force.

Fig. 2 shows the conceptual development process of the new model and Fig. 3 shows the one phase of it. It is developed by combining the advantage of the previous two models; non-existent normal force of the I-shaped mover core type and effective coil arrangement of U-shaped mover core type. Basically, it can produce two times higher thrust force than the U-shaped mover core type by jointing it in parallel way. However, the normal force is just increased by 50% comparing the U-shaped mover core type that can produce the same thrust force. This is due to the fact that the extruding pole arrangement of E-shaped core type at the both ends of the mover provides only thrust force, and the attractive forces between stator and mover are cancelled out each other. It can also reduce almost 50% of the copper for windings. This implies that winding losses of the suggested motor can be substantially decreased.

Fig. 2. Development process of new type TFLM

Fig. 3. Newly designed TFLM having E-shaped mover cores

II. ANALYSIS AND EXPERIMENT RESULTS OF TFLMS

Magnetic field is analyzed by three-dimensional equivalent magnetic circuit network (EMCN) method using a symmetry condition of flux distribution. Two-dimensional finite element analysis is also used to find the influence of the end effect of mover on the performance of TFLMs [2]. Fig. 5 shows the thrust and normal forces of TFLMs having U and E-shaped mover cores. For comparison, each value is corresponding to one-pole pair of each model when applying different magnitude of MMF. The E-shaped core type produces almost two times of the thrust force than the U-shaped core type at the all applied MMFs. But, in case of normal force, they have almost same peak levels due to the cancellation of attractive force between mover and stator at the both sides of mover in the E-shaped core type. The ratio of normal force to thrust force is decreasing with the increase of the applied MMF.

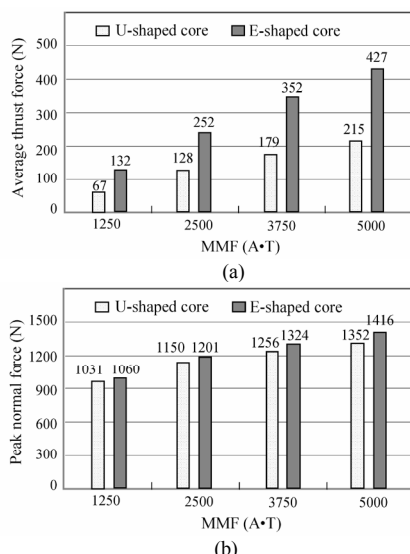

Fig. 4. Comparison of thrust and normal force (a) average thrust force (b) peak normal force

Fig. 5 and Fig. 6 show movers and stators of the U and E-shaped core type TFLM for static experiments, respectively. Fig. 7 shows the comparison of the thrust force profiles for different MMFs during the displacement of the mover between stable and unstable equilibrium positions. The averaged thrust forces are in good agreement with experimental ones. At 50% and 100% of the rated MMFs, experiment shows that the average thrust force of E-shaped core type is 2.12 and 2.15 times higher than that of U-shaped core type, respectively.

Design Strategy of Interior Permanent Magnet Synchronous Motor for Electric Power Steering Considering Cogging Torque and Torque Ripple using Current Harmonics

Soon-O Kwon¹, Jeong-Jong Lee¹, Tao Sun¹, Young-Kyun Kim², Geun-Ho Lee¹, and Jung-Pyo Hong¹

Abstract — This paper presents the design strategy of interior permanent magnet synchronous motor for electric power steering (EPS) considering cogging torque and torque ripple using current harmonics. For the EPS motor, cogging torque and torque ripple reduction are important design factors. In order to reduce cogging torque and torque ripple, optimal design methodology, such as response surface methodology (RSM) can be used and design parameters can be pole angle, slot opening, notch, etc. However, it is shown that optimal design satisfying cogging torque and torque ripple does not exist by response surface methodology in the presented design. In order to satisfy both cogging torque and torque ripple, design parameters minimizing cogging torque is determined by RSM and torque ripple is reduced by harmonic current. Therefore, minimization of both cogging torque and torque ripple can be achieved. Presented design strategy is verified by finite element analysis (FEA) and experiments.

I. INTRODUCTION

Interior permanent magnet synchronous motors have higher torque density per volume than induction motor and reluctance motor with wide operating speed range with the help of field weakening control. Therefore, it is widely applied from small power to large power such as traction motor for electric vehicles.

For the application of EPS, high power density, low torque ripple, and low cogging torque are required. To reduce cogging torque and torque ripple, various design topologies can be applied. Choice of fractional pole/slot combination or optimal geometry design etc. can be one of choice. Fractional pole/slot combination provides low cogging torque and torque ripple, however, unbalanced radial forces in air gap leads to high vibration and noise. For optimal shape design of magnetic circuit, even though computer system developed highly, huge computation time and efforts are required. Because many motor geometry parameters closely related to torque ripple and cogging torque. In addition, reduction of cogging torque and torque ripple simultaneously with shape optimization is difficult because minimum cogging torque design does not guarantee minimum torque ripple and vice versa. Therefore there should be compromise between cogging torque reduction and torque ripple reduction design. In addition, sometimes other motor characteristics should be sacrificed to satisfy cogging torque and torque ripple since both are the main constraints for comfortable driving.

On the other hand, output torque ripple can be reduced by control strategy [1, 2]. By applying appropriate current, torque ripple can be reduced. Therefore, both geometrical optimization to reduce cogging torque and current harmonic injection are used in this paper.

II. HARMONIC CURRENT ESTIMATION

The input current of synchronous motor is assumed to sinusoidal wave and correspondent output torque is produced by interaction between magnetic field by permanent magnet and armature reaction. Due to non-linear characteristics of magnetic material, output torque and torque ripple are not proportional to input current. Therefore, output torque waves for various inputs current are estimated FEA and instantaneous current which provides constant torque are calculated. Calculated current wave is composed of various harmonic components, represented by a set of function of input current and harmonic order. Therefore, in ideal case of high response speed of microprocessors, nearly 0% of torque ripple can be achieved. The results of harmonic current are firstly examined by FEA. The main process of estimation of harmonic currents is summarized as follow;

1. Calculation of output torque wave form by FEA for various sinusoidal input currents
2. Instantaneous current for required constant torque are calculated.
3. Harmonic analysis for instantaneous input current
4. Development of function of harmonic current

III. OPTIMAL DESIGN USING RSM

Table 1 shows the main specification of analysis model. The model has 10pole and 15slots with concentrated windings.

Fig. 1 shows the design variables for optimal design, and optimal design results. The IPMSM is chosen and 2 design variables of pole angle and rotor eccentricity are chosen. Like general IPMSM, permanent magnets are buried in the rotor core. To reduce cogging torque and torque ripple, notch and eccentricity are applied to stator teeth and rotor respectively. The model is optimized for cogging torque. Unlike general EPS motor, the developed motor has no skew for research purpose.

TABLE 1 BASIC INFORMATION OF DESIGN MODEL

Motor type	IPMSM
Phase number	3
Pole number	10
Slot number	15
Stator outer diameter (mm)	90
Stack length (mm)	40
Parallel circuit number	5

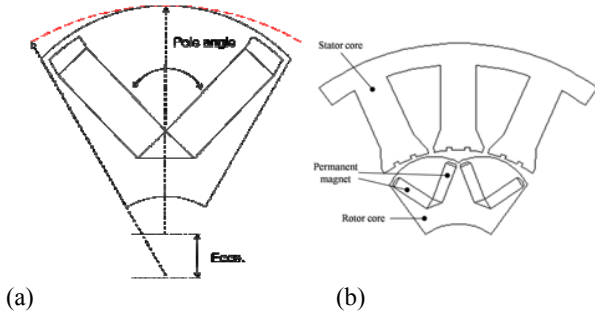

Fig. 1 (a) design variables, (b) optimal design result

Fig. 2 shows the effect of design variables on cogging torque and torque ripple. As shown in the figure, it is impossible with geometry design satisfying both cogging torque and torque ripple. The optimal value of pole angle and eccentricity are around 37 and 7mm respectively.

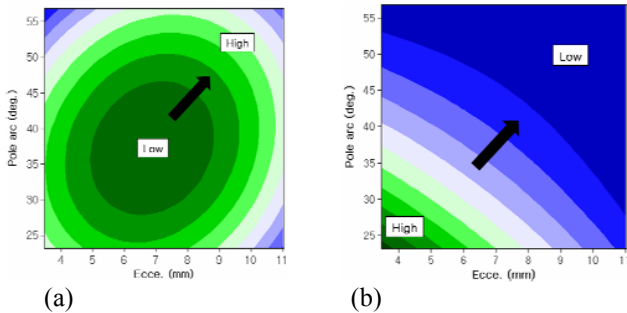

Fig. 2 Equi-plot of (a) cogging torque and (b) torque ripple.

Fig. 3 shows the output torque wave according to sinusoidal input current from 48 to 52Arms. In the figure, it is shown that the torque ripple varies with input current and rotor positions. In order to get constant torque, a straight line is drawn and current at each crossing point is estimated and overall current wave of one phase is shown in Fig. 3 (b). Unlike general current controlled synchronous motors, input current is distorted and contains large harmonic components and this is shown in Fig. 4 (a)

In Fig. 4 (b), comparison of output torque wave form between general current control and harmonic current injection is shown. In the figure, 8% of torque ripple is obtained with general current control and 0.7 % of torque ripple is obtained with harmonic current injection. The average torque is slightly reduced but the ratio is not significant and it is caused by calculation error of input current. It is expected that the current step in Fig. 3 is smaller, 0% of torque ripple can be achieved without decrease of average torque.

Fig. 5 shows the fabricated EPS motor. In the full paper, detailed design process and test results and verification will be included.

IV. CONCLUSION

This paper presented the design strategy of IPMSM for EPS to minimize both cogging torque and torque ripple. Cogging torque is minimized by optimal design of motor geometry and torque ripple is minimized by harmonic current. Presented design results are verified by experiments and could be effectively applied to the EPS motor design. In the full paper, motor control strategy, experimental verification, and other motor characteristics will be presented.

Abstract — Interior Permanent Magnet Synchronous Motor (IPMSM) produces two kind of torque that Magnetic and Reluctance torque. The permanent magnet linkage flux Ψ_a and d-axis and q-axis inductances have an important influence on the torque characteristic of IPMSM. Thus their accurate prediction is essential for predicting performance aspect such as the torque and flux-weakening capabilities. In this paper, in many causes which affect the characteristic parameters, effect of distance of Permanent Magnets will be inquired. Nonlinear characteristic of inductances is considered as calculating inductances using finite element method.

I. INTRODUCTION

Permanent magnet synchronous motor (PMSM) has many advantages, such as high torque density, high power density, high efficiency, among others. Advances in PMSM manufacturing and technology are primarily responsible for lowering the cost and increasing the applications of PMSMs. PMSMs are classified into sinusoidally fed PMSMs and rectangular fed brushless PM motors (BLDC). The magnets are either mounted on the surface of the rotor, called surface mount permanent magnet synchronous motors (SPMSM), or placed inside the rotor, called interior permanent magnet synchronous motor (IPMSM). Because the magnets of the IPMSMs are embedded inside the rotor, magnets are protected from flying away from the rotor surface from the centrifugal force. IPMSMs produce not only the magnetic torque, but also the reluctance torque, which is due to the difference between the d-axis and q-axis inductance L_d, L_q by geometrical rotor structure. Therefore, it is possible to control the machine in the wide speed range control by means of flux-weakening control method. The air-gap flux can be weakened by applying large demagnetizing current in the d-axis of the permanent magnets. The steady-state performance analysis and precise control of the IPMSM greatly depend on determining the parameters accurately. The three essential parameters of the IPMSMs are armature flux linkage of PM (Ψ_a), d-axis and q-axis inductances (L_d, L_q). The magnet flux linkage is usually estimated from the back electromotive force (EMF). It is possible to estimate accurate value of magnet flux linkage as long as rotor speed and induced voltage are measured precisely. However, estimation of d-axis and q-axis inductances needs more careful approach as it involves saturation and cross-coupling effects. There are various approaches to estimate d-axis and q-axis inductances

such as analytical methods, finite-element analysis, and experimental measurements.

This paper studies whether the distance of PM affects characteristic parameters. The inductances were estimated from the finite element method and measured by current vector control method considering saturation and cross-saturation effects.

II. INDUCTANCE COMPUTATION

The voltage equation of IPMSM which is got to be transformed into d, q axis coordinate system can be written as

$$\begin{bmatrix} v_d \\ v_q \end{bmatrix} = \begin{bmatrix} R_a + pL_d & -\omega L_q \\ \omega L_d & R_a + pL_q \end{bmatrix} \begin{bmatrix} i_d \\ i_q \end{bmatrix} + \begin{bmatrix} 0 \\ \omega \Psi_a \end{bmatrix} \quad (1)$$

Where,

$$\Psi_a = \sqrt{\frac{3}{2}} \Psi_f = \sqrt{3} \Psi_e$$

Ψ_e : the effective value of armature linkage flux of u-phase by permanent magnets

v_d, v_q : d, q elements of armature voltage

i_d, i_q : d, q elements of armature current

R_a : winding resistance

In the steady state, the differential terms are eliminated in Eq. 1.

The inductance parameters were computed from the finite element method. The finite element method is considered to be a very powerful tool to predict and estimate machine parameters. It can also give good insight into the saturation and leakage of flux inside the machine. It is available to estimate the d-, q-axis inductances in following procedure from flux linkage vector diagram shown in Fig. 3.1

1) Assuming that the motor is driven by load, open the motor terminals and rotate the rotor by FEM. Calculate the variation of flux linkage or induced voltage on phase U winding.

2) Assuming that current with magnitude i_a and phase angle β is applied. Rotate the rotor in same way like 1), calculate the variation of flux linkage or induced voltage on phase U winding.

3) Calculate the phase difference and effective values Ψ_{ua} , Ψ_{uo} of fundamental wave component for the waveform obtained through.

4) Using the equation (2)~(4), compute parameters with values obtained through 3).

$$i_d = -I_a \sin\beta \quad i_q = I_a \cos\beta \quad (2)$$

$$\Psi_a = \sqrt{3}\Psi_{ua} \quad \Psi_o = \sqrt{3}\Psi_{uo} \quad (3)$$

$$L_d = \frac{\Psi_o \cos\alpha - \Psi_a}{i_d} \quad L_q = \frac{\Psi_o \sin\alpha}{i_q} \quad (4)$$

Fig. 1. Flux linkage vector diagram of IPMSM

Fig. 2. Flux linkage waveform of phase U

III. ANALYSIS MODELS

Each Analysis model has same amount of PM. But it has different that distance of two magnets. Magnetic flux path of each model is different to each other. Thus it has different saturation region of rotor.

Fig. 3. Analysis Models

IV. TORQUE MECHANISM OF IPMSM

In IPMSM, besides magnetic torque in SPMSM, also reluctance torque by saliency arc produced. If balanced 3-

phase currents flow through stator coils distributed by 120 degree in space, rotating magnetic field is created with stator. The mathematical model of torques in IPMSM can be attained by the vector product between current vector \mathbf{i}_a and armature linkage flux vector Ψ_a .

$$T = P_n \Psi_a i_q + P_n (L_d - L_q) i_d i_q \quad (5)$$

IPMSM produce not only magnetic torque but also reluctance torque. Therefore, using flux-weakening control, IPMSMs can be driven at higher speed than surface mount permanent magnet synchronous motors (SPMSMs).

V. RESULTS

Fig. 2 shows inductance parameters of each model. Model (b), which has 2mm distance, has the largest L_d , L_q . But model (d) has the largest inductance difference $L_q - L_d$ that produce reluctance torque. As shown in Fig. 3 model (e) has the largest torque because of it has the largest linkage flux between outer PM and stator coil. Model (d) has the largest $L_q - L_d$. Thus it has the largest reluctance torque and maximum speed is high.

ranran.lin@tkk.fi, ari.haavisto@tkk.fi, and antero.arkkio@tkk.fi

Abstract—The axial magnetic induction in the core ends of a large induction machine, caused by the leakage flux of the end winding, was analyzed. The analysis is based on 3-D finite element method (FEM), involving the anisotropic property of the core ends as well as the use of the standard impedance boundary condition (SIBC) to model the eddy current in the end shield and frame. The 3-D model is validated by measuring the axial magnetic induction on the end surface of the core as well as the induced electromotive force along a search coil. The analysis results show that the eddy current, which flows in the radial-circumferential planes of the laminations, is induced in the core ends due to the presence of the axial magnetic induction. The corresponding eddy-current loss is small and most of the loss occurs within 50 mm from the end surface of the core in the axial direction. In addition, the axial magnetic induction near the tooth tips and the bottoms of the slots of the core ends is much stronger than in the yoke.

I. INTRODUCTION

In the numerical analyses of electric machines, a 2-D cross-section model is quite common because the magnetic field in the core centre is basically parallel to the radial-circumferential plane. However, due to the leakage flux caused by the end winding, the magnetic field in the end region is definitely 3-D [1]. The core ends may be affected by the leakage as well, so the axial component of the magnetic induction may occur there. The direct effect of the axial magnetic induction is the eddy current in the laminations of the core ends. Under some fault conditions, the eddy current may be large and lead to considerable loss, which affects the efficiency of the machine and goes further to cause hot spots in the structures [2, 3].

II. METHODS

A. 3-D Numerical Model and Finite Element Analysis

A 3-phase, 4-pole, 2.24-MW squirrel-cage induction machine with a form-wound two-layer diamond winding was studied. Since it was impossible to test this machine at full load in the laboratory, the rotor parts were taken away and the stator parts were tested at the rated current 830 A.

The skin depth of the end shield and frame is 1 mm at the rated frequency 50 Hz. However, if a mesh included such small elements to model the eddy current in the end shield and frame, it would be impossible to solve the large equation system by the computer. Therefore, the standard impedance boundary condition (SIBC), also called the Leontovich boundary condition, was imposed to model the eddy current in these parts. The model of the anisotropic, 150-mm-long (axial

length) core end was cut into 15 slices in the axial direction, and the axial thickness of each slice was 10 mm. Fig. 1 shows the 3-D numerical model of the induction machine.

Fig. 1. The 3-D numerical model of the induction machine (without the air region and end shield). Only the first 10 slices of the total 15 slices are used in the calculation and slice 1 is the one nearest to the end surface of the core.

A series of time-harmonic numerical analyses were carried out. The governing equation was

$$\nabla \times [\boldsymbol{\nu} \cdot (\nabla \times \underline{\mathbf{A}})] + j\omega\boldsymbol{\sigma}\underline{\mathbf{A}} - \underline{\mathbf{J}}_s = \mathbf{0}, \quad (1)$$

where $\underline{\mathbf{A}}$ and $\underline{\mathbf{J}}_s$ are complex vectors of magnetic vector potential and source current density, respectively; $\boldsymbol{\nu}$ and $\boldsymbol{\sigma}$ are tensors of reluctivity and conductivity, respectively; ω is an angular frequency; and j is the imaginary unit.

The SIBC, as shown in Fig. 1, was imposed according to

$$\underline{\mathbf{E}} - (\mathbf{n} \cdot \underline{\mathbf{E}})\mathbf{n} = Z_s \mathbf{n} \times \underline{\mathbf{H}}, \quad (2)$$

where $\underline{\mathbf{E}}$ and $\underline{\mathbf{H}}$ are complex vectors of electric field strength and magnetic field strength, respectively; \mathbf{n} is the outward-directed normal unit vector on the surface; Z_s is the standard surface impedance of a medium.

The mesh of the core end was made into many layers and the axial thicknesses of the three layers close to the end surface were 0.25 mm, 0.45 mm, 0.9 mm, to model the skin effect. Galerkin's method was used in the weak form of the method of weighted residual to construct the finite element discretization.

B. Validation of 3-D Numerical Model

To validate the model, two types of measurement were done. Firstly, a search coil was built along a coil end, and the induced electromotive force (EMF) was measured and compared. The rms value of the measured EMF was 0.61 V, and the simulation gave 0.59 V. Secondly, the magnetic induction on the end

Fig. 2. The five measured points used in the validation are distributed evenly along the middle line (dash line) of each tooth. In addition, the six positions used in the calculation are marked as A, B, C, D, E, and F.

Fig. 3. The rms values of the axial components of the magnetic induction. Dash lines: simulation results; solid lines: measurement results.

surface of the core was measured. Six successive teeth in one phase belt were chosen to be measured. Along the middle line of each tooth, five points were measured. Fig. 2 illustrates the positions of the five measured points along the middle line (dash line). The results are shown in Fig. 3. The measured values are consistent with the simulated ones. Therefore, the measurement validated the numerical model.

III. RESULTS OF FINITE ELEMENT ANALYSIS

To fully analyze the axial component of the magnetic induction in the core ends, different positions were chosen. They were A, B, C, and D in the tooth between two successive phase belts, and E near the bottom of a slot and F in the middle of the yoke, respectively, as marked in Fig. 2. Because the core end was cut into 15 slices of equal length in the axial direction, the axial magnetic induction was calculated in the middle of the axial thickness of each slice. The corresponding results in slices 1–10, as marked in Fig. 1, are shown in Fig. 4.

In addition, the eddy-current loss caused by the axial magnetic induction was calculated in each slice by

$$\overline{P}_{Ft}^{calc} = \frac{1}{2} \int_{\Omega} \text{Re} \left\{ \frac{1}{\sigma_x} \underline{J}_x \underline{J}_x^* + \frac{1}{\sigma_y} \underline{J}_y \underline{J}_y^* \right\} dV, \quad (3)$$

where \overline{P}_{Ft}^{calc} is the time average value of the eddy-current loss over a period; \underline{J}_x and \underline{J}_y are the phasors of the components of the eddy current; σ_x and σ_y mean conductivity. Fig. 5 shows the eddy-current loss, calculated by (3), in slices 1–10.

The total eddy-current loss in one core end was calculated as 144.2 W. In the core end within the skin depth 1.6 mm in

Fig. 4. The maximum values of the axial magnetic induction in slices 1–10 of the core end.

Fig. 5. The time average values of the eddy-current loss in slices 1–10 of the core end.

the axial direction, the loss was 30.2 W. Besides, in Fig. 5, most of the loss is concentrated in slices 1–5, that is, 50 mm from the end surface of the core in the axial direction.

IV. CONCLUSIONS

The axial magnetic flux and the eddy-current loss in the core ends of a 2.24-MW induction machine, caused by the end winding leakage flux, was studied. The anisotropic property of the core ends was taken into account and the eddy current in the end shield and frame was modelled as well.

The analysis results show that under the normal working condition, the total eddy-current loss in the core ends is small, by comparison with, for example, the stator copper loss, 5.4 kW. The stator end winding leakage causes the axial magnetic induction in the core ends, and it is enough to cause some loss within 50 mm from the end surface of the core in the axial direction. In the radial-circumferential planes of the laminations, relatively large axial magnetic induction occurs in the core ends near the tooth tips and the bottoms of the slots (positions A and E in Fig. 2). Moreover, there is a slight difference in the axial magnetic induction among different teeth in a phase belt. By the validation, the 3-D model proves to be feasible in analyzing both the end region and core ends.

Abstract—This paper present a study on magnet reduction in a single-phase line-start permanent magnet motor(LSPMM) by utilizing the advantage of multi-layer rotor structure. Based on an existing single-layer interior-PM design LSPMM, a double-layer interior-PM rotor design is adopted for reducing the buried PM material without deteriorating motor torque and efficiency performances. The double-layer interior-PM rotor can create higher rotor saliency that benefits to reluctance torque generation, which is utilized to compensate the decreasing of magnet torque production since the PM usage reduction. The unique hybrid torque attribute benefits to torque and efficiency improvement are emphasized in this study. Finite element analysis and test results confirmed the validity of the presented analysis method.

I. INTRODUCTION

The single-phase line-start permanent magnet motors (LSPMM) are widely used in household appliance, such as the compressor of air-condition, due to its feature operating characteristics that fed directly from the commercial electricity, without additional power electronic switching devices and position sensor [1].

Due to the conductor bars and assisted PMs buried inside rotor core, the LSPMM has the beneficial attribute of high starting torque by means of a line-start induction motor and high efficiency, high torque performance at steady state as an interior-PM synchronous motor(IPMSM).

From a cost standpoint, the reduction of magnetic material in PM motor is desired on the premise of keeping the main machine performances, such as torque and motor efficiency. In this study, the falling of machine performance of a prototype single-layer LSPMM caused by the PM usage reduction is predicted to be improved by adopting double-layer IPM rotor structure. For maintaining the maximum torque and efficiency performances, the hybrid torque characteristic is enhanced by changing the balance ratio of the hybrid torque components generated from the IPM rotor, that the reluctance torque production increased by creating a higher rotor saliency is utilized to compensate the decreasing of magnetic torque production due to less magnet usage[2].

Fig. 1. Prototype single-phase LSPMM model and its stator winding circuit

With the help of response surface methodology(RSM) simulation, an optimized double-layer IPM rotor structure is built and almost 30% PM is saved. The equivalent circuit method(ECM) coupled with finite element analysis(FEA) is performed, and the torque and efficiency performance can be predicted. The experiment results of prototype single-phase LSPMM confirmed the validity of presented analysis method.

II. MODEL AND ANALYSIS METHOD

A. Prototype Single-phase LSPMM

In this study, an existing single-phase LSPMM used as air compressor is given as prototype model, in Fig. 1 shows. The single-phase LSPMM has main and auxiliary winding arranged in the stator slot regions. In the rotor part, the conductor bars and PM segments are buried in the iron core.

TABLE I
SPECIFICATION OF PROTOTYPE SINGLE-PHASE LSPMM MODEL

Item	Value	Unit
Pole / Slot number	2 / 28	
B_r [75 °C]	1.168	[T]
Magnet volume/pole	$(4.7 \times 19.0) \times 2$	[mm ³]
Stack length	90	[mm]
Air gap length	0.5	[mm]
Input voltage	220	[V _{rms}]
Rate Speed	3000	[Rpm]
Rated torque	6.5	[Nm]

B. ECM coupled with FEA in Single-phase LSPMM

In Fig. 1, the stator windings circuit shows the single-phase LSPMM taking a time difference by capacitance and spatial phase difference of main and auxiliary windings, generating an unbalanced magnetic field, which can be considered to be a two phase motor. The FEA is performed by converting single-phase LSPMM to an ideal two-phase motor that has equal turns orthogonally on d - q plane[1].

C. PM Reduction Design

The reduction of PM usage results in the decreasing of machine performances, such as torque and motor efficiency. On the other hand, the motor performance can be improved by taking advantage of unique rotor structure, such as multi-layer IPM design. In this study, a double-layer IPM rotor design is chosen for simple manufacture. In steady state, the single-phase LSPMM is dealt with a classical IPMSM. Therefore, hybrid torque characteristic can be expressed as following[2]:

$$T_e = P_n \{ \lambda_d i_q - \lambda_q i_d \} = P_n \{ \psi_a i_q + (L_d - L_q) i_d i_q \} = T_m + T_r \quad (1)$$

The torque equation above emphasizes that the hybrid torque is composed of magnet T_m torque and reluctance torque T_r , as Fig. 2 illustrates, in which the same amplitude of hybrid torque T_{e_Max} is achieved with different balance ratio of reluctance torque and magnet torque production, in term of $\beta(=T_m/T_r)$. The increase of β suggests the higher rotor saliency effect. It is predicted that the “New” LSPMM model with ratio $\beta(7:6)$ can saving almost 30% PM material compare to the prototype LSPMM with ratio $\beta(10:3)$. In another words, the higher rotor saliency of IPM rotor helps to reduce the PM usage for achieving the identify torque performance.

Fig. 2. Hybrid torque generation Fig. 3. Torque-Efficiency map

By performing ECM, the motor torque-efficiency is mapped with different saliency ratio(L_q/L_d). The torque and motor efficiency performances are predicted according to the variation of the significant motor parameters Back-EMF and d -axis inductance, as Fig. 3 shows. It is found that the closed triangle region satisfying both torque and efficiency enlarged with the increasing of saliency ratio. According to the predicted higher saliency ratio, the design objectives of Back-EMF(line-to-line) and d -axis inductance are determined for the double-layer IPM design with less PM material.

III. OPTIMIZATION OF DOUBLE-LAYER LSPMM

RSM is a collection of statistical and mathematical techniques used for developing, improving and optimizing process[2]. It is applied to determine an optimum structure of double-layer IPM rotor for PM reduction in LSPMM.

As the torque-efficiency map prediction, the rotor saliency ratio enhance from 2.5 to 3.0, corresponding to the decrease of Back-EMF and inductance. Therefore, the double-layer design of LSPMM model is built for satisfying the predicted “New” point characteristics. Fig. 5 illustrates the basic model of double-layer IPM rotor structure with design variables and their experiment ranges are given in Fig. 4. The Back-EMF (line-to-line) and rotor saliency ratio in steady operating condition(@3000rpm, $I_m=8A, \beta=40^\circ$) are chosen as objective functions in RSM. The optimal double-layer LSPMM is obtained, as Fig. 5 shows. The main machine characteristics of prototype and optimized models are confirmed by FEA.

Optimal design model	Hi	LPM_1	LPM_2	α	Prototype LSPMM model
	Lo	9.50	18.00	26.0	
		[7.60]	[17.50]	[22.5]	
		7.50	13.00	18.0	
Back-EMF [L-to-L@3000rpm] Y1=123[Vrms]					Back-EMF [L-to-L@3000rpm] Y=160[Vrms]
Saliency ratio [Lm=8A, $\beta=40^\circ$] Y2=3.0					Saliency ratio [Lm=8A, $\beta=40^\circ$] Y=2.54

Fig. 4. Optimization of Back-EMF and saliency ratio by RSM

Fig. 5. Double-layer IPM design model and optimized double-layer LSPMM

Fig. 6. Torque performance of single-phase LSPMM by test

Fig. 7. Back-EMF (line-to-line @3000rpm) and rotor saliency characteristic

TABLE II
COMPARISON BETWEEN PROTOTYPE MODEL AND OPTIMAL DESIGN MODEL

Model	Back-EMF @3000(rpm) L-to-L[Vrms]	Saliency ratio [Lm=8(A), $\beta=40^\circ$]	Max. Torque [N*m]	Motor Efficiency [%]
Prototype [100%]PM	160.0	2.54	13.1	89.0
Optimal design [70%]PM	123.1	3.0	13.0	88.8

IV. RESULT ANALYSIS

The torque performance of prototype single-layer LSPMM is tested and well proved the validity of presented analysis, in Fig. 6. The optimized double-layer LSPMM model has lower Back-EMF and higher rotor saliency characteristics, in Fig. 7, but almost same torque and efficiency performances are achieved with saving 30% PM, as TABLE II compared.

V. CONCLUSION

This paper studied on the PM reduction design in a single-phase LSPMM. By improving the reluctance torque generation to compensate magnet torque production, the dependency of magnet usage is lowered. The optimized double-layer design LSPMM model is built with using 70% of PM used in prototype LSPMM, but achieving similar torque and efficiency performances. In conclusion, the double-layer IPM rotor design is an effective approach for improving IPM motor performance, further to realize magnet usage reduction.

Abstract: A new partial discharge (PD) location method in oil is presented based on ultrasonic phased array and wideband array signal processing in this paper. Firstly, a set of partial discharge detection system based on ultrasonic phased array is built. And the wideband array ultrasonic signals of PD are received directly and formatted through this system. Secondly, the method of RSS (Rotational Signal Subspace) is used to focusing processing to the wideband array ultrasonic signals of PD. The focused processing is to search the focusing matrix T_j and convert the signal direction matrix

$A(f_i)$ under different frequencies to the same one center frequency, which can realize the information accumulation of wideband signal. Then we can realize estimating of direction of arrival (DOA) and locating of PD source by MUSIC (Multiple Signal Classification) only for narrow band signals processing. Lastly, the results of experimental research indicate the method is correct with smaller errors.

I. BACKGROUND

The partial discharge (PD) is an important reason for the insulation deterioration of electric power equipments. The accurate PD location can provide scientific information and guidance for the state maintenance and is favorable to rapidly remove the fault, avoid the occurrence of fatal accident, reduce the losses by blackout accident and cut down the maintenance cost, so great attentions have been paid by the electric power operation departments.

At present, the PD location methods adopted at home and abroad mainly include ultrasonic method, electric method and UHF method, which have been deeply studied [1]. Xi'an Jiaotong University has firstly brought forward the ultrasonic phased array technology based on 256 array elements and beam-forming algorithm for PD location, which has improved the low sensitivity deficiency of traditional single sensor, but this method needs too many array elements to cause the great difficulty in hardware implementation and the beam-forming algorithm is restricted by the "Rayleigh limit" with poor location

accuracy. North China Electric Power University has brought forward the PD location based on MUSIC algorithm, which can prevent the restriction of "Rayleigh limit" in the beam-forming location algorithm and improve the location accuracy. Based on this, a new PD location method based on 4×4 ultrasonic plane phased array and wideband array signal spectrum estimation algorithm is brought forward in this paper.

II. PARTIAL DISCHARGE DETECTION SYSTEM OF ELECTRICAL EQUIPMENT BASED ON ULTRASONIC PHASED ARRAY

The PD detection system of electrical equipment based on ultrasonic phased array is mainly consisted of ultrasonic phased array sensor, preamplifier, high-speed synchronous data acquisition device and laptop computer (as in fig. 1).

Fig.1 PD detection system

Fig.2 The model of 16-array elements ultrasonic phased array

The ultrasonic phased array sensor[2] is 16-array element and 4-row×4-column plane structure (as in fig. 2), the single array element is 4×4×15mm cuboid column, the space between the array elements is 5mm, the material is piezoelectric ceramics and the center frequency of its received signal is designed as 150kHz. A charge preamplifier is adopted in this paper, which is a wideband sensor with frequency covering 3 kHz~10MHz and gain of

up to 40dB. The signal detected by the sensor is accessed into the acoustic emission preamplifier through the BNC interface and is output through BNC interface after being amplified. The amplifier is supplied by 12V DC power supply. The high-speed data acquisition system integrates the computer control (program-controlled amplification and band pass filtering), data acquisition and high-speed serial data transmission functions. The high-speed data acquisition device has 16 channels and the amplification factor of single channel is 1 to 256 times controlled by the software in 16 shifts. The cut-off frequency of band pass filter is 20 kHz to 300 kHz and the sampling frequency is 512 kHz to 10MHz. The high-speed data acquisition device is connected with the computer via USB interface to realize the high-speed data transmission.

III. LOCATION ALGORITHM OF ULTRASONIC WIDEBAND ARRAY SIGNAL OF PARTIAL DISCHARGE

The focused processing is the precondition for the DOA of wideband array signal and essentially is to search the focusing matrix T_j and convert the signal direction matrix $A(f_i)$ under different frequencies to the same one center frequency. The RSS [3] is to derive the focusing matrix based on the least-error principle between the directional matrix after focusing and the directional matrix of the center frequency point.

Then, the MUSIC [3] algorithm is adopted for the direction-of-arrival estimation of the acquired narrowband signal. The MUSIC algorithm builds the spatial spectrum function with the orthogonality of signal subspace and noise subspace and detects the DOA of signal through the search of spectrum peak.

Finally, on the basis of the accurate estimation of the direction-of-arrival of single PD source, the accurate single PD source location is realized through the crossing of two directions of arrival in the space with the spatial information of PD source received by two ultrasonic phased array sensors A and B.

IV. EXPERIMENTAL STUDY

The pin-to-plate discharge model is adopted in the experiment, which is put into an oil tank full of mineral oil with dimensions of 100cm×100cm×120cm to simulate the PD situation in oil and generate the ultrasonic signal. The phased array sensor is placed on the outer wall of the oil tank and is close to the outer wall with the butter. The 16-array element ultrasonic signal acquired by the data acquisition device is shown as in Fig.3 and the direction finding spectrogram is shown as in Fig.4. With the PD source location error of less than 10cm, the experimental results verify the correctness of the method in this paper.

Fig3. Signal wave

Fig.4 spectra of sensor arrays A spectra of sensor arrays B

V. CONCLUSION

A pair of plane ultrasonic phased array sensors are developed, which can directly detect and generate the ultrasonic wideband array signal of partial discharge in oil.

The RSS algorithm, MUSIC algorithm and crossover location principle are combined to realize the focusing processing, DOA estimation and geometric location of the wideband ultrasonic array signal of PD and overcome the limitation that the traditional algorithm can not directly process the actual wideband ultrasonic array signal of partial discharge.

The experimental platform for partial discharge location in oil is built for the experimental study. The location error is less than 10cm in the experiment, which verifies the correctness of the location method and provide perfect foundation for the further engineering application.

Abstract— In order to analyze noise of interior permanent magnet (IPM) motor, this paper deals with relation between deformation of stator and noise from motor. The resonance frequency is calculated by Ansys P/G and resonance frequency band based on 1/3 octave band is determined. In order to calculate deformation of stator, current considering load condition is calculated from dynamic simulation and normal and tangential force which affects on the tooth are computed by equivalent magnetizing current (EMC). After harmonic analysis for the computed forces is performed, the harmonic component of each force in the resonance frequency band put in the surface of tooth, respectively. And then, the quantity of deformation of stator is calculated and compared. Finally, the relationship between the quantity of deformation of stator yoke and noise spectrum is analyzed.

I. INTRODUCTION

Noise of motor can be classified into three sections. First of all, there are higher space and time harmonics eccentricity, phase unbalance, slot opening, magnetic saturation, and magnetostrictive expansion of the core laminations in electrical noise. Secondly, there are mechanical noises associated with the mechanical assembly. Thirdly, there are aerodynamic noises associated with flow of ventilating air through or over the motor [1].

The noise and vibration of the motor structure are the direct response of the excitation by these forces. For example, if the frequency of the radial magnetic force is close to one of the natural frequencies of the stator system and the factor order r is the same as the circumferential vibrational mode m of the stator system, significant vibration and acoustic noise can be produced [2].

For studying on the relation between deformation of stator yoke and acoustic noise in IPM motor, modal analysis, this paper deals with calculation of exciting force which is composed of tangential and normal force on the tooth, harmonic analysis for the exciting force, the quantity of deformation of stator yoke, and the comparison between calculated the quantity of deformation of stator yoke and acoustic noise.

In order to calculate electrical exciting forces which affect on the acoustic noise, the current is calculated by dynamic simulation considering load condition. The tangential and normal forces which affect on tooth of stator are calculated using finite element method (FEM). Especially, equivalent magnetizing current (EMC) method uses magnetizing current which exists on element boundary and it can directly calculate

the electromagnetic force which affects the surface of tooth [3].

The exciting forces are put in the surface of tooth of stator and the quantity of deformation of stator yoke is calculated. Finally, the tendency of calculation of the quantity of deformation of stator yoke and measured acoustic noise of analysis model is compared.

II. THEORY

A. Equivalent magnetizing current (EMC)

The differentia of tangential component of field intensity between two materials is equal to the magnetizing current on element boundary. On the element boundary, magnetizing current is calculated by eq (1).

$$I_m = \frac{1}{\mu_0} \int \nabla \times \vec{M} \cdot d\vec{s} = \frac{1}{\mu_0} (M_{1t} - M_{2t}) l_{ij} \quad (1)$$

where, M_{1t} and M_{2t} are the tangential components of magnetization on element boundary, l_{ij} is the distance on element boundary.

The electromagnetic force f_{ij} which affect on i, j element on the element boundary is written as [4]

$$\vec{f}_{ij} = \vec{I}_{ij} \times \vec{B}_{ext} \quad (2)$$

Flux density value of \vec{B}_{ext} is given as the average value for each element.

B. Spectrum analysis

The noise near the resonant frequencies, which affect harmonics of electrical exciting forces, is larger than other natural frequencies. Therefore, modal analysis for stator is performed and then center frequencies for 1/3 octave band based on the resonant frequencies of stator is designated. The center frequencies is defined by eq. (3)

$$f_c = \sqrt{f_u \cdot f_l} \quad (3)$$

where f_c is center frequency, f_u and f_l are the upper and lower half-power frequencies.

III. ANALYSIS MODEL

The specifications of analysis model are shown as Table I. The analysis model which consists of 4-pole/6-slots and concentrated windings is driven by BLAC operation and rated speed and torque are 1800rpm and 1.0 Nm, respectively. In

addition, pulse width modules (PWM) frequency is 4.0 kHz, respectively.

TABLE I
Specifications and resonant frequencies of stator

Contents	Values
Number of poles slots	4/6
Rated current (A_{rms})	1.5
Series turn number per phase (turns)	65
Rated speed (rpm)	1800
Rated torque (Nm)	1.0
PWM frequency (kHz)	4.0

IV. ANALYSIS METHOD AND RESULTS

In order to study on the relation between deformation of stator and acoustic noise, analysis method is divided into 4 steps.

Firstly, modal analysis for the stator of analysis model is performed. Fig. 1 shows that circumferential mode (m) 2 and 3 of the stator with resonant frequency. And then, center frequencies and band widths for 1/3 octave band based on modal analysis for stator are designated.

Secondly, exciting forces, which are composed of tangential and normal force, on the stator tooth versus rotor position are calculated by using the equivalent magnetizing current (EMC). And then, the harmonic components of exciting forces are calculated through harmonic analysis. It is shown in Fig. 2.

Thirdly, harmonic component of tangential and normal force versus harmonic order is assigned at the surface of tooth, respectively. It is shown in Fig. 3. It should be considering phase difference because each the harmonic component according to the change of rotor position is changed such as sinusoidal.

Finally, the quantity of deformation of stator yoke is calculated by harmonic analysis using the harmonic components of exciting force and the result of deformation of stator yoke as shown in Fig. 4. And then, the quantity of deformation of stator yoke in the band widths is summated.

The analysis results and comparisons of measured acceleration and acoustic noise will be presented in extended paper.

Abstract — This paper investigates the vibration and musical scale emitted from the brushless DC motor by introducing the d-axis current with a sound frequency. First we analyze the vibration acceleration of the motor and verify the calculation method by comparing with the measured ones. Next, we clarify the vibration characteristics by changing the sound frequency, the motor speed and the output power.

I. INTRODUCTION

Brushless DC motors with permanent magnets are widely used in industrial applications and computer peripheral devices, and they become smaller size and higher power by use of high-grade magnet. Since the permanent magnet is higher grade and the encasing is less stiff, the motor becomes more sensitive to the vibration and acoustic noise. Several papers have been published on the vibration and acoustic noise emitted from the brushless DC motor. For example, the vibration and noise of the interior permanent magnet motor have been analyzed by finite element method [1], [2], and an active noise control have been proposed to cancel the acoustic noise by adding the other noise with a phase shifted by π [rad] [3]. However, the perfect reduction of noise is very difficult.

The authors have proposed a method to convert the meaningless electromagnetic noise into a comfortable melody, and have emitted experimentally a desired melody by sequentially generating the musical scale from a brushless DC motor [4]. This paper investigates numerically the vibration and musical scale emitted from the brushless DC motor fed by a PWM inverter. First we analyze the vibration acceleration of the motor, and compare with the measured vibration acceleration and musical scale. Next, we clarify the vibration characteristics by changing the sound frequency, the motor speed and the output power.

II. ANALYSIS METHOD

The d-axis current of the brushless DC motor with surface permanent magnets (SPM) is usually controlled to be 0, because the output torque can be linearly controlled by the q-axis current. However, the sinusoidal d-axis current can generate the sinusoidal flux density, resulting in the sinusoidal radial magnetic force and then the sinusoidal vibration. Therefore, the authors have proposed the generation method of the musical scale from the brushless DC motor with SPM by controlling the d-axis current as follows,

$$i_d = I_s \sin(2\pi f_s t) \quad (1)$$

where f_s is a sound frequency.

In this paper, we investigate theoretically the vibration and musical scale emitted from the brushless DC motor. First, the magnetic field in an experimental brushless DC motor is calculated by 2D non-linear finite element method, and the electromagnetic force is calculated by the Maxwell's stress tensor method. Next, the vibration acceleration of the motor is calculated by solving the following equation with 2D finite element method.

$$[\mathbf{M}]\{\ddot{x}\} + [\mathbf{C}]\{\dot{x}\} + [\mathbf{K}]\{x\} = \{f\} \quad (2)$$

where, $\{x\}$ is the node displacement, $\{f\}$ is the electromagnetic force, and $[\mathbf{M}]$, $[\mathbf{C}]$ and $[\mathbf{K}]$ are the global mass matrix, viscous friction matrix and stiffness matrix, respectively.

III. SIMULATION AND MEASUREMENT

The experimental motor used for verification purpose has 1kW power, 4 pole-pairs and 7.8A stator current. Fig.1 shows the calculated vibration acceleration when $f_s = 349\text{Hz}$ corresponding to a music scale of "fa", and the motor speed is 675min^{-1} , that is, the rotating frequency $f_m = 90\text{Hz}$. There are big vibration accelerations at the frequency of $2pf_m$, f_s and $f_s \pm 2pf_m$, where p is the number of pole pairs. Fig.2 shows the measured vibration acceleration and sound. The vibration acceleration was measured with a piezoelectric accelerometer placed at the top of the stator and a preamplifier and a signal analyzer. The sound was measured with a noise level meter and the signal analyzer. Fig.2 (a) shows the measured vibration acceleration when $i_d = 0$. There are many peaks at npf_m and mf_{source} , where f_{source} is the frequency of the line source 50Hz and n and m are the integer. Fig.2 (b) shows the vibration acceleration when $i_d = I_s \sin(2\pi \times 349t)$. We can find the big vibrations at $f_s = 349\text{Hz}$ and 481Hz. The frequency of 481Hz is $f_s + 12f_m$, therefore it is the frequency of rotor vibration, which is produced by the number of stator slots 12 and the sound frequency. It is shown from fig.2(c) that there is a big sound at the frequency of "fa". Therefore, the simulation has verified that the d-axis current with a sound frequency generates the musical scale.

Fig.3 shows the vibration acceleration by changing the sound frequency f_s . It is shown that this motor can generate bigger vibration acceleration and thus bigger sound at higher sound frequency. Fig. 4 shows the vibration acceleration by changing the motor speed. It is shown that the vibration acceleration does not depend on the motor speed very much, if

the rotating frequency does not match or close to the sound frequency.

IV. CONCLUSIONS

This paper has analyzed the vibration acceleration of the brushless DC motor, and has verified that the d-axis current with sound frequency generates the musical scale. In addition, a desired melody can be generated by sequentially generating the musical scale, and the generation of musical scale does not affect the speed response of the brushless DC motor with SPM.

Abstract—A novel model based on winding function theory are presented for the simulation of major internal faults in the long-stator linear synchronous motor (LSM) of maglev train. The potential internal faults of LSM generally contain single-phase, double-phase short circuit and single-phase open circuit, etc. When different fault occurs, the impedance matrix related to inductance is accurately computed with winding function. Through the comparison of the simulation results under different fault conditions, the proposed method has showed that it is useful to diagnosis of internal faults.

Index Terms—Winding function, linear synchronous motor, internal faults.

I. INTRODUCTION

High-speed maglev train system is a new transportation system which first appeared in Shanghai for the commercial use in 2003. The advantages over its high speed, low noise and non-pollution make it suitable to long distance transportation. However, as the critical technology of maglev train system, the internal faults of long stator linear synchronous motor will cause serious consequences of endangering the passengers on the trains. So quickly simulating and diagnosing the faults of LSM become very important to prevent from extensive failure and make preparations for further uses.

In order to establish an appropriate mathematical model for LSM, a more accurate method, for calculation of the inductances of windings in the stator and moving parts, is very necessary. Most of the literature introduces the traditional dq0 model, but it's not suitable for the stator internal faults modeling. So this paper presents a new method based on winding function theory, which can take into account of the effect of all space harmonics and the asymmetry armature windings in case of internal faults of LSM. In the fault conditions, the faulty armature phase can be separated into two or three parts to simulate the effects brought by faults so that the fault models can easily be established.

The paper is arranged as follows. In section II, a new formulation for inductances calculation is derived and the voltage equations under normal condition are set up based on the winding function theory. In section III, the current waveforms under three kinds of internal faults are obtained by calculating the corresponding inductance matrix and linear equations. The results show that electromagnetic forces are not stabilized under internal fault conditions.

II. SIMULATION MODEL

A. Winding function theory

In a conventionally rotational machine, the mutual inductance of two armature windings a and b can be written, using winding function, as follows [1]-[4]:

$$L_{ab} = \mu_0 r l \int_0^{2\pi} g^{-1}(\varphi, \theta) N_a(\varphi, \theta) N_b(\varphi, \theta) d\varphi \quad (1)$$

where μ_0 is the permeability of air, r is the average radius of the air-gap, l is the axial stack length of the armature, and $g^{-1}(\varphi, \theta)$ is the inverse air-gap length function, $N(\varphi, \theta)$ is the winding function. In the case of LSM, equation (1) should be modified, because the winding function of LSM isn't the function of the rotor angle any more but the function of the relative position of the secondary. It can be expressed as $N(x, x')$, which is the function of displacement of the stator and mover, the inverse air-gap function should be modified accordingly. The modified formula is used to calculate the self inductances of LSM and the mutual inductances between stator and excitation windings, shown in fig.1.

Fig. 1 The mutual inductances between stator and excitation windings

B. Voltage equation

For the purpose of establishing the exact coupled mathematical model for LSM, we need to make some appropriate simplifications such as neglecting the effects of iron saturation and magnetic hysteresis. Under the normal condition, the LSM is usually described as a system with three-phase circuit loops in stator and an excitation loop in the secondary. The voltage equations of LSM can be written as:

$$[U] = [R][I] + [L] \frac{d}{dt} [I] + \frac{d}{dt} [L][I] \quad (2)$$

And

$$L = \begin{bmatrix} L_{aa} & L_{ab} & L_{ac} & L_{af} \\ L_{ab} & L_{bb} & L_{bc} & L_{bf} \\ L_{ac} & L_{bc} & L_{cc} & L_{cf} \\ L_{af} & L_{bf} & L_{cf} & L_{ff} \end{bmatrix}, \quad R = \begin{bmatrix} r & 0 & 0 & 0 \\ 0 & r & 0 & 0 \\ 0 & 0 & r & 0 \\ 0 & 0 & 0 & r_f \end{bmatrix}, \quad I = \begin{bmatrix} i_a \\ i_b \\ i_c \\ i_f \end{bmatrix}$$

where the inductance matrix contains the self and mutual inductances between the armature windings and the mutual inductances between armature and excitation windings.

Equation (2) can also be written as:

$$\frac{dI}{dt} = -[L^{-1}(R + \frac{dL}{dt})]I + L^{-1}U \quad (3)$$

With substituting the corresponding calculated inductance and resistance parameters into (3), the differential equation can be solved by using the numerical integration method, and hence the current waveforms, the propulsion and the levitation forces can all be obtained. When the internal fault occurs, we only need to recalculate the inductance and resistance matrix according to the different fault type and the short circuit ratio, but the mathematical model keeps the same, the simulation results in section III are derived from this method.

III. SIMULATION RESULTS

It's likely to occur three typical types of internal fault in LSM, single-phase and double-phase short circuit and single phase open circuit. As an example, the double-phase short circuit is discussed here. The internal fault voltage equation can be described as:

$$[U'] = [R'] [I'] + [L'] \frac{d[I']}{dt} + \frac{d[L']}{dt} [I']$$

$$\text{where } [U'] = [U_a, U_{b1}, U_{b2}, U_{c1}, U_{c2}, U_f]^T \quad (4)$$

$$[I'] = [I_a, I_{b1}, I_{b2}, I_{c1}, I_{c2}, I_f]^T$$

An equivalent circuit of the faulty coil is formed. The corresponding inductance matrix should be recalculated due to the short circuit ratio of phase bc .

Fig.2 shows us the current waveforms, the propulsion and the levitation forces under 50% double-phase short circuit. And with the increment of short circuit ratio, the amplitude of the waveforms increases and the harmonic components also strengthen. The more the number of short turns is, the more differences can be observed between normal phase and faulty phase. These simulation results are the basis of analysis of further fault diagnosis.

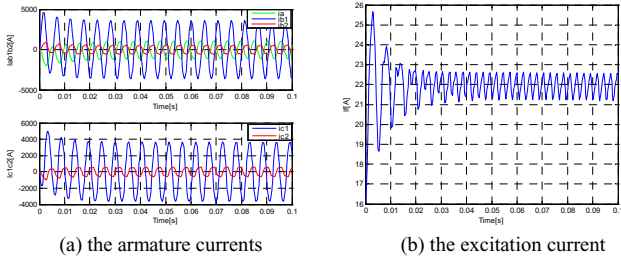

Fig .2 The simulation results of the 50% ratio of double-phase short circuit currents

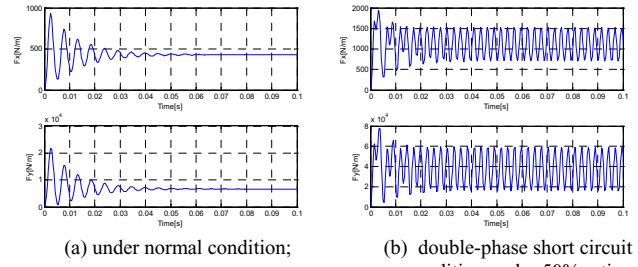

Fig .3 The simulation results of the propulsion and levitation forces

In Fig.3 (a), it can be seen that when the maglev train system operates in steady-state, that is to say the speed and the system power angle keep constant, the propulsion and levitation forces also tend to stabilize. However, the electromagnetic force can't keep stable when double-phase short circuit occurs shown in Fig.3 (b).

According to the simulation results of LSM under normal and internal faults conditions, the fault law can easily be found. Whatever the fault happens, the waveforms of fault currents and electromagnetic forces all appear a certain extent oscillation. Through specific wavelet packet transforming, the harmonic components can be obtained, which can also be used for fault diagnosis.

IV. CONCLUSIONS

In this paper, a useful internal fault model is proposed based on the winding function theory. This method has distinctive advances compared to the previous ones. The calculation of the impedance matrix mainly including inductances under normal and internal fault conditions is not only simpler but also accurate. Furthermore, the programmed software package for LSM internal fault simulation and analysis can realize the man-machine conversation.

Effects of Magnetic Saturation on Spindle Motor Characteristics

Jaenam Bae, Seung-Joo Kim, Sung-Chul Go, Dong-Woo Kang, Sang-Hwan Ham, and Ju Lee
 Hanyang University
 17 Haengdang-dong, Sungdong-gu, Seoul, 135-111, South Korea

Abstract — In spindle motor for disk memory devices, constant torque is very important. There are three kinds of source for the torque ripple viz. harmonics, cogging torque, reluctance torque. Because the motor has uniform airgap and a permanent magnet for the motor is magnetized on the special fixture, the effect of harmonics and reluctance torque is not considerable but cogging torque is the most influence to the torque ripple. However, when the ferromagnetic material is saturated, we get unexpected results such as torque fluctuation. In this paper, effect of magnetic saturation on spindle motor is presented. FPM is used to consider the saturation in FEA simulation.

I. INTRODUCTION

M brushless DC motors are widely used for the spindle motor in disk memory devices such as a CD-ROM drive system. In current disk drive system, the motor with slotted laminations and NdFeB magnets is the most common for use as the spindle motor [1]. Because an ODD speed and torque characteristics depends on spindle motor, it is very important the spindle motor has constant torque independent of the rotor position.

There are three sources for torque pulsation. First is the field harmonic torque due to non-ideal spatial distribution of flux density in the airgap and another is cogging torque or detent torque and third is reluctance torque, produced due to unequal reluctances of the d- and q- axis [2]–[4]. Because a magnet for the spindle motor is magnetized very sinusoidal, spatial distribution of flux density in the airgap is also sinusoidal. Moreover most of them have a fractional pole-slot combination which results in filtering high frequency component of induced voltage. Besides it has uniform airgap and equal reluctances of the d- and q-axis therefore it doesn't have reluctance torque. In conclusion, the most important source in the spindle motor is cogging torque in three of them.

There are several researches about cogging torque reduction in [5][6]. However they don't take into account magnetic saturation. As known, an important part of electrical machines is made of ferromagnetic materials. These materials consist of nonlinear magnetic characteristics. When the total magnetic motive force in the machine increases saturation of the ferromagnetic parts appears [7]. The result of the saturation effects is a variation of the stator and rotor inductances. For an optimized design of electrical machines, it needs designing the machines near the saturation point. Therefore the magnetic saturation effects should be considered.

Kwak et al. suggests Fixed Permeability Method (FPM) to get more accurate motor parameters (d- and q-axis inductance,

Fig. 1. Spindle motor for the study. It has 16 poles and 12 slots

back-EMF constant) by dividing the total magnetic flux linkage into the flux linkage due to the PM and to the stator current in [8]. The method can be also applied in a magnetic saturation effects. In this paper, an effect of the magnetic saturation on the motor characteristics is investigated using the FPM.

II. STUDY MODEL

Fig. 1 shows the spindle motor for the study. The motor has 16 poles and 12 slots and the NdFeB bonded magnet is mounted on the rotor inner surface. Ring magnet is used for cost reduction and it is magnetized on a special magnetizing fixture for sinusoidal distribution. Actually the magnet has both of radial and tangential components on its body, but only radial component is considered in the study because influence of the tangential component is very lower than that of the radial component. The radial component of the magnetization is defined as (1)

$$M_r = \frac{B_r}{\mu_0 \mu_r} \cos\left(\frac{N_p}{2} \theta\right) \quad (1)$$

where μ_0 and μ_r is permeability of the free space and relative permeability of the magnet respectively, B_r is residual flux density of the magnet and N_p is the number of poles.

III. TORQUE CONSIDERING MAGNETIC SATURATION

Voltage equation for a phase is given by

$$v = Ri + e$$

$$\therefore e = \frac{d\lambda}{dt} = \frac{d\lambda}{d\theta} \frac{d\theta}{dt} + \frac{d\lambda}{di} \frac{di}{dt} \quad (2)$$

where e is back-EMF, R is a resistance of the phase and λ is a flux linkage.

The flux linkage λ is varying to the rotor position but not to the current when magnetic saturation is not considered. However, in condition of saturation, λ is varying to the current and it makes distortion of back-EMF. Output power is a product of back EMF and input current thus it makes torque ripple. The effects of saturation can be considered by fixed permeability method (FPM). The procedure is presented below.

1. Calculating permeability when motor operates in given condition.
2. Calculating torque remaining only field excitation sources with the permeability calculated previously.

Fig. 2 shows torque waveform considering magnetic saturation. In the figure, torque produced by input current is not considered but only represent torque by permanent magnet with saturation core. Negative torque is produced when the core is saturated by input current. This can be explained with the Fig. 3. In the figure, the rotor is positioned to the 3.75 deg and therefore the tooth in a circle is aligned to the center of two poles. In the condition of unsaturated, the tooth has symmetric flux distribution.

Force on an object is calculated by

$$F = \left. \frac{dW(s,i)}{ds} \right|_{i=const} = \frac{\partial}{\partial s} \left[\int_V \left(\int_0^H \mathbf{B} \cdot d\mathbf{H} \right) dV \right] \quad (3)$$

where $W(s,i)$ is the magnetic coenergy of the system. The current, i , is held constant.

Calculating force on the rotor including permanent magnet, it is canceled by symmetry condition. But in case of saturated condition, the distribution is not symmetric. Right side of the tooth is more saturated than left side therefore the rotor has attraction force to the right direction and negative torque is produced.

The Optimal Design of the Secondary Reaction Plate Shape of Single-Sided Linear Induction Motor for Urban Maglev Train

Sang-Hwan Ham, Sung-Gu Lee, Su-Yeon Cho, Chang-Sung Jin, and Ju Lee
 Department of Electrical Engineering, Hanyang University
 17 Haengdang-dong, Seongdong-gu, Seoul, 133-791, Korea
 goodhami@hanmail.net

Abstract — The edge effect of the secondary reaction plate is influenced on performances of single sided linear induction motor (SLIM). Considering shapes of the secondary reaction plate, it will be optimized thrust force and efficiency-power factor product of SLIM. Thickness and overhang length of reaction plate are weighty design factors for optimal design. For the optimal design, magnetic equivalent circuit is used [1]. Two and Three dimensional finite element analysis is applied for validation of design parameter. And SLIM testing machine is used for validity of design optimization.

Introduction

In recent decades, there have been many researches for a linear motor in urban maglev. And single-sided linear induction motor (SLIM) with reaction plate that covered the secondary solid or laminated core is widely used for propulsion in urban maglev because of its linear motion characteristics [2]. SLIM for railroad system can provide higher efficiency of the total system and smaller construction cost in tunnel than traditional system.

Conventional trains using a rotational motor are faced with difficulty for complicated structure of power transmission from rotational torque to linear thrust force. As rapid development of power electronics and switching devices, SLIM replace the rotating motors with a gear. However SLIM have unique characteristics like a longitudinal end effect and a transverse edge effect. Because of these reasons, the optimal design of SLIM is very difficult. In this paper, we will archive the optimal design for high thrust force and efficiency-power factor product by reducing a transverse edge effect. Main influence of a transverse edge effect is increasing the equivalent resistance of secondary reaction plate. And in general, length of reaction plate is longer than length of primary core. Eddy current of surface on secondary reaction plate is non-uniform by transverse edge effect (Fig.1).

I. METHODS FOR OPTIMIZATION

Many methods for optimization of SLIM are existed. Among of them, we analyze the characteristics by changing shapes of the secondary reaction plate. Shape of reaction plate affects performance through changes in the effective secondary impedance [3]. The secondary impedance, consist of impedances both reaction plate and secondary core, is determined from the electromagnetic field distribution at the surfaces of that [4]-[5]. Thrust force and efficiency – power

factor product of SLIM are usually the most important performances in urban maglev train, thus the optimal design is focused on these two characteristics by changing of reaction plate shape. Thickness and overhang length of reaction plate are important design factors for optimal design..

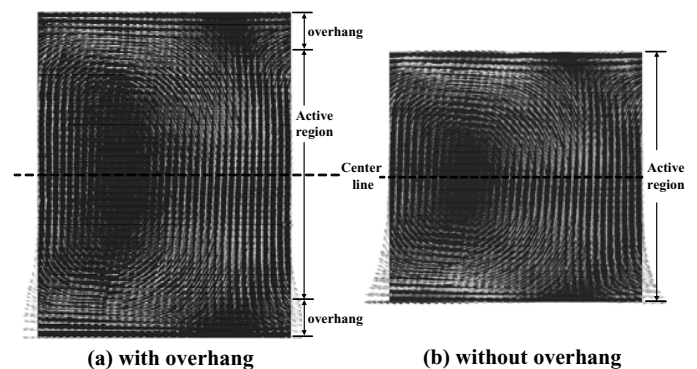

Fig. 1 Overhang effect on secondary reaction plate

And Using single-stator test, no-load test, and blocked-rotor test by 2D FEM analysis, we estimated the parameters of equivalent circuit of a common induction motor. Winding resistance and leakage reactance of primary is calculated by single-stator test. By no-load test, magnetizing reactance is estimated. And winding resistance and leakage reactance of secondary is calculated by blocked-rotor test.

Fig. 2 2D FEM model of LIM

And design of experiments is applied for optimizing design factors. Design specifications of LIM are shown in table I. For analyzing the equivalent circuit, 2D FEM model (Fig.2) is applied.

II. VARIATION OF DESIGN PARAMETER

For validation of design parameters, the two dimensional (2D) and the three dimensional (3D) finite element analysis (FEM) is applied. The 2D FEM is used for analyzing the influence by changing the thickness of reaction plate, because the 3D FEM is very complicated and time consuming. Arc type model is used for matching the testing machine [6]. The 3D FEM is employed to analyze the overhang effect by changing the shape. Fig.3 is the 3D FEM model and this model has only one pole for reducing calculation time. Fig. 4 is shown the LIM testing machine for validity of design optimization. And LIM testing machine is a reduction model in the ratio of ten to one for retrenching the cost and the space. An experiment using LIM testing machine is going in progress with Korea Railroad Research Institute (KRRRI). In the course of time, the results of experiment will be derived and then we will compare the result with simulation.

The impact of static eccentricity on rotor bar current distribution in case of one broken bar in Induction Motor

H. Razik, and F.M. Sargos
GREEN, BP 239

E-mail: Hubert.Razik@green.uhp-nancy.fr, Francois.Sargos@ensem.inpl-nancy.fr

Abstract — This paper deals with the effect of static eccentricity on the rotor current dispersion when the motor operates with a broken rotor bar. Even if the induction motor has the reputation to be a world-beater for its robustness, such a defect sometimes occurs. Moreover, it presents a natural asymmetry due to the construction of the machine. It can accelerate the damage of the motor, leading it to the breakdown of a process. We only focus our attention on the alteration depending on the eccentricity severity. The study of this type of faulty condition is significant for the condition monitoring of induction motors and for better understanding the ageing acceleration of the motor.

I. INTRODUCTION

Even if the induction motor has been studied for a long time either in healthy or faulty conditions, as far as we know, few or none researches have been made considering the presence of broken bar and static eccentricity. In that case, the induction motor operates in strongly environment. Many researches have been made for the last two decades on the analysis of particular faults, but none on the simultaneous faults. It is obvious that faults generate specific signatures allowing the diagnosis and the estimation of the *State Of Health* (SOH) of the induction motor. They are generally well known in case of an individual fault but the conjunction of two or more faults is actually a huge challenge.

The monitoring of the SOH of the induction motor has been based on the *Motor Current Signature Analysis* (MCSA) for a long time [1]. This is a passive technique in comparison with specific signals injections in the stator current. Nevertheless, all techniques outline on the electric signals due to the magnetic disturbance or magnetic asymmetry in faulty conditions [2-3].

In this paper, we point out the distribution of the rotor bar currents when the motor operates under one broken bar and a static eccentricity. The main idea is to highlight the growing rate of ageing due to the dispersion of the rotor bar currents which depends on the static eccentricity severity.

II. STATIC ECCENTRICITY AND BROKEN BAR

For this study, the induction motor operates at nominal load condition and has one pair pole. The magnetic field distribution is evaluated thanks to the FEMM 4.0 software. It depends on the mechanical dimension of the electric motor and on the material used. The static eccentricity is one of the

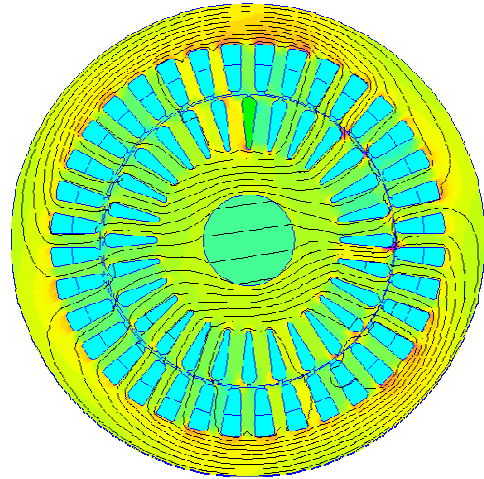

Fig. 1. Magnetic field distribution: the 8th rotor bar is broken and the static eccentricity is equal to 90%

three types which are: static, dynamic and mixed. In case of static eccentricity, the rotational axis of the rotor is a little bit displaced from the stator axis. Consequently, the air-gap is not constant (Fig. 1). The broken bar is showed in green. The entire machine is considered as to obtain the magnetic field because there is no geometrical symmetry.

The diffusion equations for the stator and for the rotor are respectively:

$$j\omega\sigma A + \nabla \times \frac{1}{\mu_r} (\nabla \times A) = \mu_0 J \quad (1)$$

$$j\omega s\sigma A + \nabla \times \frac{1}{\mu_r} (\nabla \times A) = 0 \quad (2)$$

where: μ_r is the relative magnetic permeability, A is the magnetic vector potential, σ is the conductivity of the material, ω is the supply frequency and J is the complex current density. The slip s is considered as equal to 4.6% at the nominal load. A broken rotor bar is considered as an increased value of its resistance. So its conductivity is characterized as being equal to the healthy case divided by a huge scalar. In case of healthy consideration, σ is equal to 4.45Ms/M for the aluminum. The currents flowing in the stator are as follows:

$$i_{A,B,C}(t) = I \cos(\omega t + \varphi_{(0, 2\pi/3, 4\pi/3)}) \quad (3)$$

III. SIMULATION RESULTS

The model of the induction motor as it was established allows an accurate estimation of the magnetic field in the case of mechanical and electrical rotor asymmetry. Moreover, the rotor current distribution clearly appears whatever the rotor fault severity is.

In order to highlight the impact of the eccentricity, we present some relevant figures. The first one (Fig. 2) shows the magnitude of all the 28 rotor bar currents in function of the static eccentricity, which varies from 0% to 95% of the air-gap. The first consequence of the broken bar is the modification of the rotor current distribution at its neighborhood (Fig. 3). Moreover, when static eccentricity occurs, all the rotor current distribution is modified. The greater the eccentricity is, the greater the dispersion is. The dispersion of all rotor bar currents is represented in Fig. 4. It shows that the dispersion could be close to 10% at 95% of static eccentricity. Figure 5 illustrates the dispersion under a different angle of view. As a consequence, rotor bars at the neighborhood of the broken one have higher current and the static eccentricity modifies their values as well. The results obviously depend on the broken bar relatively to the rotating field. There are given here for a quadrature position, which corresponds to the 8th bar.

Fig. 2. Module of the rotor bar currents in function of the eccentricity

Fig. 3. The rotor bar currents in function of the eccentricity

Fig. 4. Dispersion of the rotor bar currents in function of the eccentricity

Fig. 5. Dispersion of the rotor bar currents in function of the eccentricity

IV. CONCLUSION

This study emphasizes the influence of the static eccentricity on the currents flowing in each rotor bar in the presence of one broken bar. The magnitude of the current in all rotor bars are altered and more especially at the neighborhood of the broken bar. This study used the software FEMM 4.0 in order to estimate the magnetic field inside the motor and the rotor bar currents. This approach, without discussion, shows that the dispersion of each rotor bar currents is important. As a consequence, the magnetic field distribution and the asymmetric rotor current dispersion in case of static eccentricity accelerate the ageing of induction motor. Thus, other rotor bars will be defective earlier. Consequently, early fault detection is necessary in order to prevent from disastrous failures.

Abstract — It is necessary to modify the state-of-the-art of speed control theory because of the phase asymmetry in the Linear Induction Motor (LIM) and in order to the constant speed control of mover (aluminum plate) using single vector control inverter system, it is important that primary stack is located in appropriated intervals in the 3D conveyer system using LIM because of control parameters are varied.

The dynamic characteristic analysis method of the vector controlled LIM using coupled FEM and control algorithm taking into account the movement is proposed.

Moreover, in order to obtain the detailed intervals, optimization algorithm, sequential unconstrained minimization technique (SUMT) is used.

The focus of this paper is the analysis relative to selecting primary stack intervals in order to constant speed control in the 3D conveyer system using LIM.

To prove the propriety of the proposed method, the Digital Signal Processor (DSP) installed experimental devices are equipped and the experiment is performed.

I. INTRODUCTION

Linear Induction Motor (LIM) has been developed for use in the industry, transportations, OA, FA, because of the merits of direct drive and simple structure.

This paper deals with the three dimensional conveyer systems for light objects out of the auto conveyer systems.

In this system, since LIM is turn on only when carrier is over it, it can be reduced much energy and obtained many merits of high speed, automation (acceleration and deceleration control, the control of precision position), and removing the power supply cable or lead wire.

For the constant speed control of mover using single vector control inverter system, it is important that primary stack is located in appropriated intervals. And for a LIM, the constants of each phase are different due to the motor structure.

Thus, it is difficult, especially in moving secondary plate system, for the accurate speed control of LIM by the state-of-the-art of rotating machine theory.

The finite element approach has been gaining progressively greater importance than the equivalent circuit method in solution of non-linearity, anisotropy characteristic and motion analysis, especially selecting appropriated motor intervals of this paper, etc.

These approaches, which are coupled with control algorithm and

numerical analysis method, have an interest for researchers now [1]-[3].

In this paper the dynamic characteristic analysis method of the controlled LIM sets of 3D conveyer system using coupled FEM and control algorithm taking into account the movement is proposed and it has been selected a appropriated interval of primary motors in order to constant speed control through the optimization algorithm (SUMT).

II. ANALYSIS MODEL

Fig. 1 Analysis model of LIM

The two dimensional model of LIM is shown in Fig.1

The primary stack intervals increasing (2m, 1.6m, 1.2m, 0.8m, 0.6m, 0.4m) are considered by enlarging full boundary condition of both sides to x direction.

The mesh should be changed according to the movement of the mover in moving mesh area. A moving line is introduced to save computing time and to perform the process efficiently in FE analysis.

III. ANALYSIS METHOD

Fig. 2 shows the block diagram of system. Asymmetrical slip angular velocity algorithm is applied to the control logic for the comparison with flux angle of FEM.

The proposed analysis method is applied to the step velocity command (2.0 m/sec) in the vector control logic part using 10(μ sec) sampling time.

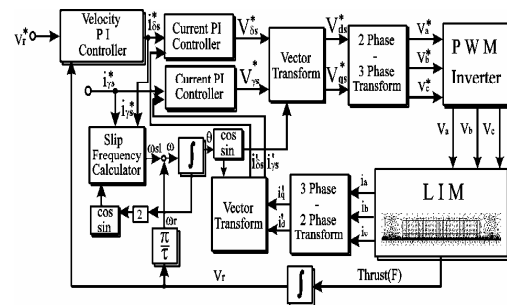

Fig. 2. Block diagram of the system

IV. SIMULATION & DISCUSSION

Fig.3 show the flux plot of analysis model example considered movement out of numerous data.

Fig 4 (a) – (e) shows the primary stack intervals (2m, 1.6m, 1.2m, 0.8m, 0.6m, 0.4m) due to the enlarging full periodic boundary condition of both side.

In the case of each primary stack intervals, it is observed that whereas speed responses highly oscillate as motor intervals is wider, speed responses in the 0.4m and 0.6m motor interval is nearly match constant speed commend 2 m/sec as shown in Fig. 5.

Fig. 6, Fig.7 represents forward-reverse speed response characteristics of each primary stack intervals.

It is observed that whereas speed responses in the 0.4m motor interval is nearly match constant speed commend, others highly delayed as motor intervals is wider and constant speed responses (2 m/sec) in 0.6m motor interval is nearly match, but especially, forward-reverse speed response is delayed as shown in Fig. 6, Fig. 7.

Therefore stator stack interval between 0.4m and 0.6m can be defined as the optimum ones for the speed vector control of the 3D conveyor system.

Moreover, in order to obtain the detailed intervals, optimization algorithm, sequential unconstrained minimization technique (SUMT) is used as shown in Fig. 8.

The more detailed optimum procedure and discusses will be represented in next extended version.

To prove the propriety of the proposed method, the Digital Signal Processor (DSP) installed experimental devices are equipped and the experiment is performed.

Abstract — This paper suggest a novel magnetic circuit method for simualting permanent magnet motors without time-consuming numerical methods. Generally, because the conventional magnetic circuit method gives us period average values like average torque, average power, getting instantanious characteristics like cogging torques, torque ripples are very hard with the magnetic circuit method. But the convolution operations according to relative angle variations of stator magnetic circuits and rotor magnetic circuits can make considering instantanious values possible. The authors compare the novel mothod with the finite element method and verify the simulation results with the measured cogging torque profile.

I. INTRODUCTION

Since permanent magnets were adopted in motors, many researchers have been studied on the analysis method of motors and the methods can be divided into two ways roughly. The first one is so-called “lumped-sum parameter method” in which method, the magnetic system is considered as a circuit and average magnetic flux values per pole are calculated for obtaining the average torque or power. This method is very convenient and simple to calculate but not easy to get instantaneous torque or back-emf values.

The other method is the distributed parameter methods like finite element method (FEM). This method is suitable for analyzing instantaneous values and can consider the magnetic saturation effect of the iron steel core so that the analysis of motors using this method is getting popular these days. But the method takes a lot more times than the lumped-sum parameter method and needs experiences of experts in the industry[1][2].

For improving these methods, some researchers have studied several new methods like Electro-Magnetic Circuit Network (EMCN) method but this improved method has same problems of taking a lot of times to obtain the results[3].

II. METHOD DESCRIPTION

In this study, the authors proposed a novel method for analyzing permanent magnet motors using divided magnetic circuits and convolution method. This new method can calculate permanent magnet motor characteristics like cogging torque and back-emf values which were considered as very

difficult characteristics to get without using some special methods or techniques.

This method is very powerful because the finite element analysis of the permanent magnet motors which is a laborious and time-taking job cannot be finished in minutes while this method can be done in several minutes.

A pole-pair structural period of motor rotor is divided into several parallel magnetic circuits and the stator magnetic circuits of one tooth period including various airgap permeances are also composed as parallel circuits. The convolution calculation of these two groups of parallel circuit values can give us the motor characteristics of cogging torques or back-emf values.

Fig. 1 shows the HDD spindle motor which uses outer-rotor type permanent ring magnet and back-yoke outside of the magnet.

Fig. 1. HDD spindle motor

Fig.2 shows the inside of the spindle motor. There are the stator teeth and the ring-type magnet and backyoke rotor in the spindle motor. To strengthen the mmf of the magnetic circuit and prevent the leakage flux, the backyoke is supposed to be outside of the magnet.

Fig. 2. The stator teeth and the ring-type magnet and backyoke rotor of the spindle motor

Fig.3 shows the stator and rotor magnetic circuits of the spindle motor and concept of convolution method. Because the magnet is not segmented, there are dead-zone between magnet poles and these dead-zone must be considered in analyzing the motor characteristics also.

Fig. 3. Stator and rotor magnetic circuits of the spindle motor and concept of convolution method

The most strong point of this method is that when the design parameters are changed, the design result can be obtained very easily. For an example, the cogging torque profile changes can be easily checked out instantaneously when the slot open width(length between a tooth and neighbor tooth) is changed from 1mm to 1.5mm. Fig. 4 shows the calculated cogging torque when the slot open is 1mm and fig. 5 shows the result when the slot open is 1.5mm.

The changes in the magnetization profile and the changes in tooth shape are also can be considered by this method very easily.

The extended paper will contain more detail method and the comparison with the finite element analysis and the measured values.

Fig. 4. Calculated cogging torque when the slot open is 1mm.

Fig. 5. Calculated cogging torque when the slot open is 1.5mm.

III. CONCLUSION

The permanent magnet motors are very important devices in modern industry. So, it is important to find out new method of predicting the performance of the permanent magnet motors much faster than finite element analysis. This paper is very useful to the researchers who search the method to analyze the permanent magnet motors.

Design of copper die-cast rotor bar of single phase induction motor for high starting torque

Kwangsoo Kim, Jong-Bin Im, Seung-Joo Kim, Won-Ho Kim and Ju Lee, Senior Member, IEEE
 Dept. of Electrical Engineering, Hanyang University
 17 Haengdang-dong, Seongdong-gu, Seoul, 133-791, South Korea
 nicekwangsoo@naver.com

Abstract — This paper describes design of rotor slot of single phase induction motor with copper die-cast rotor cage for high starting torque. We applied die-cast copper rotor cage to single phase induction motor for premium level high efficiency. But Efficiency increases slightly and starting torque is extremely reduced due to higher conductivity of copper rotor bar. Therefore we design the optimal shape of copper rotor bar of single phase induction motor for high starting torque and high efficiency. This study is base on the FEM analysis.

I. INTRODUCTION

Recently the oil price is continuously increasing and the natural resources are getting reducing so that the attention of the energy saving and environmental protection is getting higher. Therefore, it is not a future problem for us to make the motors have a high efficiency. The single phase induction motor is used widely by all the industrial, residential and commercial applications in the present day and we need to develop high efficiency induction motor [1].

In recently, there has been an effort to make high efficiency induction motor. The copper die-cast rotor bar has been also applied to high efficiency induction motor for higher efficiency [2, [3]. In case of single phase induction motor, it needs to have high starting torque as well as high efficiency. But there is trade-off between efficiency and starting torque. Therefore we study design shape of rotor slots of the single phase induction motor using FEM analysis for high efficiency and high starting torque.

II. COPPER DIE-CAST MOTOR

First, we design high efficiency single phase induction motor with aluminum die-cast rotor bar. The specification of motor is 1.12 kW, 4 pole and capacitor - run & start type. To make premium efficiency level motor, copper die-cast rotor bar is applied this motor. It is important to note that the improvements in motor performance by substituting copper for aluminum in this rotor were made without re-design for the copper die-cast. Table I. shows characteristics of aluminum die-cast motor and copper die-cast motor using FEM analysis and experiment result.

TABLE I
 EFFICIENCY AND STARTING TORQUE OF TWO TYPES SPIM

Material of die-cast	Efficiency [%]	Starting torque [Nm]
Aluminum (FEM)	85.4	11.39
Aluminum(Exp.)	84.2	11.5
Copper (FEM)	86.4	8.09

Though just only experiment of aluminum die-cast motor is performed but we can estimate results of copper die-cast motor from FEM analysis. The copper die-cast motor has higher efficiency but far lower torque than the aluminum die-cast motor. This motor should be satisfied twice of rate torque, 6[Nm]. Figure 1 shows that adjustment starting capacitance has limit to improve starting torque. Therefore, to improve starting torque, the double cage bar is chose for copper die-cast rotor bar. Because we can achieve both of high starting torque and high efficiency using double cage rotor bar [4].

Fig. 1. Starting torque according to start capacitance

III. DESIGN PROCESS OF SPIM WITH COPPER DIE-CAST ROTOR BAR

Figure 2 show design process of SPIM with copper die-cast bar for high efficiency and starting torque. First, the stator and basic rotor shape of high efficiency SPIM is designed using magnetic equivalent circuit. Next, we should choose and design the basic shape of double cage bar using numerical method. Finally, we can obtain optimal shape of double cage bar through parametric analysis using FEA.

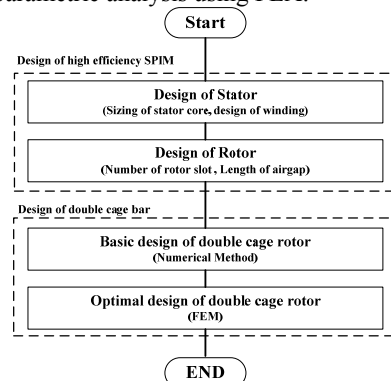

Fig. 2. Design process of double cage bar for premium efficiency level SPIM

IV. BASIC DESIGN OF DOUBLE CAGE ROTOR BAR

There are various types of double cage rotor. Among them, the basic model is shown in Figure 3. First, the basic shape of model is designed considering of rotor resistance and leakage reactance [4]. The starting resistance is at start

$$(R_r)_{s=1} = \frac{t_{LR} P_n}{3 \cdot 0.95 \cdot I_{LR}^2} \quad (1)$$

And from the equivalent circuit at start, rotor leakage inductance at start(S=1) is

$$(L_r)_{s=1} = \left(\sqrt{\left(\frac{V_{ph}}{I_{LR}} \right)^2 - (R_s + (R_r)_{s=1})^2} - L_{ls} \right) \frac{1}{\omega_1} \quad (2)$$

Using (1), (2), the resistances of working bar and starting bar can be calculated. And we can calculate working bar and starting bar cross section as following equation (3).

$$A_{w,s} = \frac{\rho_{Co} L}{R_{be}} \quad (3)$$

Here, L is length of stack, $R_{be,bs}$ is working bar and starting bar approximate resistance. The middle bar is designed using parametric analysis in chapter V.

Fig. 3. Basic shape of double cage bar and design parameter for optimization

V. OPTIMAL DESIGN OF ROTOR SLOT OF SPIM WITH COPPER DIE-CAST BAR

Figure 3 shows design parameter for optimization using parametric analysis. Also, main effects of design parameters are analyzed for starting torque and efficiency by FEM analysis in shown figure 4.

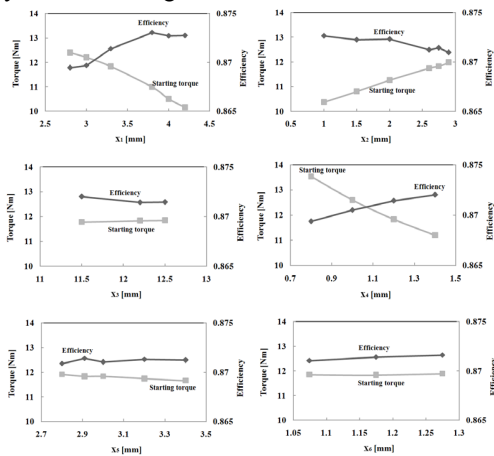

Fig. 4. Parametric analysis of design variable

Through the parametric analysis, we may choose the design main parameters x_1, x_2, x_4 . Other variables are fixed at their optimal values. The selected parameters are optimized by parametric analysis again. Through the design process, we can obtain the optimized model shown Figure 4.

Fig. 4. Optimal shape of double cage rotor slot

Finally, we need to adjust the starting capacitor to make higher starting torque. Through adjustment of starting capacitance, starting torque increases by 11.8 Nm. Figure 5 shows experiment instrument of load test. And table III shows FEA result and experiments result. The optimized motor has higher efficiency and starting torque. Here, there is the difference of efficiency between two methods due to copper die-cast skill.

In this paper, we designed premium level high efficiency single phase induction motor with high starting torque using FEA method.

TABLE II
THE RESULTS OF OPTIMIZED DOUBLE CAGE BAR SPIM WITH COPPER DIE-CAST BAR

Method	Efficiency [%]	Starting torque [Nm]
FEA method	87.59	11.8
Experiments	89.2	12.01

Fig. 5 Experiment instrument of load test

Abstract — In this paper, we proposed a simulation algorithm for driving characteristics considering nonlinear parameters of interior permanent magnet synchronous motor (IPMSM) for electric vehicle such as d-axis and q-axis inductances. D-axis and q-axis inductances are changed according to both current magnitude and current angle between q-axis and current axis because of nonlinearity of magnetic flux density in rotor core. Therefore, the calculation of d-axis and q-axis inductances with nonlinearity of magnetic flux density is performed by using FEM. We can get precise driving performance of traction motor for electric vehicle adopting nonlinear d-axis and q-axis inductance table. Finally driving performance by proposed algorithm was verified by experiment of proto type.

I. INTRODUCTION

It is important to calculate the exact value of d-axis and q-axis inductances at the design step of interior permanent magnet synchronous motor (IPMSM) because these parameters are related to torque and speed characteristics of IPMSM closely if it is controlled by flux weakening control mode [1], [2]. It is very difficult to calculate the exact d-axis and q-axis parameters in an application area which is needed for compact and high power density design owing to magnetic flux saturation effect in its core. Analytical method by using equivalent magnetic circuit makes the error of d-axis and q-axis inductance values maximize under the extreme magnetic saturation area [3]. Therefore, d-axis and q-axis inductances considering nonlinear characteristics according to current angle between q-axis and current axis as well as magnitude of armature current should be analyzed by FEM.

In the paper, a simulation algorithm for driving performance of IPMSM considering nonlinearity of d-axis and q-axis inductances according to current angle and current magnitude is studied. Moreover, the algorithm is very effective for performance analysis with field weakening control which needs the information on the d-axis and q-axis inductances according to current angle. The driving performance considering constant value of d-axis and q-axis inductances is compared with proposed one. Finally, the validity of proposed algorithm is verified through the experiment of proto type.

II. INDUCTANCE CALCULATION

Fig. 1 shows analysis model of IPMSM for the paper. It is a 4kW traction motor of small automobiles whose power source is 48V battery.

There are several methods for the calculation of d-axis and q-axis inductances [4]. In the paper, we adopted the inductance calculation method derived from two-axis vector diagram of IPMSM as shown in Fig. 2. In the figure, we can calculate d-axis and q-axis inductances by using following equations, respectively.

$$L_d = \frac{\Psi_0 \cos \alpha - \Psi_a}{i_d} \quad (1)$$

$$L_q = \frac{\Psi_0 \sin \alpha}{i_q} \quad (2)$$

where, Ψ_0 is linkage flux of phase winding at load operation, Ψ_a is linkage flux of phase winding at no load operation and α is angle between Ψ_0 and Ψ_a .

D-axis and q-axis inductances are changed according to both input current magnitude and current angle between q-axis and current axis. The inductance calculation results by using FEM are showed in Fig. 3(a) and Fig. 3(b), respectively. The conditions for the analysis of Fig. 3(a) are fixed load angle δ and variable input current i_a . On the other hand, the conditions for the analysis of Fig. 3(b) are variable load angle δ and fixed input current i_a which is rated current at continuous mode, 46.5A.

(a) Inductance characteristics according to input current.

(b) Inductance characteristics according to load angle (or current angle)
Fig. 3. The analysis results of d-axis and q-axis inductances by FEM.

III. ALGORITHM FOR DRIVING PERFORMANCE OF TRACTION MOTOR FOR ELECTRIC VEHICLE

In general, IPMSM for electric vehicle is controlled with maximum power control mode. However, d-axis and q-axis inductances have nonlinearity due to magnetic saturation in the core. Therefore, we proposed driving performance algorithm of IPMSM considering nonlinear d-axis and q-axis inductances in the paper. Fig. 4 shows the flowchart for driving performance algorithm which is divided into two control modes of constant torque and constant power. It is important to deal with inductance table between load angle and current magnitude in order to consider nonlinearity of d-axis and q-axis inductances. From the algorithm, we can calculate voltage, current, efficiency, power factor, torque, output power according to motor speed.

If we ignore nonlinearity according to load angle, we have remarkable errors, especially near high speed region. The comparison results of driving performance considering between linear value of inductances and nonlinear ones are shown in Fig. 5. It corresponds to the torque and power characteristics according to motor speed in case of intermittent operation with input current, 120A.

IV. CONCLUSION

In the paper, FEM analysis method of nonlinear d-axis and q-axis inductances of IPMSM and the algorithm of driving performance with maximum power control mode considering the nonlinear d-axis and q-axis inductances are proposed and

verified through experiment. The proposed algorithm can make efficiency map of IPMSM with ease which is main design target of traction motor for electric vehicle.

Abstract — This paper deals with the characteristics analysis & optimum design of Synchronous Reluctance Motor (SynRM) with anisotropy rotor using a coupled Finite Element Method (FEM) & Response Surface Methodology (RSM). The focus of this paper is the characteristics analysis & optimum design relative to the output power on the basis of rotor materials of a SynRM. The coupled Finite Elements Analysis (FEA) & Preisach model have been used to evaluate nonlinear solutions. Comparisons are given with characteristics of normal synchronous reluctance motor and those of anisotropy rotor SynRM (ANISO-SynRM), respectively. The feasibility of using RSM with FEM in practical engineering problem is investigated with computational examples and comparison between the fitted response and the results obtained from an analytical solution according to the design variables of rotor in anisotropy rotor SynRM.

I. INTRODUCTION

The performance of a synchronous reluctance motor (SynRM) in terms of torque and power factor depends on the two-axis inductance L_d and L_q of the machine. The large difference of (L_d-L_q) and L_d/L_q ratio is good for the machine's properties. Therefore, Considerable attention has been paid in the past to improve rotor design of SynRM [1] – [3].

However the mechanical problems related to a segmented type of rotor have been disregarded up to now. A relevant advantage of the segmented structure (with respect to the axially laminated one, for example) is the rotor laminations can be punched, as in an induction motor: of course, thin ribs have to be left between adjacent segments.

The presence of these ribs introduces an additional q-axis flux and the torque performance is lowered.

In construction, the simplest way is to accept this loss of performance and to reduce it by accurately proportioning and positioning the rib width. Another solution is to proceed as before (punching), then cast the rotor of a suitable material and, finally, machine-out the ribs. The casting material should be non-conduction in order to avoid eddy currents and related effects. A plastic material can be used but some problems arise because of the low elasticity module.

By adding a proper quantity of permanent magnets the torque density and power factor of SynRM can be greatly increased. It is called Permanent Magnet Assisted Synchronous Reluctance Motor (PMASynRM) [4]-[5].

New solution is to use as anisotropy materials, then wire cut the rotor of a suitable material and, finally, removed flux of the ribs.

This paper deals with the characteristics analysis & optimum design of Synchronous Reluctance Motor (SynRM) with anisotropy rotor using a coupled FEM & RSM.

II. ANALYSIS MODEL

The approximation consists of a priori imposing the working flux density of the rib iron B_s : this depends on the applied mmf and on the rib length, of course, but cannot increase beyond a certain (practical) limit because of the iron saturation.

Moreover, equal width ribs can be supposed as shown in Fig. 1. Each width would follow from the mechanical (finite element) design; however, a practical limit exists in cutting very thin ribs, and an equal width seems a reasonable hypothesis, at least for small machines.

Owing to the above hypotheses, the flux flowing in a rib is given by (1). The torque equation is modified, in this case, as in (3), showing the torque loss due to rib flux of (2)

$$\phi_{wk} = B_s w l \quad (1)$$

$$\lambda_r = \frac{4}{\sqrt{3}} w l N B_s \quad (2)$$

$$T = \frac{3}{2} \frac{P}{2} (k_{dq} \lambda_{md} i_q - \lambda_r i_d) \quad (3)$$

By using a proper anisotropy material of rotor the torque density and power factor of SynRM (removed second term of (3)) can be greatly increased as shown in Fig. 2.

Fig. 1. Rib profile & path of rib flux

Fig. 2. Rib flux path of anisotropy model

III. ANALYSIS USING COUPLED FEM AND PREISACH MODELING

Fig. 3, 4. show the effects of anisotropy rotor structure that the q axis rib flux is assumed to completely cancel at some positions (except ribs from 0 degree to 5 degree and from 175 degree to 180 degree, no all rib) as shown in Fig. 5, 6. Flux distribution for q-axis excitation, for the normal SynRM and ANIRO-SynRM with a conventional stator having 24 slots and two poles, are shown in Fig. 5, 6.

Whereas the rotor rib tangential flux is appeared in a normal SynRM, the rotor rib tangential flux would have nearly zero since the spatial anisotropy in an ANIRO-SynRM is constructed, resulted in Fig. 3, 4.

Fig. 3. Radial rib flux density distribution of SynRM and ANIRO-SynRM

Fig. 4. tangential rib flux density distribution of SynRM and ANIRO-SynRM

Fig. 5. q-axis plots of SynRM

Fig. 6. q-axis plots of ANIRO-SynRM

IV. OPTIMIZATION PROCEDURE

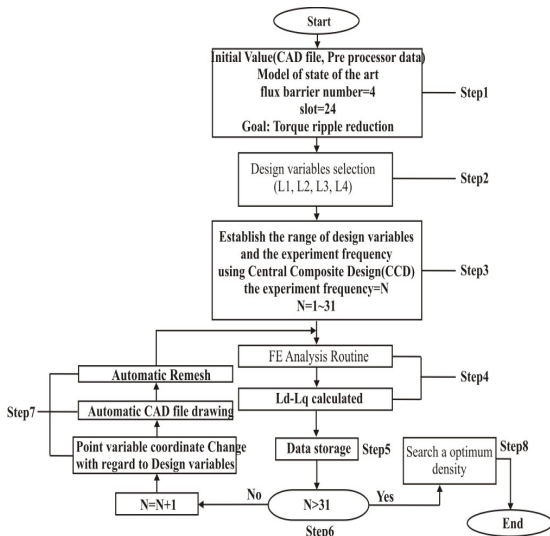

Fig. 7. The flow chart of design procedure

Fig. 8. Design variables and variation direction of the SynRM

Fig. 7 shows the flow chart of total design strategy.

Fig. 8 shows design variables and variation direction for the shape transformation according to flux barrier width.

Design procedure according to the flow chart is as follows;

Step1. : Set the initial value (CAD file, Pre-processor data). And the initial model is assigned to flux barrier=4, slot=24.

Step2. : flux barrier width (L1~L4) in rotor are adopted the design variables related to torque density in the SynRM. However, the ribs have a fixed value due to inherent manufacturing limitations.

Step3. : The range of design variables and experiment frequency is established by using the central composite design (CCD). The experiment frequency (N) is 31th.

Step4. : Finite element analysis (FEA) is performed and Ld-Lq is calculated.

Step5. : The Ld-Lq obtained from FEA, are stored.

Step6. : The experiment frequency (N) > 31?

► Yes: Search a optimum torque density. ► No: N=N+1

Step7. : The example of the point variables and variation direction of flux barrier rotor is well shown Fig. 9.

When the rotor shape according to variables (L1~L4) is varied, they have a difficulty in performing a lot of the pre-processor for FEA. For this reason, the new CAD file is redrawn with regard to the change of the design variables automatically. Next the process of automatic mesh generation follows. In mesh generation, mesh data doesn't change the node number, element number, region, boundary condition, etc., but only x, y coordinate data of the design variables. In this way, the proposed pre-processor procedure can be performed in a short period of time. In this way, this procedure goes on until N=31.

Step8. : The response surface model is created by data obtained from FEA according to an established range. Therefore, it is possible to get optimum torque density.

The RSM seeks to find the relationship between design variable and response through statistical fitting methods, which are based on the observed data from system.

More detailed results and discussion will be given in final paper. And the mathematical expressions for response surface methodology will be also given in extended version

Irreversible Demagnetization on Permanent Magnet Motors

Luiz von Dokonal, Flavio J. H. Kalluf
Whirlpool S.A. – Embraco Compressors Unit
Rua Rui Barbosa, 1020, Caixa Postal 91, Joinville – SC, Brazil
ldokonal@embraco.com.br

Abstract — Permanent magnet electromagnetic devices generate induced voltages (EMF) at any electrical conductor submitted to its magnetic field. These induced voltages are proportional in module and frequency to the rotational speed.

Low impedance circuits crossing this magnetic field can generate high induced currents, and, since the direction of the field is always opposed to the source field, in some cases the magnet can be irreversibly demagnetized.

The irreversible demagnetization degenerates the startability, reduces the efficiency and overheats the motor, so it must be avoided by all means.

The main goal of this study is the evaluation of this phenomenon, trying to reproduce it by analytical and FEA analysis.

I. INTRODUCTION

The electrical motors can be classified in terms of quality mainly by its performance, cost, robustness and reliability. It means the product attractiveness cannot be measured only by its performance, but also for how good it can cope with overloads, voltage fluctuations, high or low temperatures and other environmental issues. Also, the reliability is related to the product ability to predict and prevent possible problems, which can come from an external source or even a not previewed fail mode of the motor and its control.

Regarding permanent magnet motors, many fail mode are covered by the control, and most of them are easy to be detected since the current can be monitored. In the other hand, some problems can occur internally on the motor, generating closed loops that are difficult to be detected by the control.

The specific fail mode to be analyzed by this study is the stator closed loop generated by a short circuit between the stator turns. At first, an analytical approach will be suggested for didactic reasons and, finally, a FEA analysis example will be presented.

II. DEMAGNETIZATION BASICS

A permanent magnet as show in Fig.1a has a demagnetization curve as shown in Fig.1b.

Fig. 1a - Example of magnetic circuit with magnet and source coil

Fig. 1b - Magnetization curve for Fig.1a circuit

The effective air gap g in Fig.1a represents the magnet thickness plus the air gap thickness. B_0 is the magnetic induction in the air gap generated by the magnet at operation point. N is the number of turns and I is the demagnetization current.

The demagnetization can take place when is applied a current to the winding so as to generate a reverse field to the magnet, moving the magnet operation point beyond H_c ($H_c = H(P1) - N \cdot I / g$). In this case, even when the source current is removed, the magnet original remanent induction will not be restored (point $P2$ in Fig.1b). The new $P2$ point location will depend on how severe was the demagnetization. The induction value at this point can even be zero or lower (reverse magnetization). The solid line in Fig.1b shows the normal operation region and the dashed curve shows the behavior of the magnet during the demagnetization procedure, caused by the reverse field.

The demagnetization phenomenon depends on the following factors:

- Magnet class (H_c and B_r are related only to the magnet class);
- Demagnetizing field magnitude;
- Effective air gap thickness (magnet thickness + air gap thickness).

B_0 and H_0 values (which are constant at any point of the magnet, since rectangular magnets do not have significant flux fringing) depend on the magnet thickness, air gap thickness and B_r (remanent induction), according to the following relations:

$$B_0 = B_r \cdot L_m / (L_m + g)$$

$$H_0 = (B_r - B_0) / \mu_0$$

where,

$$L_m = \text{magnet thickness}$$

$$\mu_0 = 4 \cdot \pi \cdot 10^{-7}$$

For permanent magnets which have radial field orientation, mounted externally on rotor surface, the B_0 value varies as a function of the magnet radius. In the full version of the paper the equations that describe the variation of B_0 will be shown in a simplified form. These simplified equations lead to a good precision for almost all cases where the magnet thickness is less than 30% of the rotor radius.

III. GENERATED EMF AND DEMAGNETIZATION CURRENT

Now let us suppose a short-circuit coil is placed on the circuit as shown in Fig.2

Fig. 2 - Example of magnetic circuit with with a short-circuit coil

The short-circuit coil, which is linking the alternating flux generated by the source coil will produce an induced voltage, proportional to the frequency and magnitude of the flux. This voltage will generate currents which setups a magnetic flux in opposed direction to the source field (Lenz's Law). Fig. 3a and fig. 3b shows the field map for both cases.

Fig. 3a - Field map for fig.1a circuit

Fig. 3b - Field map for fig.2 circuit

Note that in fig.3b, the demagnetizing effect is clearly seen (red arrow). Note only the pink color denotes a magnetic induction above B_c (minimum induction to prevent demagnetization). By the same principle, the demagnetization can take place on most permanent magnet motors, as can be seen on figs.4a, 4b and 4c.

Fig. 4 - Demagnetization effect on a brushless-DC motor

IV. CONCLUSION

The previous examples show how a short-circuit fail can lead to demagnetization in permanent magnet devices. In the full paper version a theoretical approach will be used to calculate the minimum induction value, in order to quantify the risk of demagnetization on a didactic motor.

Abstract — This paper presents useful improvements of FE Post-processors for machine designer, specially in the case of PM fractional slot machines with sinusoidal current supply. The computation of maximal flux densities on each stator mesh during one half of electrical period provides more information than instantaneous values of magnetic fields. Implementation method is detailed for linear and non-linear solving process to perform fast analysis of iron losses with flux weakening operations and efficiency optimization. As an example, a 12 slot-10 pole PM machine with concentrated winding is presented to illustrate this method and compare different iron loss models.

I. INTRODUCTION

Design of electrical machines is often based on an analytical method with an estimation of no-load flux densities in the air-gap to calculate the dimensions of the magnetic circuit. Next step is to perform a Finite Element Analysis (FEA) to optimize geometry, to compute the equivalent circuit parameters and to validate performances of the machine for rated operation. Well-known post-processors [1] can be applied for conventional machines, but some improvements are required to study fractional slot machines because the magnetic field pattern under load is not repetitive for each rotor pole. Indeed, the distribution of magnetic flux densities for a given rotor position or a given simulation time step does not provide useful information for designer and is not significant. It's better to compute the maximal flux densities in each stator mesh on a half electrical period, with movement of the rotor and sinusoidal rated current supply. The method is efficient to investigate possible stator modifications, to compare different winding configurations and to analyze the effect of different supply current control angles for flux weakening operation. Same approach is used to investigate iron loss.

II. MACHINES WITH FRACTIONAL SLOT WINDING

Some synchronous machines have a fractional number of slots per pole and per phase to reduce the EMF harmonic content (hydraulic alternators [2]), to simplify winding realization (machines with concentrated winding [3]) or to minimize cogging torque ripple (permanent magnet machines [3]). In such a case, the phase coil arrangement in the stator is not repetitive under every pole of the rotor and this generates some MMF sub-harmonics when the machine is fed by sinusoidal currents [2]. This phenomenon is very important in PM machines with concentrated windings because there is only a single coil per pole. When the stator magnetic reaction is

greater than 0.5 pu, there are local magnetic saturation zones in the yoke that increase the magnetic losses and torque ripple. The distribution of the flux densities is very different from that obtained during no-load operation and this modification must be taken into account in the design of the machine. However, saturated zones are difficult to identify when one uses drawings and computations from instantaneous values of magnetic field.

III. POST-PROCESSOR IMPROVEMENTS

The calculation of the values of maximal flux densities is very easy to implement with a non-linear solving approach, as illustrated by Fig.1. However, very fast analysis can be performed with post-processors using results from linear solving method and a single matrix inversion. It is possible to calculate separately, the field of permanent magnets for different rotor positions and the field of stator phase windings using a constant value of current density. Linear combinations of these results with a post-processor is particularly powerful to simulate flux weakening with sinusoidal current waveforms and compute a large number of steady state operation points to perform efficiency analysis. This method also permits to estimate the magnetic losses in each mesh with an analytical expression for the specific magnetic losses density [4]. In this case, one can apply a constant value of maximal flux density limit to simulate magnetic saturation effect. Generally this assumption is valid during flux weakening operation of a surface mount PM machine if magnetic circuit is not saturated during a maximal torque control ($I_d=0$). These methods will be detailed in the final paper.

IV. ANALYSIS OF A 12 SLOT-10 POLE MACHINE WITH CONCENTRATED WINDINGS

We have selected a 3 phase, 12 slot and 10 pole PM machine to illustrate analysis of flux weakening operation using post-processing approach. Fig. 2 shows the distribution of full-load instantaneous magnetic flux densities for a given rotor position and a given supply current with a small amount of flux weakening. This data is difficult to use in design process because of variable values of flux densities in each stator part. Fig. 3 shows the distribution of the maximal values of the magnetic flux densities computed with results from several rotor positions, during no-load operation. In this case, it is easier to measure maximal flux densities in any part of the machine (tooth tips, teeth, yoke) for a validation of magnetic saturation effect. Fig.4 shows the distribution of maximal

values of full-load flux densities calculated by the same approach for the same machine with a single layer winding. One can see important modifications of flux density pattern in the yoke compared to Fig.3. Stator magnetic reaction decreases maximal flux densities in the teeth and tooth tips but increases flux densities in some parts of the stator yoke. This is a particularity of fractional slot machine revealed by maximal flux densities drawings. Fig.5 shows the distribution of the local magnetic loss densities with conventional laminated material. The combined hysteresis and eddy current losses per kg are calculated using following equation [4]:

$$P_{mag_{i,j}} = k_h \cdot f \cdot B_{Maxij}^2 + k_e \cdot f^2 \cdot B_{Maxij}^2 \quad (1)$$

The loss density distribution is similar to maximal flux density pattern. Some parts of stator yoke have high losses and it will be interesting to increase the section of magnetic circuit in these regions and decrease sections in the others. Table I shows a comparison of iron losses in different parts of magnetic circuit with no load and flux weakening operation.

Abstract—This paper describes a combination of Direct Torque Control (DTC) and Space Vector Modulation (SVM) for an adjustable speed sensorless induction motor (IM) drive. The motor drive is supplied by a two level SVPWM inverter. The inverter reference voltage is obtained based on input-output feedback linearization control, using the IM model in the stator d-q axes reference frame with stator current and flux vectors components as state variables. Moreover, a robust full-order adaptive stator flux observer is designed for a speed sensorless DTC-SVM system and a new speed-adaptive law is given. By designing the constant observer gain based on LMI, the stability of the observer systems is ensured. Finally, the effectiveness and validity of the proposed control approach is verified by computer simulation results.

I. INTRODUCTION

Direct torque control based on space vector modulation (DTC-SVM) preserve DTC transient merits, furthermore, produce better quality steady-state performance in a wide speed range. At each cycle period, SVM technique is used to obtain the reference voltage space vector to exactly compensate the flux and torque errors. The torque ripple of DTC-SVM in low speed can be significantly improved.

In this paper, SVM-DTC technique based on input-output linearization control scheme for induction machine drives is developed. Furthermore, a robust full-order speed adaptive flux observer is designed for a speed sensorless DTC-SVM system and a speed-adaptive law is given. The constant observer gain, which is obtained by solving two bilinear matrix inequalities (BMIs) using LMI Toolbox in MATLAB [1], can overcome the real-time computational complexity of the adaptive observer gain in [2]. The stability of the speed adaptive stator flux observer is also guaranteed by the constant gain in very low speed. The proposed control algorithms are verified by extensive simulation results.

II. DTC-SVM BASED ON INPUT-OUTPUT LINEARIZATION

The DTC-SVM scheme is developed based on the IM torque and the square of stator flux modulus as the system outputs; stator voltage components defined as system control inputs and stator currents as measurable state variables.

Define the controller objectives e_1 and e_2 as

$$e_1 = T_e - T_{\text{eref}} \quad (1)$$

$$e_2 = |\psi_s|^2 - |\psi_{\text{sref}}|^2 \quad (2)$$

where, T_{eref} , T_e , ψ_{sref} , ψ_s are reference and real value of electromagnetic torque, stator flux respectively.

According the model of induction, the time derivative of e

is as (3),

$$\begin{bmatrix} \dot{e}_1 \\ \dot{e}_2 \end{bmatrix} = \begin{bmatrix} g_1 \\ g_2 \end{bmatrix} + \mathbf{D} \begin{bmatrix} u_D^* \\ u_Q^* \end{bmatrix} \quad (3)$$

where, $g_1 = p_n \left[c(\psi_D i_Q - \psi_Q i_D) + \omega_m (\psi_D i_D + \psi_Q i_Q) - \frac{\omega_r}{\sigma L_s} |\psi_s|^2 \right]$,

$$g_2 = -2R_s (\psi_D i_Q + \psi_Q i_D), \quad \mathbf{D} = \begin{bmatrix} (i_Q - \frac{\psi_Q}{\sigma L_s}) & -(i_D - \frac{\psi_D}{\sigma L_s}) \\ 2\psi_D & 2\psi_Q \end{bmatrix}$$

where ψ_D , ψ_Q , u_D , u_Q , i_D , i_Q are respectively the d-q axes of the stator flux, stator voltage and stator current vector components, ω_m is the rotor electrical angular speed, L_s , L_r , L_m are the stator, rotor, and magnetizing inductances, respectively, $\sigma = 1 - (L_m^2 / L_s L_r)$ and R_s , R_r are the stator and rotor resistances, respectively. $c = -1 / (\sigma(R_s / L_s + R_r / L_r))$

According to $i_s = \frac{\psi_s}{\sigma L_s} - \frac{L_m}{\sigma L_s L_r} \psi_r$, the characteristic

determinant of \mathbf{D} is as follows

$$\det(\mathbf{D}) = -\frac{4L_m}{\sigma L_r} p_n |\psi_r| \cdot |\psi_s| \cos(\psi_r, \psi_s) \quad (4)$$

From (4), \mathbf{D} is a nonsingular matrix since the inner product of stator flux vector and rotor flux vector can not be physically zero.

Based on input-output feedback linearization, the following control inputs are introduced.

$$\begin{bmatrix} u_D^* \\ u_Q^* \end{bmatrix} = \text{inv}(\mathbf{D}) \begin{bmatrix} -g_1 + u_x \\ -g_2 + u_y \end{bmatrix} \quad (5)$$

where, u_x , u_y are the auxiliary control inputs and are defined based on the pole placement concept of the linear control systems so that

$$u_x = -c_1 e_1, \quad u_y = -c_2 e_2 \quad (6)$$

where, c_1 and c_2 are positive constants.

III. SPEED ADAPTIVE STATOR FLUX OBSERVER

The state observer, which estimates the state current and the stator flux together, is given by the following equation[2].

$$\frac{d\hat{x}}{dt} = \hat{\mathbf{A}}\hat{x} + \mathbf{B}u + \mathbf{G}(\hat{i}_s - i_s) \quad (7)$$

$$\hat{i}_s = \mathbf{C}\hat{x} \quad (8)$$

where $\hat{\cdot}$ denotes the estimated values and \mathbf{G} is the observer gain matrix which is chosen so that the stability of the flux observer can be guaranteed. In order to derive the adaptive scheme, Lyapunov theorem is utilized. Now, let us define the following Lyapunov function

$$V = \mathbf{e}^T \mathbf{P} \mathbf{e} + (\hat{\omega}_r - \omega_r)^2 / \lambda \quad (9)$$

The time derivative of V along error equation (4) becomes:

$$\frac{dV}{dt} = \mathbf{e}^T \left[(\mathbf{A}_1 - \mathbf{G}\mathbf{C})^T \mathbf{P} + \mathbf{P}(\mathbf{A}_1 - \mathbf{G}\mathbf{C}) + \omega_r (\mathbf{A}_\omega^T \mathbf{P} + \mathbf{P}\mathbf{A}_\omega) \right] \mathbf{e} - (\hat{\mathbf{x}}^T \Delta \mathbf{A}^T \mathbf{P} \mathbf{e} + \mathbf{e}^T \Delta \mathbf{A} \hat{\mathbf{x}}) + \frac{2}{\lambda} (\hat{\omega}_r - \omega_r) \frac{d\hat{\omega}_r}{dt} \quad (10)$$

Let

$$-(\hat{\mathbf{x}}^T \Delta \mathbf{A}^T \mathbf{P} \mathbf{e} + \mathbf{e}^T \Delta \mathbf{A} \hat{\mathbf{x}}) + \frac{2}{\lambda} (\hat{\omega}_r - \omega_r) \frac{d\hat{\omega}_r}{dt} = 0, \quad (11)$$

if we select observer gain matrix \mathbf{G} so that the validity of the inequality

$$(\mathbf{A}_1 - \mathbf{G}\mathbf{C})^T \mathbf{P} + \mathbf{P}(\mathbf{A}_1 - \mathbf{G}\mathbf{C}) + \omega_r (\mathbf{A}_\omega^T \mathbf{P} + \mathbf{P}\mathbf{A}_\omega) < 0 \quad (12)$$

can be guaranteed, the state observer is stable.

The adaptive scheme for speed estimation is given by

$$\hat{\omega}_r = \left(K_p + \frac{K_i}{p} \right) (\hat{\psi}_s^T) \mathbf{J} (\mathbf{i}_s - \hat{\mathbf{i}}_s) \quad (13)$$

By the Lyapunov stability theory, the state observer is asymptotically stable if there is symmetric positive definite matrix \mathbf{P} and matrix \mathbf{G} such that (12) hold.

Suppose ω_{\max} is upper bound of permitted rotor speed. For ensuring system with a certain reliability and robustness, ω_{\max} is selected larger than rated speed of IM in general.

When the speed changed in the interval $[-\omega_{\max}, \omega_{\max}]$, the state observer is stable can be guaranteed by the following two matrix inequalities:

$$(\mathbf{A}_1 - \mathbf{G}\mathbf{C})^T \mathbf{P} + \mathbf{P}(\mathbf{A}_1 - \mathbf{G}\mathbf{C}) + \omega_{\max} (\mathbf{A}_\omega^T \mathbf{P} + \mathbf{P}\mathbf{A}_\omega) < 0 \quad (14)$$

$$(\mathbf{A}_1 - \mathbf{G}\mathbf{C})^T \mathbf{P} + \mathbf{P}(\mathbf{A}_1 - \mathbf{G}\mathbf{C}) - \omega_{\max} (\mathbf{A}_\omega^T \mathbf{P} + \mathbf{P}\mathbf{A}_\omega) < 0 \quad (15)$$

Inequality (14) and (15) are bilinear matrix inequalities (BMIs) about matrix variables \mathbf{P} and \mathbf{G} . Noticing that if fixed matrix \mathbf{G} , BMIs (14) and (15) will become linear matrix inequalities (LMIs) about matrix variable \mathbf{P} ; and if fixed \mathbf{P} , BMIs (14) and (15) will become linear matrix inequalities (LMIs) about matrix variable \mathbf{G} . So, the feasible solution of BMIs (14) and (15) can be obtained by LMI toolbox in MATLAB [1].

IV. SIMULATIONS

To verify the DTC-SVM scheme based on input-output linearization and adaptive observer, simulations are performed in this section. The block diagram of the proposed system is shown in fig.1. The speed and torque response curves of conventional DTC and DTC-SVM are shown fig. 2. The command speed value is 5 rpm in both two systems. At startup, the system is unloaded, the load torque is changed to 17Nm at $t=1s$, then the load torque is changed from 17Nm to 10Nm at $t=1.5s$. In order to highlight validity of the sliding-mode observer, the stator resistance and rotor resistance are set to twice of the rated value in simulation. The stator flux observer curve is shown in fig.3. Compared with conventional DTC,

the DTC-SVM has much smaller torque ripple. From fig.3, it can be seen that the adaptive observer can estimate the stator flux well and truly.

V. CONCLUSIONS

A new DTC-SVM scheme has been presented for the IM drive system, which is on the basis of input-output linearization control. In this control method, a SVPWM inverter is used to feed the motor, the stator voltage vector is obtained to fully compensate the stator flux and torque errors. Furthermore, a robust full-order adaptive flux observer is designed for a speed sensorless DTC-SVM system. By designing the constant observer gain based on LMI, the stability of the observer systems is ensured. Compared with the conventional DTC, the proposed drive system has much smaller torque ripple in very low speed and exhibits good dynamic and steady-state performance.

Abstract— This paper presents an application of a new permanent magnet MAGFINE, *polar anisotropic bonded NdFeB PM*, to a small size DC motor. The new PM gives very high residual magnetic flux density and energy product with lower cost than a sintered NdFeB PM. An application of this PM to a small size DC motor shows it can reduce the volume and weight of a motor up to fifty percent.

I. INTRODUCTION

DC motors employing sintered ferrite permanent magnets (PMs) have, so far, been widely used in automotive applications such as seat, blower and sunroof. These days, PM motors are required to have higher efficiency for energy saving, better performance with smaller volume and lighter weight, and even higher power density. In the design of DC motor, therefore, PMs having high energy density, such as NdFeB, are more attractive to get high power to volume ratio [1].

The NdFeB magnets are usually classified into *sintered* and *bonded* PMs according to their manufacturing process, and also *isotropic* and *anisotropic* PMs by their microstructure. The popular types, however, are limited to *isotropic bonded* PMs having $(BH)_{\max}$ of $80(\text{kJ}/\text{m}^3)$ and *anisotropic sintered* PMs of $400(\text{kJ}/\text{m}^3)$ due to some technical difficulties. Conventionally, for small size DC motors, *isotropic bonded* NdFeB PM, made by compression process of the NdFeB powder and binders, is preferred to a sintered one because it gives lower assembling costs and more flexibility.

Very recently, *anisotropic bonded* NdFeB PM, named MAGFINE having high energy product up to $200(\text{kJ}/\text{m}^3)$, has been developed by Aichi Steel Corporation and Jahwa Electronics [2]. Comparing with a sintered NdFeB PM, the MAGFINE gives little bit lower residual magnetic flux density (1.0T) and costs around 40(%) cheaper. Since the *anisotropic bonded* NdFeB PM has high energy product and residual magnetic flux density and is cheaper than the sintered NdFeB PM, it is expected to give higher air-gap magnetic flux density and power density with low cost when it is applied to a DC motor. The PM, furthermore, gives precise dimensions, roundness and concentricity after housing assembly process. The research on its application to PM motor, however, is still in early stage, and more discussions and researches are strongly required.

In this paper, a ring-type *anisotropic bonded* NdFeB PM is applied to a small size DC motor by replacing the conventional segment-type sintered ferrite PM to achieve a high power to volume ratio of the motor. In the application, *anisotropic* directions of each part of the ring-type *anisotropic*

bonded NdFeB PM were investigated, and the shape of rotor teeth are optimized.

II. 4 POLE POLAR ANISOTROPIC BONDED NDFEB PM

A 2-pole 10 slot ferrite PM DC motor, of which maximum output is 25(W) and specifications are shown in Table I, for the sunroof of a car is taken as a model. In order to develop a high power density motor, the *anisotropic bonded* NdFeB PM, JHMF23 made by Jahwa Electronics Co. Ltd., KOREA, of which magnetic performances are $B_r=1.0(\text{T})$, $iH_c=0.96(\text{MA}/\text{m})$, $bH_c=0.6(\text{MA}/\text{m})$ and $(BH)_{\max}=175(\text{kJ}/\text{m}^3)$, respectively, is selected. It is a ring-type 4 pole *polar anisotropic* PM as shown in Fig. 1. The PM is manufactured as follows:

Step 1. The *anisotropic bonded* NdFeB compound containing 2(wt%) of resin is prepared through the blending process under Ar atmosphere.

Step 2. With the compound, a mold for compression with magnetic fields is filled with a filling density of $4000(\text{kg}/\text{m}^3)$ as shown in Fig. 1(a). In order to align the magnetic particles in *polar anisotropic* directions, the magnetic powder is exposed to a magnetic field of 1200 (kA/m) while keeping the mold temperature in the range of 120~150 °C, and then compressed under the pressing pressure of 4 (ton/cm²). Fig. 1(b) shows the distribution of the magnetic flux density, obtained from a transient FEM analysis at moment of peak current, and Fig. 1(c) the maximum applied magnetic field intensities, during the compression process, at the compound. The final directions of the magnetic particles, obtained from that of magnetic fields, are shown in Fig. 1(d), and the *anisotropic bonded* NdFeB compound is ready to be magnetized in 4-pole *polar anisotropic* PM.

Step 3. The PM, compressed compound, is magnetized by

TABLE I
SPECIFICATIONS OF FERRITE PM AND PROPOSED MOTORS

Section	Item	Ferrite PM motor	Anisotropic bonded PM motor
PM	Number of pole	2	4
	B_r (T)	0.4	1.0
	Outer diameter (mm)	36.6	25.8
	Inner diameter(mm)	26	23.8
Armature	Axial length(mm)	54	27
	Outer diameter(mm)	25	23.2
	Number of slots(mm)	10	10
Return yoke	Axial length(mm)	44	25
	Thickness(mm)	1.7	2

using magnetizing fixture.

III. CONSTRUCTION OF A MOTOR AND TESTS

A DC motor employing the proposed PM is initially designed with air-gap of 0.3(mm) as shown in Fig. 2, and its specifications are compared, in Table I, with those of a model motor. Fig 3 shows the distributions of the magnetic flux density generated by the proposed *polar anisotropic bonded NdFeB PM* with and without an armature core where teeth width and slot opening are set to 2.2 (mm) and 1.6 (mm), respectively.

In order to decide the teeth width (Tw) and slot opening (So) optimally, the parametric analyses using FEM are performed over the range of $1.3(\text{mm}) \leq Tw \leq 2.2(\text{mm})$ and $1.2(\text{mm}) \leq So \leq 3.0(\text{mm})$, respectively. The upper limit of the teeth width is decided considering an enough winding space. During the analyses the air-gap between the PM and armature is fixed to 0.3(mm).

Fig. 4 shows that the torque constant increases as the teeth width increases. It is partially because the armature core is easily saturated in the narrow teeth, and means the proposed PM provides sufficient magnetic flux. With regard to the slot opening, the optimum condition is found at 1.6(mm). Through these analyses, the thickness of PM, teeth width and slot opening are decoded as 1(mm), 2.2(mm) and 1.6(mm), respectively.

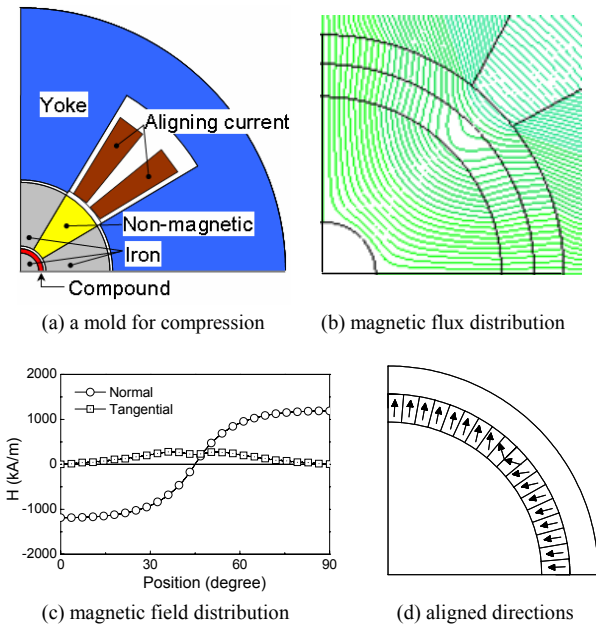

Fig. 1. Analysis results.

Fig. 2. Design of 4-pole polar anisotropic NdFeB PM motor.

Fig. 5(a) shows a comparison of the motor performances, measured at supplied voltage of 12(V), and sizes between the proposed 4-pole *polar anisotropic bonded NdFeB PM* motor and 2-pole conventional Ferrite DC one. It can be seen, from Table I and Fig. 5, that the proposed motor gives almost same performances with 50% reduced volume and weight.

Optimum Design For Premium Efficiency of 250 kW Traction Induction Motor Using Response Surface Methodology & FEM

Jung Ho Lee, *Member, IEEE*, Sung Ju Mun, Tae won Yun
 Dept. of Electrical Engineering, Hanbat National University
 Dukmyung-Dong Yuseong-Gu, Daejeon, 305-719, KOREA
 E-mail: lucasmsj@nate.com

Abstract —This paper deals with optimum design criteria for premium efficiency of 250kW traction induction motor using response surface methodology (RSM) & finite element method (FEM). The RSM has been achieved to use the experimental design method in combination with Finite Element Method and well adapted to make analytical model for a complex problem considering a lot of interaction of design variables.

The proposed procedure allows to define the rotor copper bar shape, stator slot and stator, rotor dimensions starting from an existing motor or a preliminary design.

I. INTRODUCTION

Recently, saving energy is a most important task in the world. Thus, obtaining high efficiency electrical machines and apparatus is a very important task.

Induction Motors are very important in industry. For many years, the efficiency of three-phase induction motors has been the subject of numerous investigations aimed at increasing efficiency values by minimizing losses during the operation.

Induction motor design principles have not changed dramatically over the years, whereas the tools and the knowledge of engineers have improved considerably.

This better understanding has led to continuous improvements for reducing losses in electric motors.

Systematically analyzing the root causes of losses and the possibilities for improvements requires a complete and new approach, looking into not only the electrical area but also mechanical areas such as cooling, temperature levels, and outer diameter (OD) versus length ratio, etc. In this article, we apply a systematic and optimized new design approach for 250 kW Traction Induction Motor.

The electromagnetic factors for improving efficiency are as follows:

- 1) increase the amount of active material
- 2) utilize high-performance lamination materials
- 3) optimize the stator/rotor geometries
- 4) optimize the air gap dimensions

All the factors have to be carefully looked at and investigated, because most of them are not independent from each other and may negatively influence the efficiency gains in one case or the other. Secondly, the commercial impacts have to be strongly considered, since with higher efficiency the premium paid may limit the savings seen.

The RSM has been achieved to use the experimental design method in combination with Finite Element Method and well

adapted to make analytical model for a complex problem considering a lot of interaction of design variables [1]-[3].

The focus of this paper is found firstly a design solution through the comparison of torque and losses according to rotor bar shape and stator, rotor dimensions variations and, Secondly, a mixed resolution with central composite design (CCD) is introduced and analysis of variance (ANOVA) is conducted to determine the significance of the fitted regression model.

II. DESIGN ALGORITHM AND MODEL

The variables for optimization design are shown in Fig. 1.

In Fig. 1, design variables that are slot depth and width of stator, slot depth and width of rotor and air gap width, are determined to improve torque performance of 250kW traction induction motor.

Analysis data is obtained through finite element method based on central composite design mostly used in RSM, and optimum point is determined through analysis of the data.

Finally, it can be obtained the maximum torque density & minimum loss of 250kW traction induction motor.

Fig. 1 shows the point variables and variation direction example for the shape change according to slot depth and width of stator and rotor.

Points of W1-W8 and P1-P8 move as a condition that slot depth and width.

Fig. 1. The initial model, design variables and variation direction of 250kW traction induction motor

III. CONCEPT OF RESPONSE SURFACE METHODOLOGY

TABLE I
ANALYSIS OF VARIANCE

Source of Variation	Degree of Freedom	Sum of Squares	Mean Square	F_0
Regression	k	SS_R	$SS_R / k = MS_R$	MS_R / MS_E
Residual	$n-k-1$	SS_E	$SS_E / (n-k-1) = MS_E$	
Total	$n-1$	S_{yy}		

It is always necessary to examine the fitted model to ensure that it provides an adequate approximation to the true response and verify that none of the least squares regression assumptions are violated. In order to confirm adequacy of the fitted model, analysis-of-variance (ANOVA), shown in Table I is used in this paper. In Table I, n is the total number of experiments and k is the number of parameters in the fitted model.

IV. OPTIMIZATION PROCEDURE

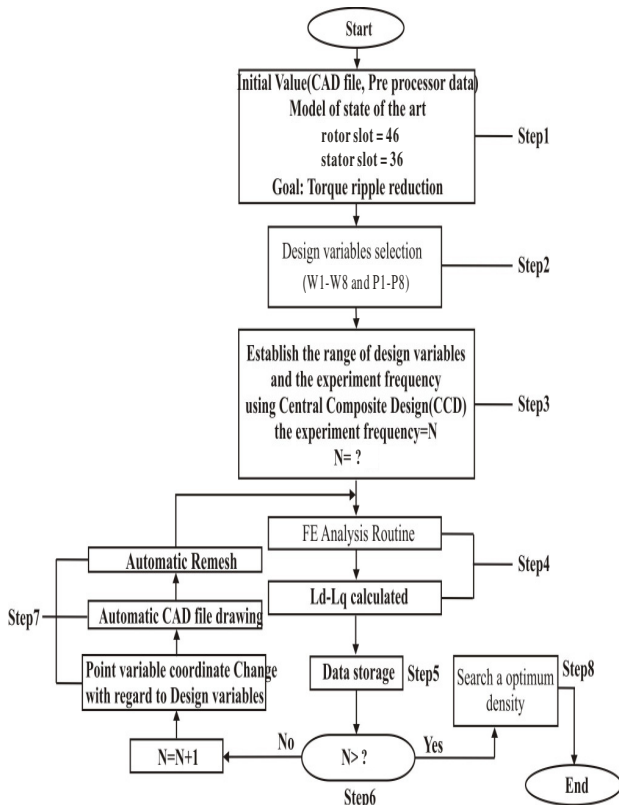

Fig. 2. Flow chart of design procedure

Fig. 2 shows the Flow chart of design procedure.

Design procedure according to the flow chart is as follows;

Step1 : Set the initial value (CAD file, Pre-processor data). And the initial model is assigned to rotor slot=46, stator slot=36.

Step2 : Width and depth in rotor and stator are adopted the design variables related to torque density in 250kW traction

induction motor. However, the ribs have a fixed value due to inherent manufacturing limitations.

Step3 : The range of design variables and experiment frequency is established by using the central composite design (CCD) shown Table I and II. The experiment frequency (N) is 2^k .

Step4 : Finite element analysis (FEA) is performed and Ld-Lq is calculated.

Step5 : The Ld-Lq obtained from FEA, are stored.

Step6 : The experiment frequency (N) > ?.

► Yes : Search a optimum torque density.

► No : $N=N+1$.

Step7 : The example of the point variables and variation direction of flux barrier rotor is well shown Fig. 2.

When the rotor and stator shape according to variables is varied, they have a difficulty in performing a lot of the pre-processor for FEA. For this reason, the new CAD file is redrawn with regard to the change of the design variables automatically. Next the process of automatic mesh generation follows. In mesh generation, mesh data doesn't change the node number, element number, region, boundary condition, etc., but only x, y coordinate data of the design variables. In this way, the proposed pre-processor procedure can be performed in a short period of time. In this way, this procedure goes on until $N=?$.

Step8 : The response surface model is created by data obtained from FEA according to an established range. Therefore, it is possible to get optimum torque density.

The RSM seeks to find the relationship between design variable and response through statistical fitting methods, which are based on the observed data from system.

The response is generally obtained from real experiments or computer simulations. Therefore finite element analysis (FEA) is performed to obtain the data of 250kW traction induction motor in this paper.

There are many experimental designs for creation of response surface. In this paper the central composite design (CCD) is chosen to estimate interactions of design variables and curvature properties of response surface in a few times of experiments. The CCD has been widely used for fitting a second-order response surface. [4]

More detailed results and discussion will be given in final paper. And the mathematical expressions for response surface methodology will be also given in extended version.

Optimal PM Design of PMA-SynRM for Wide Constant-Power Operation and Torque Ripple Reduction

Won-Ho Kim, Kwang-Soo Kim, Seung-Joo Kim, Jong-Bin Im, and Ju Lee, *Senior Member, IEEE*
 Department of Electrical Engineering, Hanyang University, Seoul, Korea
 wonho79@nate.com

Abstract— This paper presents the design process of permanent magnets to enable a wide range of constant-power operation and reduce the torque ripple by using analytical and numerical methods in PMA-SynRM. For a wide range of constant-power operation, the minimum d-axis flux-linkage of the permanent magnet is designed to be close to zero. Moreover, the unbalanced flux density in each segment is adjusted by changing the size of each permanent magnet to reduce the torque ripple. Finally, control simulations and experiments will be conducted to prove the validity of the suggested process.

I. INTRODUCTION

Existing permanent magnet designs, such as the BLDC and IPM, were designed after the D²L method to determine the outer diameter of the rotor first. However, for the permanent magnet assisted synchronous reluctance motor (PMA-SynRM) design, in which the permanent magnet is inserted into the existing SynRM, many parameters have been designated, and therefore the existing methods can't be applied.

This paper presents the design process of permanent magnets to enable a wide range of constant-power operation and reduce the torque ripple by using analytical and numerical methods in PMA-SynRM.

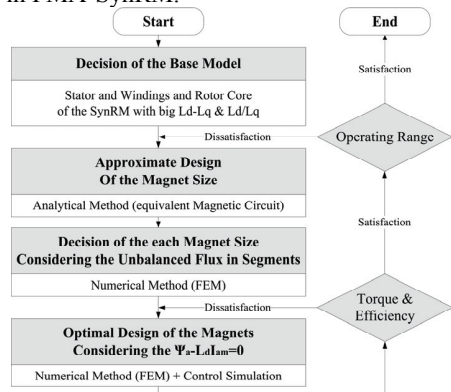

Fig. 1. Flowchart for the magnet design of PMA-SynRM

II. PERMANENT MAGNET DESIGN PROCESS

The most important factors when converting the existing SynRM into PMA-SynRM are the magnet location and designing the size. For wide constant-power operation, the magnet designing process is divided into three steps in this thesis. Prior to designing the magnet, the SynRM model was selected and the stator, windings, and rotor core were considered as the base models. After the base models were selected, the equivalent magnetic circuit method is used to largely design the permanent magnet. Additionally PM design is conducted for the correction of the unbalanced flux density in segments. Finally, in order to meet the ideal condition to

acquire no power limit, maximum power scope and constant-power operation scope, optimized designing for the permanent magnet is conducted. Follow contents give a full detail of three steps. The designing process is shown in Fig. 1.

Fig. 2. Equivalent magnetic circuit of the PMA-SynRM

III. EQUIVALENT MAGNETIC CIRCUIT METHOD

The location of the permanent magnet can be limited upon the shape of barriers because the permanent magnet is inserted to the existing SynRM, therefore, the thickness of the permanent magnet is limited to the thickness of the barriers. Thus, width designing of the permanent magnet is focused in this thesis. For the model of this thesis, the shapes that allow inserting three magnets in the center were adopted and magnetic circuit of this model is shown in Fig. 2.

$$w_1 = \frac{3\Phi_g \cdot l_m}{\{3H_c l_m - NI - \frac{(R_{b1} + R_{b2} + R_g)\Phi_g}{2}\} \cdot \mu_{rec} \mu_0 L} \quad (1)$$

Formula (1) shows the equations related width of the permanent magnet by summarizing the magnetic circuit, and value is assumed by considering the machine parameters of existing SynRM and target specification and finally the approximate size of the permanent magnet is determined by applying the value on the formula.

IV. DESIGN CONSIDERING THE UNBALANCED FLUX

All the magnet sizes are assumed to be same in the above hypothesis. However, Fig. 3(a), which shows the flux density distribution calculated through FEM, shows that segment-1, -4 have saturation but there is almost no magnetic flux in the segment-2, -3. This phenomenon increases the use of permanent magnet unnecessarily and also can cause problems such as torque ripple due to the unbalanced flux in each segment. To solve this problem, the width of the permanent magnet located in the layer-2 was increased and the width of the permanent magnet located in the layer-1, -3 were decreased to balance the flux in the overall segments. During this process, the sum of magnet sizes were maintained as same as the existing. Fig. 3(b) shows the flux density distribution of the model with the optimized ratio of permanent magnets. In addition, torque ripple decreased significantly compared to the existing model in Fig. 4.

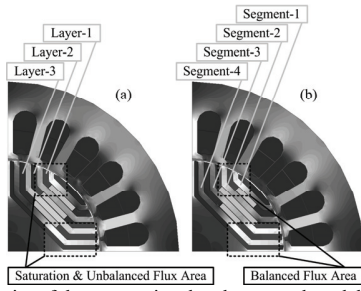

Fig. 3. Flux density of the conventional and proposed model at 15A, 500rpm

Fig. 4. Torque of the proposed model and conventional model@500rpm, 15A

V. PM DESIGN FOR WIDE CONSTANT-POWER OPERATION

If the voltage and current limitation are considered, the maximum power scope can be acquired by properly controlling the current vector. In order to broaden the scope of the constant-power operation, the optimized design for permanent magnet is conducted to meet $\Psi_a = L_d I_{am}$. [2] At this time, width ratio of the permanent magnet that was designed in the above is used.

Fig. 5. Reluctance and magnetic and total torque@500rpm, 10.5A

A. FEM Analysis

In order to accurately calculate the inductance by considering the non-linear characteristics, RMS value of EMF and flux-linkage at no load, RMS value of flux-linkage when the current is applied, and phase difference between two flux-linkage were acquired through FEM.

In Fig. 5, reluctance torque and magnetic torque were calculated separately by means of the calculated inductance and result of Maxwell stress tensor method to prove the validity of the inductance calculation method in Fig. 5.

B. Maximum Power Control Simulation

The parameters that considered the calculated non-linear characteristics were used to conduct the maximum power control simulation. Constant-torque mode is controlled by means of Maximum Torque / Current Control Method and the formula for the reference current is shown in Formula (2).

$$i_{d_cr} = \frac{\Psi_a}{4(L_q - L_d)} - \sqrt{\frac{\Psi_a^2}{16(L_q - L_d)^2} + \frac{I_{am}^2}{2}} \quad (2)$$

In the constant-power torque, the Flux-Weakening Control Method is used to control and the current vector formula that is required during the flux-weakening is shown in Formula (3).

$$i_{d_cp} = \frac{\Psi_a L_d - \sqrt{(\Psi_a L_d)^2 + (L_q^2 - L_d^2) \left\{ (L_q I_{am})^2 - \left(\frac{V_{om}}{\omega} \right)^2 \right\}}}{L_q^2 - L_d^2} \quad (3)$$

Based on this, the locus of the current phase angle according to the speed of the final model is expressed in Fig. 6 as well as the limitation for voltage and current. Fig. 7 shows the torque and power versus speed.

Fig. 6. Locus of the current phase angle in proposed model

Fig. 7. Torque and power versus speed of proposed model

VI. EXPERIMENT AND CONCLUSION

The final model is manufactured for experiment and evaluation. The experiment results are shown Fig. 5 to prove the validity of the simulation. Finally, this model has simulated parameter $\Psi_{dmin}=0.003$ and measured parameter $\Psi_{dmin}=0.004$. This results shows the validity of the proposed design method.

Abstract — This paper deals with the study of static and dynamic rotor eccentricities of a synchronous generator using 3D FEM. First, both eccentricity cases are introduced as well as the used approach. Then, the model of the structure, based on the vector potential formulation is presented. Results obtained for magnetostatic case related to both defects and their combination are presented and discussed. The saturation effect is highlighted.

I. INTRODUCTION

Synchronous generators are widely used in high power conversion plants and their predictive maintenance constitutes a very important task in order to avoid an interruption of production. Therefore, the forecast and/or the detection of eventual defects are essential.

A very common defect in the rotor of such generators is eccentricity. Many techniques for diagnosis of this type of failure have been proposed, including analysis of the current in parallel windings [1], analysis of the rotor and stator vibrations [2], analysis of the shaft voltage, use of capacitive sensors [3] and use of flux probes in the stator iron stack [4]. Another approach is based on the measure of the magnetic field density in the air gap of the machine [5]. The last method is employed in this work. Thus, it is useful to arrange signatures of eccentricity defects to detect them.

In this paper, we present the study of the rotor static and dynamic eccentricities of a synchronous generator using 3D finite element analysis. Once both defects and the detection method presented, we introduce the used 3D-FEM model which is based on the potential vector formulation. Finally results for a specific synchronous generator are given for both defects and their combination. The effects of the steel saturation in the machine are highlighted.

II. ECCENTRICITY CASES AND MEASUREMENT METHOD

Generally, we can distinguish two eccentricity cases. In the static case, the rotor rotates around its own rotation axis but this one is displaced with regard to the stator axis (Fig. 1.a).

Fig. 1: Eccentricities: a) static b) dynamic.

In the case of dynamic eccentricity the center of the rotor axis is the same as the center of the stator one but it does not correspond to the rotation axis of the rotor (Fig. 1.b). These cases can be found alone or combined. When they are combined, the center of the rotor is not the same as the center of the stator and the rotor rotation axis is displaced.

It must be noticed that, in the experimental detection of these defects, when measuring the induction signal on only one point of the machine air-gap, it is impossible to verify whether there is a static eccentricity or not, because there is no variation of the radial flux in only one point. To overcome this problem, two 90° spatially shifted signals are subtracted and a Fast Fourier Transform (FFT) of the obtained waveform is analyzed.

III. FINITE ELEMENT METHOD APPROACH

To study the structure, we use three dimensional finite element method. In the magnetostatic case, the computation is carried out with the magnetic vector potential A formulation:

$$\text{rot} \frac{1}{\mu} \text{rot} A = J \quad (1)$$

with μ the magnetic permeability and J the current density. For the conductive region (damper windings), A - φ formulation is used to compute the eddy current:

$$\text{rot} \frac{1}{\mu} \text{rot} A + \sigma \left(\frac{\partial A}{\partial t} + \text{grad} \varphi \right) = 0 \quad (2)$$

with σ the electrical conductivity and φ the electrical scalar potential. Furthermore, the magnetic materials are modeled taking into account the non-linear $B(H)$ curve. At last, the movement is implemented through the locked step method.

To take into account the static eccentricity, all the nodes inside the slip surface (i.e. the nodes of the rotor, of the inner part of the air gap and the ones on the slip surface) must be moved (Fig. 2.b) with the same distance. In the case of the dynamic eccentricity, only the nodes of the rotor have to be moved while the slip surface remains at its initial position (Fig. 2.c).

Fig. 2: Eccentricities techniques: a) healthy machine b) static c) dynamic.

To simulate the combined eccentricities (static and

dynamic) the slip surface and the node of the rotor must be moved but not with the same distance.

IV. APPLICATION

A. Description of the machine

To validate the approach, we study a turbo-generator of small size, similar to a French nuclear plant generator. This machine, of about 26.7 kVA at 50 Hz, has four poles, 48 slots in the stator and 36 slots in the rotor. Besides, the rotor has 36 short-circuited damping bars. The constant air-gap thickness is 1,5mm. The used mesh is constituted of 29160 nodes and 29014 elements. A cross section view is given in Fig. 3.

Fig. 3. Cross section view of the turbo-generator mesh.

B. Results

For each type of eccentricity, with the same 0.3 mm magnitude, simulations are carried out at no load conditions. Two cases are investigated: a non-saturated case with an excitation current I_{ex} of 5A and a very saturated case with $I_{ex}=30$ A.

Fig. 4. Subtraction of the two signals in the air-gap, $I_{ex} = 5$ A.

Fig. 5. FFT of the subtraction of the two signals in the air-gap, $I_{ex} = 5$ A.

Figures 4 and 6 show the subtraction of the two signals in air-gap for $I_{ex}=5$ A (Fig.4) and $I_{ex}=30$ A (Fig.6). In figures 5

and 7, the FFT of these signals are shown. While the signals of the healthy machine are harmonic free, for both cases, the static eccentricity induces a significant 50Hz-harmonic while dynamic eccentricity yields harmonics of 25 Hz and 75 Hz. Furthermore, the saturation introduces much more harmonics than those present in the linear case.

Fig. 6. Subtraction of the two signals in the air-gap, $I_{ex} = 30$ A.

Fig. 7. FFT of the subtraction of the two signals in the air-gap, $I_{ex} = 30$ A.

V. CONCLUSIONS

In this paper, we studied the static and dynamic eccentricities at no load using 3D-FEM. Two 90° shifted magnetic induction signals in the air gap, can lead to the detection of the eccentricities and to differentiate their type by studying their harmonic content.

In the final paper, more details related to the numerical model will be given. Furthermore, results in magnetodynamic case will be presented and discussed in order to quantify the effect of the damper windings currents.

FE-Circuit Coupled High Frequency Model of Electric Machines for Simulation and Evaluation of EMI Issues in Motor Drives

O. A. Mohammed

Florida International University

ECE Department, Energy Systems Research Laboratory, Miami, FL, USA

mohammed@fiu.edu

Abstract—An FE-circuit coupled high frequency model is proposed to simulate electromagnetic interference (EMI) due to terminal overvoltage and ground current of electric machines and their driving circuits. The high frequency effects due to PWM drive were considered in the transient FE-circuit coupled model of the motor using a two-step procedure. First, the resistance in each individual winding turn is evaluated by time harmonic FE analysis considering skin and proximity effects. The capacitances between the winding were calculated by an electrostatic FE analysis to form a distributed parameter model of the winding in each conductive region. Second, a lumped parameter model for the conductive regions was obtained through matrix reduction technique. The lumped models of the distributed coils were connected in series to form a per phase winding model. The FE-circuit coupled model of the motor is laboratory tested in a motor drive to evaluate the terminal over voltages and ground currents. The numerical results were successfully verified by laboratory testing.

I. INTRODUCTION

High frequency motor models play important roles in the evaluation of EMI in an integrated motor drive system. In earlier work by these authors, the high frequency phase variable model of PM synchronous motor was developed and implemented in Simulink environment [1]. In this model, the per phase distributed winding circuit was developed considering the high frequency effects and then lumped to form the high frequency winding branch. This branch was connected in parallel to the low frequency phase variable model to form the high frequency phase variable model which can be used for dynamic simulations.

In this paper, the full FE model was used directly to couple the driving circuit rather than creating the phase variable model first. This can be used when the high frequency interactions are needed to evaluate EMI issues without the need for including low frequency effects. The model can also be used for new motor design development when the motor is utilized in a developmental driving circuit as Hardware-in-the-loop. This model can be used to further verify the accuracy of the previously developed high frequency phase variable

The model is coupled to an external circuit to include various capacitances dominant under high frequency operation. The circuit is excited by an external voltage source modeled in Simulink. To simplify the circuit, the machine windings were divided into several sections. Each coil represents one section. A 2D magnetodynamic analysis was performed to find the resistance of each turn of the coil as a function of frequency while an electrostatic analysis was performed to find the capacitance between the various

parts of the coil. The coupled circuit-FE model was exported to Simulink environment for use in the integrated drive system.

II. DISTRIBUTED PARAMETER MODEL OF THE COIL

Simulations were performed on a small 3-phase, 42-V, 10-pole, 0.28-HP, 3600-rpm, 7.8-A PM synchronous motor. The simulated motor model was built based on its actual geometry information. The individual turns in each coil were considered. The motor has double layer windings with random winding arrangement. There are four coils per phase; each coil has 13 turns. Therefore, each half slot contains 13 conductors. Each turn is made of wire gauge number 22. All the slots were modeled so that the effects of geometrical variation in the magnetic circuit on the machine circuit parameters can be considered. The machine was modeled to take into consideration the conductor skin and proximity effects. The resistance value at high frequency can be much higher than the low frequency value. The inductance value decreases with an increase in the operating frequency while the capacitance effect comes into effect at high frequencies.

Fig. 1 Mesh details (a) in individual turn (b) in half geometry model

Fig. 1(a) shows the FE mesh inside each individual turn used to solve magnetodynamic analysis while fig. 1 (b) shows the FE mesh inside the half geometry model used to solve the transient FE analysis. The current is supplied to each individual turn in a coil with a set of frequency value ranging from 5 kHz to 1 MHz. The voltage of each turn was obtained to provide the impedance. Using the impedance, the resistance was calculated at the corresponding applied frequency. The same procedure was repeated for the turns in all other coils. The frequency range mentioned above covers the PWM practical switching frequencies and their associated harmonic components. Since the capacitances are dependent only on the geometry of the motor and less dependent on the covered PWM frequency range, an electrostatic analysis was performed

for its calculation. The machine's core was considered as ground for the calculation of capacitance values to ground.

Fig. 2 shows the distributed parameter model a coil where N represents the number of turns in the coil. The self and mutual capacitances between the various turns of the coil were considered. Each turn has a self capacitance and mutual capacitances with other turns in the coil. The lumping of the turns parameters in each coil was performed to reduce the order of the model [2]. The lumped winding model for each phase is shown in fig.3. In this figure, A1, A2, A3, A4 represent the coils in each phase. These coils were assigned to the FE domain to consider the high frequency effects in the coupled FE-circuit model.

Fig. 2. The distributed parameter model of a coil

Fig.3 Lumped winding model for each phase

The coupled field and circuit equations were solved simultaneously during the magnetodynamic and transient problems. The equations used for the coupled problem are as follows:

$$\nabla \times H = J_s + J_e \quad (1)$$

$$[E_m] = [R_m][I_m] + [L_m] \frac{d}{dt}[I_m] + (1/C_m) \int I_m dt + [\gamma_m] \quad (2)$$

Where, H is the magnetic field intensity, J_s is the source current density, J_e is the induced current density. In equation (2), R_m represents the resistances matrix, L_m is the inductances matrix, C_m is the capacitances matrix, γ_m is the matrix of non-linear voltage drops, I_m is the matrix of currents. E_m is the matrix of voltage sources.

The resistance value of the coils was obtained from the FE solutions to account for the skin and proximity effects of each turn in the lumped model. Small value resistances were added to capacitances for numerical stability.

The capacitances C1 to C5 represent the coil to ground capacitance while C6 to C9 represent mutual capacitances between different coil sections. The coil capacitances were obtained by lumping the turn capacitance network. The matrix reduction technique was used for lumping the parameters [2]. The resulting matrix is of the order 2N following a process of shifting internal capacitances towards pre-established section nodes. Once the capacitances are moved to section nodes, the conductor

resistances were lumped. Similar winding model was formed for each phase.

III. EXPERIMENTAL AND SIMULATION RESULTS

A real time distributed simulation environment with the actual motor and drive implemented on PC-cluster was used for performing the experimental verification. Results for overvoltage and ground current were obtained and compared with the simulation results.

Fig. 4. (a) Experimental overvoltage (b) simulation overvoltage

For simulation, the high frequency models of the integrated system components including inverter and cable in addition to the motor were built and implemented in Simulink. The model was tested for the motor terminal overvoltage and ground current. During transient simulation, the FE model, drive and control equations were solved simultaneously with the same time step. Fig. 4 shows a comparison between experimental and simulation results of overvoltage. The magnitude of overvoltage is about 75 volts. The time period of $2\mu s$ shows the same number of oscillations. Thus the results show good agreement in terms of magnitude and frequency of oscillations. Both results are captured with different time steps since the same time step can not be maintained in experiment and simulation and at different instants of time. However, the correspondence between two is satisfactory. Complete results will be given in full paper.

IV. CONCLUSION

The coupled FE-circuit electric machine model for simulating EMI issues in a motor drive was presented. The model can accurately predict the EMI caused by ground current and motor terminal overvoltage. Use of this procedure could prove economical as it would help designers develop new motor designs for low and high frequency operating conditions numerically. Using the proposed model, this is achieved without the need for repeated build and test procedures in the development stage.

Abstract — The inducting coils typically used in Eddy Current Testing (ECT) of tubular structures, dominated by longitudinal dimensions, are much more effective for *azimuthal* than for *longitudinal* defects. This paper shows how *azimuthal* inducting currents are well suited for *longitudinal* defects. In addition, the paper proposes a new concept of exciting coils, *azimuthally* shaped, longitudinally displaced and suitably powered; it is showed how, by suitably driving the coils current, the resulting excitation field can be controlled in position, shape and speed in such a way to optimize the defect searching and sizing.

I. INTRODUCTION

Eddy current testing is one of the most diffused methods for nondestructive inspection of metallurgical products. It uses a time varying magnetic field, designed to induce in the sample a suitable current pattern. Of course, the actual current distribution is affected by defects, eventually located in the sample. As a consequence, the analysis of either the resulting magnetic field or the impedance of the coils could provide useful information for the defect characterization.

A relevant field of application of ECT is the testing of tubular metallic structures. The practical solution firstly proposed was based on the use of rotating components [1], or encircling coils [2]. Successively, fixed systems generating rotating fields have been proposed [3]-[8], and finally multi-frequency currents have been introduced [9].

Most of the proposed layouts were based on the use of *longitudinal* currents, whose shape match the main direction of the tube. Such driving systems are well suited to localize *azimuthal* defects, because the currents they induce are in the longitudinal directions.

In this paper an *azimuthal* induction system is illustrated and its effectiveness for catching *longitudinal* defects is investigated. In addition, a flexible strategy is proposed to drive the inducting currents with the aim of patrolling the suspected region, to try to localize the defect and to identify its main characteristics.

It is well known that a rotating field can be created by driving a suitable set of *longitudinal* coils with a poliphase set of currents [11]; in similar way, here it is shown that a sort of *traveling* field can be easily produced by a poliphase set of currents driving a suitable set of *azimuthal* coils. Of course, each actual coil has to include both *longitudinal* and *azimuthal* coils, because of the needs for current closure. In the full paper a suitable 3D short “saddle” coil, able to highlight *azimuthal* effects, will be analyzed, while in this short version, a simplified 2D *azimuthal* coil system is used to assess the effectiveness of the method.

II. PRELIMINARY RESULT

The mathematical formulation of the problem has been previously reported, and can be considered rather standard [3]. Therefore, its description with some details will be given in the full version while reserving here a larger room for the system description and for the discussion of the preliminary results.

In order to assess the proposed technique, a conductive non-magnetic tubular structure has been considered and a set of 18 *circular* coils has been introduced to induce eddy current maps in the tube (see Table I and Fig. 1)

TABLE I
GEOMETRICAL AND ELECTROMAGNETICAL CHARACTERISTIC

Parameter	Value
Tube length	10 m
Tube diameter	0.3 m
Tube thickness	0.03 m
Tube conductivity	6.0e7 S/m
Tube permeability	1.27 10 ⁻⁷ H/m
Number of coils	18
Coils cross section	12 cm ²
Coil distance	0.1 m
AC current frequency	200 Hz
Current amplitude	65 A

It should be noticed that the tube is long enough to neglect the effect of *longitudinal* boundary effects. In addition, the frequency has been fixed in such a way to provide a penetration depth (in order of 0.15 m) much higher than the tube thickness.

Fig. 1. – Overview of the excitation system. The phase of each coil is also shown.

When connected in opposite series, three couples of coils form a “three phase *longitudinal* polar couple”. Of course several polar couples can be generated by juxtaposing suitable

sets of six coils. In the case here described, the 18 coils are combined to create three *longitudinal* polar couples (in Fig.1 just one of them is reported). Such a system, if driven with a symmetric three-phase currents system, is able to generate a magnetic field *traveling* in *longitudinal* direction.

In order to evaluate the capability of such a system to perform an effective ECT, the Ohmic power density related to the eddy currents induced in the tube has been calculated in a number of tube positions (Fig. 2), and it is reported in Fig. 3 for each evaluation point. Of course, the power density shows a doubled frequency, because of the square of the current density in the power expression, and reaches its maximum just near the coils. Note that the higher the power density is at the suspected defect location, the more sensible the detection system becomes to perturbations induced by defects.

Fig. 2 Test points in the tube.

Fig. 3 Ohmic power density in the test points for a *travelling* field

However, a more general power supply system can generate a magnetic field distribution characterized by different shape and velocity. For example, the *traveling* field can be *stopped* if, instead of a set of three-phase currents, three *in-phase* currents are used with suitable amplitudes, and the actual position of the *stopped* field depends only on such current amplitudes. As an example, in Fig. 4 the power density time variation is shown for a field *stopped* in correspondence of the point P₂ (see for comparison Fig. 3).

Fig. 4 Ohmic power density in the test points for a *stopped* field

III. CONCLUSION

An effective use of longitudinal and azimuthal inducting currents combined with independent control of the driving currents allows to increase the ECT performance in testing tubular structure. In the full paper, a detailed description of the mathematical model for the proposed excitation system will be given, and 3D saddle coils will be used.

Department of Electrical Engineering, Engineering Research Institute, Gyeongsang National University
Jinju-si, 660-701, Korea
Ktheoung@gnu.ac.kr

Abstract— Many different converter topologies have been developed to reduce the converter construction cost by using minimum number of switches. Among of the solutions, four-switch converter topology with a novel PWM control technique based on the current controlled PWM method is treated as a good solution. In this paper, one introduces a two dimensional time-stepped voltage source finite-element method (FEM) to analyze the characteristics of a Flux-Reversal Machine (FRM) with the 4-switch converter. To prove the proposed computational method, the digital signal processor (DSP) installed controller and the prototype FRM are built and experiments are performed.

I. INTRODUCTION

Because the principle of operation is similar to the brushless DC machine (BLDCM), 3-phase Flux-Reversal Machine (FRM) needs quasi-square current waveforms, which are synchronized with the back-EMF to generate constant output torque and have 120° conduction and 60° non-conducting regions. Also, at every instant only two phases are conducting and the other phase is inactive. This control action can be realized using 6-switch converter topology. However, these days, many different converter topologies have been developed to reduce the converter construction cost by using minimum number of switches. One of them is 4-switch converter topology, which is shown in Fig. 1 with a novel PWM control technique based on the current controlled PWM method [1]. However, the FRM under 4-switch converter is supplied by different voltage level, so that the load current are reduced by $\sqrt{3}$ with respect to the current obtained when the same voltage and the 6-switch converter is used. Also, due to supplying voltage irregularity and lack of a phase control freedom, the phase current can be much more fluctuated, resulting in torque ripple. Therefore, when the 4-switch FRM is used for a certain application, one should understand and analyze the overall performance with respect of torque ripple and iron losses, compared with 6-switch FRM.

In this paper, the authors introduce the computational method to analyze the characteristics of the FRM under the 4-switch converter using a two dimensional time-stepped voltage source finite-element method (FEM). To produce the 4-switch converter and perform the experiment, the digital signal processor (DSP) installed controller and the prototype FRM are built. From the analysis and experimental results, it can be verified that the proposed analysis method is suitable to

analyze a FRM under 4-switch converter.

Fig. 1. 4-switch 3-phase FRM drive system

II. FINITE ELEMENT FORMULATIONS

At each instant, the interaction between the 4-switch converter circuitry and electromagnetics is achieved by defining the winding current in terms of the electrical circuit parameters [2]. The actual phase currents of the 4-switch FRM are controlled by hysteresis current controller. Therefore, the detailed voltage equations taking account of the current regulation using hysteresis controller should be derived.

A. Voltage Equation when current is flowing through phases B and C

With reference to Fig 1, consider a 60-degree period when current is flowing through phases B and C. The switch S4 is turned on and off according to the current regulation in this mode, so that the flow of current can be categorized into four cases as shown in Figs. 2. Fig. 2(a) and (b) show the current flows at the commutation instant when switch S4 is turned on and off, respectively. In these cases, the current continues to flow in open phase A due to its inductance L . As the result, two voltage equations can be derived as:

$$R_c i_c + L_{lc} \frac{di_c}{dt} + \frac{d\Phi_c}{dt} + R_b i_b + L_{lb} \frac{di_b}{dt} - \frac{d\Phi_b}{dt} = V_1 \quad (1)$$

$$R_c i_c + L_{lc} \frac{di_c}{dt} + \frac{d\Phi_c}{dt} + R_a i_a + L_{la} \frac{di_a}{dt} - \frac{d\Phi_a}{dt} = V_2 \quad (2)$$

where R is the resistance of phase winding, L_l is the leakage inductance of the stator coil ends and Φ is the flux linkage of phase winding. V_1 and V_2 represent voltage and Table II shows there values. V_{CE} and V_F are the forward

voltage drop across the transistor and the diode, respectively.

If the current in the open phase A decays to zero and switch S4 is turned on and off, only the main voltage equation exists as shown in Figs. 2(c) and 2(d). In these cases, the voltage equations are identical to (1).

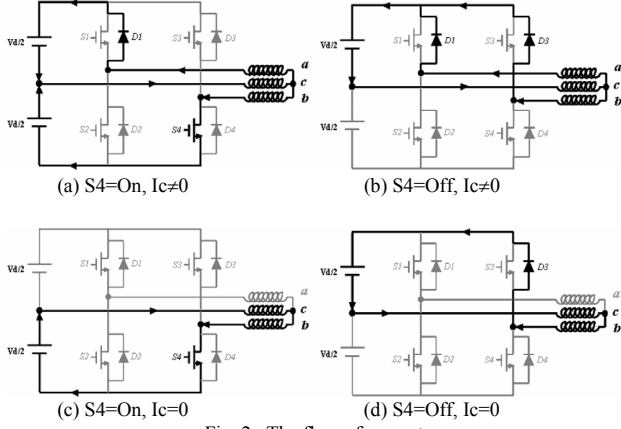

Fig. 2. The flow of current

B. System Matrix

After deriving the circuit voltage equations at each Mode, the backward difference method is adopted to treat the time derivative terms and to construct system matrix.

In the case there is one current loop as shown in Figs. 2(c) and (d), the system matrix can be expressed as (3). In the case of having two circuit voltage equations as shown in Figs. 2(a) and (b), the system matrix can be obtained as (4).

$$\begin{aligned} & \begin{bmatrix} [S] & \{Q\} \\ [F]/\Delta t & 2R + 2L_l/\Delta t \end{bmatrix} \begin{bmatrix} \{A\}^{t+\Delta t} \\ I_1^{t+\Delta t} \end{bmatrix} \\ & = \begin{bmatrix} [0] & \{0\} \\ [F]/\Delta t & 2L_l/\Delta t \end{bmatrix} \begin{bmatrix} \{A\}^t \\ I_1^t \end{bmatrix} + \begin{bmatrix} \{G\}^{t+\Delta t} \\ V_1^{t+\Delta t} \end{bmatrix} \end{aligned} \quad (3)$$

$$\begin{aligned} & \begin{bmatrix} [S] & \{Q_1\} & \{Q_2\} \\ [F_1]/\Delta t & 2R + 2L_l/\Delta t & R + L_l/\Delta t \\ [F_2]/\Delta t & R + L_l/\Delta t & 2R + 2L_l/\Delta t \end{bmatrix} \begin{bmatrix} \{A\}^{t+\Delta t} \\ I_1^{t+\Delta t} \\ I_2^{t+\Delta t} \end{bmatrix} \\ & = \begin{bmatrix} [0] & \{0\} & \{0\} \\ [F_1]/\Delta t & 2L_l/\Delta t & L_l/\Delta t \\ [F_2]/\Delta t & L_l/\Delta t & 2L_l/\Delta t \end{bmatrix} \begin{bmatrix} \{A\}^t \\ I_1^t \\ I_2^t \end{bmatrix} + \begin{bmatrix} \{G\}^{t+\Delta t} \\ V_1^{t+\Delta t} \\ V_2^{t+\Delta t} \end{bmatrix} \end{aligned} \quad (4)$$

where, S is the stiffness matrix, Q and F are the matrix related to the stator winding and back-EMF, respectively. G is the forcing term by a magnet.

III. RESULTS AND DISCUSSIONS

Fig. 3 compares the measured and the calculated current in each phase. It is noted that the experimental results closely match the simulation ones of the proposed analysis method. As phases A and B are activated, these phases are supplied by the full of dc-link voltage, so that during one PWM period, the

current is increased more than the other operating modes. Moreover, independent control of phases A and B results in current ripple in phase C during the silent periods, resulting from the difference between the phase A and phase B currents. Even though it contains more current ripple than case of the six-switch converter, it can be acceptable and also can be reduced by controlling the hysteresis band size. From the detailed investigation of the experimental results, it is noted that the authors successfully utilize the four-switch converter topology to drive the 3-phase FRM and the validity of the developed direct current controlled PWM is fully verified.

Fig. 3. Comparison of current waveforms (0.5A/Div.)

IV. CONCLUSION

In this paper, a 2-dimensional time-stepped voltage source finite element method in 4-switch converter system has been proposed. To prove the propriety of the proposed analysis method, the prototype FRM and a DSP installed experimental devices were equipped and the experiment has been performed. As a result, accurate solutions can be obtained by the proposed method and the 4-switch converter topology with a direct current controlled PWM can be successfully utilized to drive the 3-phase FRM.

EEG inverse problem solution with minimal influence of the conductivity

Bertrand Russel Yitembe¹, Guillaume Crevecoeur², Roger Van Keer¹, and Luc Dupré²

¹Dept. of Mathematical Analysis, Ghent University, Galglaan 2, B-9000 Ghent, Belgium

²Dept. of Electrical Energy, Systems & Automation, Ghent University, Sint-Pietersnieuwstraat 41, B-9000 Ghent, Belgium

Abstract—In this paper, we propose a novel method that improves the accuracy of the estimation of neural electrical dipoles when solving the EEG inverse problem. A spherical head model is used where we limit the influence of the unknown conductivity brain-skull ratio on the inverse problem. We redefine the cost function that is used in the EEG problem where only relevant information is taken as input in the inverse problem. In contrast to previous approaches, weighting factors are used so that the impact in the inverse problem of each electrode is strategically chosen in order to reduce the error made on EEG dipole source localization. The proposed method enhances the source localization accuracy from approximately 9mm to 1mm for dipoles near the edge and from 2.1mm to 0.4mm for dipoles near the center of the brain.

I. INTRODUCTION

ELECTROENCEPHALOGRAPHY (EEG) is a medical imaging technique that neurologists use to investigate neurological disorders. Using metal electrodes, brain activity can be recorded non-invasively. EEG source analysis is particularly useful in the diagnosis of neurological disorders like epilepsy. Indeed, the determination of the origin of specific EEG waveforms helps neurologists to pinpoint the origin of the epilepsy and to evaluate the patient for resective surgery. However, when coupling the non-invasive EEG measurements to a numerical method, inaccuracies in the neural source localization are introduced. Indeed, the accuracy of EEG source analysis is mainly determined by the noise in the measurement and the accuracy of the numerical head model parameters. Also, the source modelling of the brain activity introduces an error. Since the brain electrical activity of patients suffering from epilepsy are characterized by a limited number of electrical dipoles [1], we do not investigate the influence of the used source model. The head model on the other hand has a large impact on the solution of the EEG inverse problem where important errors are introduced by the uncertainties of the values of the electrical conductivity of the brain and the skull. The quantitative values of the electrical conductivity of the brain and the skull remain a very important parameter that attract a lot of debates in EEG source analysis field, see e.g. [2], [3]. In numerical methods, the brain to skull ratio of the conductivity is the important parameter and may vary between 1/9 to 1/60. This paper presents a novel numerical scheme, the so-called Reduced Conductivity Dependence (RCD) method, that minimizes the influence of the conductivity uncertainty on the localization errors. This method introduces a selection procedure of the EEG electrodes

that are minimally influenced by the conductivity values. We validate the method onto a widely-used approximation of the head: the semi-analytical spherical head model. Comparisons are made with traditional least-squares minimization methods. For simplicity of analysis, we impose that the neural activity is represented by a single electrical dipole.

II. EEG SOURCE ANALYSIS

A. Forward problem

The forward problem starts from a given electrical dipole and calculates the potentials at the electrodes. For this, the brain to skull ratio of the conductivity X needs to be provided. The spherical head model is a widely-used approximation of the head where the head is represented by three spheres: the inner sphere represents the brain, the intermediate layer represents the skull and the outer layer represents the scalp. The forward problem needs to solve the Poisson's equation:

$$\nabla \cdot (\sigma(\mathbf{r})\nabla V(\mathbf{r})) = \mathbf{d} \delta(\mathbf{r} - \mathbf{r}_d) \quad (1)$$

with $\sigma(\mathbf{r})$ the place dependent conductivity determined by X , $V(\mathbf{r})$ the place dependent potential, \mathbf{d} the dipole orientation vector (with intensity $I = \|\mathbf{d}\|$) and \mathbf{r}_d the dipole location vector. $\delta(\cdot)$ is the three-dimensional delta Dirac function. An analytical expression for the potential values can be calculated using [4]. In this study, a standard configuration of $m = 27$ electrodes is used. For given \mathbf{r}_d and dipole orientation \mathbf{d} , the electrical potential values at the given electrodes can be calculated: $\mathbf{V}_m(\mathbf{r}_d, \mathbf{d}) \in \mathbb{R}^{m \times 1}$. The potential values are a linear function of the dipole orientation: $\mathbf{V}_m = \mathbf{L}(\mathbf{r}_d) \cdot \mathbf{d}$ with $\mathbf{L} \in \mathbb{R}^{m \times 3}$ the so-called lead field matrix.

B. Traditional solution of EEG inverse problem

The aim of the EEG inverse problem is to start from measured EEG potentials $\mathbf{V}_{\text{meas}} \in \mathbb{R}^{m \times 1}$ and to recover the neural dipole location \mathbf{r}_d^* and orientation \mathbf{d}^* . This is carried out by minimizing a cost function, the so-called relative residual energy (RRE):

$$\{\mathbf{r}_d^*, \mathbf{d}^*\} = \arg \min_{\mathbf{r}_d, \mathbf{d}} \text{RRE}(\mathbf{r}_d, \mathbf{d}) \quad (2)$$

with

$$\text{RRE}(\mathbf{r}_d, \mathbf{d}) = \frac{\|\mathbf{V}_{\text{meas}} - \mathbf{V}_m(\mathbf{r}_d, \mathbf{d})\|}{\|\mathbf{V}_{\text{meas}}\|} \quad (3)$$

where $\|\cdot\|$ is the L_2 norm. The number of parameters in this least-squares cost function can be reduced by considering

the optimal dipole components: $\mathbf{d}_{\text{opt}} = \mathbf{L}^\dagger \cdot \mathbf{V}_{\text{meas}}$ with \mathbf{L}^\dagger the Moore-Penrose pseudo inverse of the lead field matrix. Equation (3) becomes then, see e.g. [5]:

$$\text{RRE}(\mathbf{r}_d) = \frac{\|\mathbf{V}_{\text{meas}} - \mathbf{L}(\mathbf{r}_d)\mathbf{L}(\mathbf{r}_d)^\dagger\mathbf{V}_{\text{meas}}\|}{\|\mathbf{V}_{\text{meas}}\|}. \quad (4)$$

The widely Nelder-Mead simplex method is used here to find the global minimum of the Relative Residual Energy (RRE).

III. REDUCED CONDUCTIVITY DEPENDENCE (RCD) METHOD

A. Description of the method

The RCD method proposes an alternative cost function that needs to be minimized for EEG source analysis. The main idea lies in the selection of electrodes that provide useful information in the sense that the electrodes which are selected, are minimally affected by the unknown conductivity in the forward model. Indeed, depending on the location of the electrical dipole and its orientation, some potentials are highly affected by X and others are not. The selection procedure needs to be performed in each iteration k of the minimization scheme, in this case the Nelder-Mead simplex method. In the following, we explain the basic steps taken by the RCD method.

Step 1: Start value $\mathbf{r}_d^{(0)}$ is evaluated in the forward model, yielding the lead field matrix $\mathbf{L}(\mathbf{r}_d^{(0)})$, and simulated potential values $\mathbf{V}_m(\mathbf{r}_d^{(0)}) = \mathbf{L}(\mathbf{r}_d^{(0)})\mathbf{L}(\mathbf{r}_d^{(0)})^\dagger\mathbf{V}_{\text{meas}}$. Initialize $k = 0$.

Step 2: Calculate the sensitivity \mathbf{W} and the normalized sensitivity \mathbf{w} of the simulated electrode potentials to the conductivity for a certain conductivity ratio X_0 :

$$\mathbf{W} = \frac{\partial \mathbf{V}_m(\mathbf{r}_d^{(k)})}{\partial X} \Big|_{X=X_0}, \quad \mathbf{w} = \frac{|\mathbf{W}|}{\|\mathbf{W}\|} \quad (5)$$

In the case of the spherical head model, \mathbf{W} and \mathbf{w} can be calculated analytically. When considering more complex realistic head models, this can be calculated by numerical differentiation.

Step 3: Selection of least sensitive electrodes, based on (5). Largest values are not considered in the EEG inverse problem, since their potential values are affected by the conductivity. A new set of potential values are obtained: $\mathbf{S}_m \in \mathbb{R}^{N \times 1}$ and the corresponding set of measured EEG potentials are considered $\mathbf{S}_{\text{meas}} \in \mathbb{R}^{N \times 1}$. N is the number of selected potentials.

Step 4: Calculation of RCD cost function:

$$\text{RCD}(\mathbf{r}_d^{(k)}) = \frac{\|\mathbf{S}_{\text{meas}} - \mathbf{S}_m(\mathbf{r}_d^{(k)})\|}{\|\mathbf{S}_{\text{meas}}\|} \quad (6)$$

Step 5: Based on (6), the next iterate $\mathbf{r}_d^{(k+1)}$ can be calculated. If the termination criteria of the minimization procedure are met, i.e. $\text{RCD}(\mathbf{r}_d^{(k)})$ reaches tolerance, then stop the algorithm. Otherwise, go to step 2.

B. Results and discussion

The efficiency of the RCD method is illustrated by performing Monte Carlo simulations. Starting from known dipole locations $\tilde{\mathbf{r}}$ and a given conductivity ratio X_0 , we compute EEG

Fig. 1. Plot of Conductivities vs Error with $X_0 = 1/25$ (left) and for several noise levels (right) at $X=1/40$, for dipoles located near the center of the head.

potentials. Gaussian noise is added to these potentials in order to simulate real measured EEG potentials. Dipole locations $\hat{\mathbf{r}}$ are then estimated using the traditional method, i.e. solution of (2), and estimated using the RCD method, explained in III.A. The accuracy of both methods is determined by the error $E = \|\tilde{\mathbf{r}} - \hat{\mathbf{r}}\|$ for different values X and noise levels. The white zero mean Gaussian noise with standard deviation Σ has a noise level defined as $n = \frac{\Sigma}{\mathbf{V}_{RMS}}$ with \mathbf{V}_{RMS} the root mean square of \mathbf{V} . Fig. 1 illustrates the decrease in localization error due to the use of the RCD method (with varying number of selected potentials $N=4, 6, 8, 10$ in step 3 of III.A.) compared to the traditional method ($N=27$). A reduction of the error is introduced due to the use of the RCD method.

For dipoles located near the center of the head, the localization error can be reduced from 2 mm to 0.4 mm, while for dipoles located near the edge of the head from 9 mm to 1 mm. These results are obtained when using $X_0 = 1/25$ for constructing the “measured” electrode potentials and when assuming $X = 1/40$ for solving the inverse problem. The influence of noise has almost no effect on the relative localization error between the RCD and the traditional RRE method.

IV. CONCLUSION

This paper proposes a method that decreases the error introduced by the uncertainties of the conductivity. The results show that the EEG inverse problem can be solved with considerably improved quality, as compared to the traditional inverse solutions.

Modeling and Extraction of Parasitics in IGBT Modules

Zarife Cay, Olaf Henze, Stephan Koch, and Thomas Weiland

 cay@temf.tu-darmstadt.de

Abstract — One of the most dominant parasitics causing even fatal problems in PWM inverters is the parasitics of IGBT modules. In this paper, the parasitic parameters of a high-power multi-chip IGBT module are modeled and extracted. The extraction approach is verified by comparing the S-parameters of the proposed network model with the S-parameters of the electromagnetic model of the module.

I. INTRODUCTION

PWM inverters are nowadays the most commonly used adjustable speed drives (ASDs) mainly because of superior, dynamic performance benefit of low cost, fast switching insulated gate bipolar transistors (IGBTs). High switching speed of IGBTs, however, induces high rates of change of voltage and current with respect to time (dv/dt , di/dt) which, in turn, increase the action of parasitic components in printed circuit boards (PCBs) and packages of power inverters. These parasitics are reported to have severe negative effects on the electrical efficiency and electromagnetic compatibility of ASDs [1]. Therefore, it is necessary to obtain high frequency (HF) electrical models of ASDs including dominant parasitics at the early design stage.

Parasitic elements of IGBT modules are one of the major parasitics deteriorating the good performance of PWM inverters. In this paper, these parasitics are modeled for an IGBT module.

II. MODELING AND EXTRACTION OF PARASITICS

A. Six-pack IGBT Module

An IGBT module consisting of six chips, three IGBTs and three anti-parallel diodes, is studied. Fig. 1 shows a picture of the module.

Fig. 1. Six-pack IGBT module

B. High Frequency Electromagnetic Analysis

The electromagnetic (EM) analysis is conducted using the

frequency domain solver of CST MW Studio® capturing the 3D geometrical effects and the high frequency effects, such as skin and proximity effects, of the design. Table I summarizes the details of the computational analysis. The simulation model is illustrated in Fig. 2.

C. Modeling and Parasitic Extraction Approach

The parameter extraction tool of CST MW Studio® based on the transmission line method is employed to compute the parasitics of the structure. This tool extracts a SPICE-compatible network model consisting of lumped R, L, C, G, M elements from previously calculated S-parameters [2]. As S-parameters represent the high frequency behavior of a 3D EM model equivalently, it is expected that the derived circuitry responses nearly the same as physical device at the input/output terminals. The proposed network model of the module is depicted in Fig. 3. Table II gives the extracted parasitics. The typical values of the two circuit parameters reported in the data sheet of the module are displayed in Table III [3]. The computed inductances are consistent with the typical value of the stray module inductance. The typical lead resistance is obviously smaller than the extracted ones. The HF effects can lead to such large differences in the ac resistance as the frequency increases.

A. Verification of Parasitic Extraction Approach

As the analytical calculation of parasitics for such a complex geometry is too complicated, the constructed parasitic circuit model is verified numerically. For this

purpose, the circuit model is implemented in CST Design Studio™. The S-parameters for the case, when the transistor labeled as T1 is on and the current flows from the power supply to the AC motor, are computed. These results are presented in Fig. 4 together with the S-parameters of the EM model for the same case. The network parameters extracted at 1 MHz are used. Thus, the agreement between the results is best at 1 MHz. At higher frequencies, the agreement is less good due to the frequency dependence of the extracted lumped element parameters.

Fig. 4. S-Parameters of (a) the EM model and (b) the parasitic network model

III. CONCLUSIONS

A parasitic network model of an IGBT module is developed using the network parameter extraction tool of CST MW Studio® based on transmission line models. The electrical model and the extracted parameter values are verified by comparing the S-parameters of both the electromagnetic and the circuit model. A more detailed discussion of the parasitic extraction technique and further results will be presented in the full paper.

Modelling Motion, Stiffness and Damping of a Permanent-Magnet Shaft Coupling

A. Niemenmaa¹, L. Salmia¹, A. Arkkio¹, J. Saari²

¹Helsinki University of Technology, P.O. Box 3000, FIN-02015 TKK, Finland

²Hamilton Sundstrand Associate Fellow
asko.niemenmaa@tkk.fi

Abstract— Different methods for modelling the motions, torques and losses in a permanent-magnet shaft coupling are studied. The containment shroud of the coupling is a homogeneous conducting cylinder. Its motion can be modelled using the motional electromotive force, i.e. the $v \times B$ term. The moving-band technique is used for modelling the relative motion of the magnet cylinders of the coupling. Using the motional electromotive force for the shroud gives reliable results while the computational effort is kept at minimum. The stiffness and damping coefficients of the coupling are obtained from a numerical impulse response test.

I. INTRODUCTION

Fig. 1 show a cross-sectional view of a magnetic shaft coupling. These couplings are used when pumping a reactive fluid and absolutely hermetic handling is required. The outermost cylinder is composed of a ferromagnetic yoke, permanent magnets and a stainless steel cover over the magnets for their protection. Typically, the outer part is mechanically connected on the shaft of an electrical motor and rotated say at 1500 rpm. The thin stationary cylinder in the middle is the containment shroud. It makes the hermetic seal. The shroud material is stainless steel resistant to the aggressive fluid. It should also have a large specific resistance to reduce the eddy-current loss. The innermost cylinder is a mirror image of the outermost one and made of the same materials. The inner part is typically connected on a rotor shaft of a pump. The field from the permanent magnets provides the magnetic coupling and torque transfer from the electrical motor to the pump. The magnets are either of NdFeB or SmCo type depending on the operation temperature of the coupling.

Fig. 1. Cross-sectional view of a permanent-magnet coupling. The thin shroud in the middle is moving with respects to the other parts at a speed of 13 m/s (downwards).

This cylindrical coupling arrangement has some challenge from the modelling point of view as all the three cylinders may be in relative rotation with respect to each other. The shroud is a simple homogeneous cylinder, and there are several ways of modelling its motion. Davat et al. [1] have studied motion within finite element analysis, and Sadowski et al. [2] have studied the torque computation, among others. Similar methods are also studied in the present paper in association with the permanent-magnet shaft coupling.

The aim is to find the most efficient methods of magnetic field analysis for the structural optimisation of this type of a coupling. In addition, the torsion oscillations of the coupling and the passive electromagnetic damping of these oscillations are studied.

II. METHODS OF ANALYSIS

A. Magnetic field analysis

The length to pole-pitch ratio of the coupling studied is about 16. Thus, the magnetic field of the coupling can be assumed to be two-dimensional. The magnetic vector potential A and finite element method are used.

B. Modelling motion and computing the torques

The motion of the shroud is modelled either by using the motional electromotive force $v \times B$ or by applying the moving-band technique [1] in the air gaps on both sides of the shroud.

Fig. 2 shows a finite element mesh for the moving-band technique. It is built up of five sub-meshes, rigid ones for the three cylinders and changeable ones for the two air gaps. The vector potentials of the sub-meshes are coupled through periodic boundary conditions. Thus, the field of each sub-mesh region is modeled in its own frame of reference and the vector potential is forced to be continuous from mesh to mesh by the periodic boundary conditions. The air gaps on both sides of the shroud are discretised in two layers of elements. One of the element layers is used for the rotation, the other one for torque computation.

The torques are calculated applying the equation [3]

$$T = \frac{l}{\mu_0(r_o - r_i)} \int_{S_{ag}} r B_r B_\phi dS \quad (1)$$

on the non-changing finite element layers chosen for the purpose (Fig. 2). l is the axial length, r_o the outer radius and r_i the inner radius of the air gap. B_r and B_ϕ are the radial and circumferential components of the flux density and r is the radius. S_{ag} is the cross-sectional area of the air gap.

Fig. 2. Second-order isoparametric elements were used for the analysis.

C. Analysis of losses

The eddy-current losses induced in the conducting structures of the coupling are obtained by integrating the eddy-current loss density

$$p_e = \frac{1}{\sigma} \mathbf{J}^2 = \sigma \left(-\frac{\partial \mathbf{A}}{\partial t} + \mathbf{v} \times \mathbf{B} \right)^2 \quad (2)$$

over the conducting volume. The eddy-current loss is the only component of loss included in the present analysis.

D. Torque stiffness and damping

To study the damping characteristics of the coupling within numerical analysis one can either apply harmonic torsion-angle excitation or a numerical impulse response test [4]. In the harmonic excitation, the inner magnet cylinder is forced to torsion oscillation at a single frequency. In the impulse test, the innermost cylinder is displaced from its stationary position for a short period of time and returned back to its original position. The excitation and response signals are recorded and Fourier transformed, and when the transformed signals are divided frequency by frequency, a frequency response function based on numerical analysis is obtained. The advantage of the impulse response test is that a wide range of frequencies is excited and modelled in a single simulation. The harmonic excitation test has to be repeated for each frequency of interest.

The stiffness of the coupling K (spring constant) is related to the real part of the frequency response function and the damping coefficient C to the imaginary part [4].

III. RESULTS

Table 1 shows the results computed for the rated steady-state operation point of the coupling. In a reference frame fixed to the outer cylinder, the field is a dc field and it can be solved by a dc solver using the motional electromotive force for the shroud. In addition, both the electromotive-force formulation and moving-band technique can be used within time-discretised analysis. The three methods give almost similar results. The power balance seems to be fulfilled

slightly better by the two cases in which the motional electromotive force is used. The time step used was 0.1 ms. The power balance of the moving-band technique can be improved by using a shorter time step but the simulation time increases accordingly.

Fig. 3 shows the frequency response function obtained from the numerical impulse test. This type of a coupling has very little dynamics within the range of its potential torsion oscillations. The stiffness coefficient K is about 8000 Nm/rad and the damping coefficient C is only 0.17 Nms/rad².

TABLE I
RESULTS FOR THE RATED STEADY-STATE OPERATION OF THE COUPLING.

	dc solution	time-discretised	time-discretised
	motional emf	motional emf	moving band
Torque in the outer air gap [Nm]	320.58	320.58	320.65
Torque in the inner air gap [Nm]	298.73	298.73	298.67
Shaft power on the shroud [W]	3431.98	3431.98	3452.87
Resistive loss in the shroud [W]	3432.1	3432.1	3411.44
Error in power balance [W]	-0.12	-0.12	41.43
Error percent [%]	0.00	0.00	1.21

Fig. 3. Frequency response between the torque transmitted by the coupling and the torsion angle. The continuous curves are from the numerical impulse test, the dots from time-harmonic torsion-angle excitation.

IV. CONCLUSION

The motional electromotive-force formulation gives good results when modelling the motion of the shroud of a magnet coupling while the computational effort is kept at minimum. The results from the moving-band technique, a method validated by measurements in several other problems, verify the results of the motional electromotive-force formulation.

Abstract—We present a model of the cathodic region in a Proton Exchange Membrane (PEM) fuel cell, where a segmented electrode is considered. The model, based on the discrete geometric approach, couples a discrete formulated steady state current conduction problem in a non isotropic medium with electrochemical reaction at the catalyst layer described by means of the Butler-Volmer equation. The model allows to analyze either the constant voltage operation or the constant current operation of the fuel cell.

Index Terms—PEM fuel cells, Steady state current conduction, Discrete geometric approaches.

I. INTRODUCTION

During the last decade the idea of a sustainable development based on eco-compatible technologies has taken more and more relevance, with particular attention to the energy production by clean, efficient and low impact processes, such as the chemical processes within the fuel cells, [1], [2]. These devices produce electric power by direct conversion of hydrogen or an aqueous solution of methanol. Fuel cells are an important technology for a potentially wide variety of applications including auxiliary power, transportation power, and stationary power for buildings and other distributed generation applications. These applications are encountered in a large number of industries worldwide. Among a variety of fuel cells available, proton exchange membrane (PEM) fuel cells are considered to be most suitable for transportation and portable applications due to attractive features like low operation temperature, high energy density and efficiency. In this context, a correct acquisition in situ of the parameters that determine their functioning, requires the implementation of mathematical models that could remarkably contribute to the interpretation of experimental results and to the determination and optimization of useful geometric configurations to further optimize their performance.

One of the aspects that needs to be improved in a typical PEM fuel cell is to achieve an higher average current density at any given operating cell voltage. On the other hand, uniformity of current density distribution across the entire active area is crucial for performance optimization.

In the electrochemical reactions of the PEM fuel cells, hydrogen (or methanol) at the anode provides protons, freeing electrons in the process that must pass through an external circuit to reach the cathode. The protons, which remain solvated

with a number of water molecules, migrate, through the membrane, to the cathode to react with oxygen and the returning electrons. Water is subsequently produced at the cathode. In a PEM, Nafion is used as the membrane placed between the anode and the cathode. Furthermore, it is also employed as an important component of the active layer, where the catalyst is present.

The aim of this paper is to develop a numerical simulation model, based on Discrete Geometric Approach, [3], [4], [5], of the electronic conduction in the so called Gas Diffusion Layer (GDL) region of the PEM fuel cell attached to a segmented graphite current collector region, concurring to analyze the potential distribution in the cathodic region, [6], [7]. From the potential distribution it is straightforward to compute the current density distribution in order to estimate its degree of uniformity through the entire active area of the electrodes. In this way, it is possible to increase the current density for a given working cell potential.

II. A DISCRETE GEOMETRIC MODEL

We propose a 2D discrete geometric model of the cathodic region, where electronic conduction occurs; we model a portion of the periodic structure corresponding to a segmented electrode fuel cell. We denote with D the domain of interest, consisting of a GDL region D_{GDL} and one half of two adjacent graphite current collectors plates D_a, D_b respectively separated by an insulating region D_i , Fig. 1. The upper part of the boundary of D_{GDL} region is in contact with the catalyst layer, where electrons react with protons during the electrochemical reaction; the catalyst layer is modeled here as a zero-thickness region. We introduce in $D_{GDL} \cup D_a \cup D_b$ a pair of interlocked grids, one dual of the other, where the primal grid consists of nodes n , edges e , faces f and volumes v , [4], [5]; the volumes are prisms with a triangular base. The dual grid is obtained from the primal by means of the barycentric subdivision and it consists of dual volumes \tilde{v} , dual faces \tilde{f} , dual edges \tilde{e} and dual nodes \tilde{n} . Since the problem is 2D and electric E and current density J vector fields are in a plane, we consider the projection on a plane of such a pair of interlocked grids; therefore the primal volumes coincide with the triangles of the mesh and the primal faces coincide with the edges of the mesh.

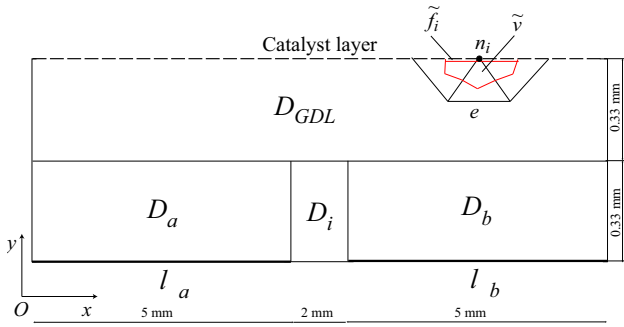

Fig. 1. Geometry of the 2D model of a portion of the periodic structure corresponding to a segmented electrode fuel cell; the draw is not to scale.

The electron current I_n^s across a dual face \tilde{f}_n , in a one to one correspondence with node n in the catalyst layer (refer to Fig. 1), can be modeled according to Boutler-Volmer equation¹ [6], [7]

$$I_n^s(V_n) = -|\tilde{f}_n|J_0(10^{[(V_n - E^0)/\eta_c]} - 10^{[-(V_n - E^0)/\eta_c]}), \quad (1)$$

where E^0 is the equilibrium potential characteristic of the electrochemical reaction, η_c is the cathode Tafel slope at 30 C, J_0 is the apparent exchange current density and $|\tilde{f}_n|$ is the area of the dual face \tilde{f}_n ; $I_n^s(V_n)$ is a non linear function of the electric potential V_n in a neighborhood of node n .

Next, we can formulate the steady state current conduction problem according to the Discrete Geometric Approach, [8], [9] as

$$-(\mathbf{G}^T \boldsymbol{\sigma} \mathbf{G} \mathbf{V})_i - (\mathbf{I}_s(\mathbf{V}))_i = 0, \quad (2)$$

where \mathbf{V} is the array of the electric scalar potentials V_i associated with a primal node n_i , \mathbf{G} is the incidence matrix between the orientations of the a primal edge and a primal node, $\boldsymbol{\sigma}$ is a square matrix of dimension $N^2 - N$ being the number of primal nodes— representing a discrete counterpart of the constitutive relation at continuous level $\mathbf{J} = \boldsymbol{\sigma} \mathbf{E}$, [8], [9], [10]; in the case of D_{GDL} region, it is important to note that the conductivity tensor $\boldsymbol{\sigma}$ is diagonal, but it represents an anisotropic conductivity along orthogonal directions ($\sigma_{xGDL} = 0.785$ S/cm, $\sigma_{yGDL} = 3.14$ S/cm), while the conductivity of the bulk graphite collector regions D_a, D_b is isotropic, $\sigma_{D_{a,b}} = 670$ S/cm. The subscript $(\mathbf{x})_i$ denotes the i -th entry of the array \mathbf{x} , in a one-to-one correspondence with the node n_i ; if the node n_i belongs to the catalyst layer, then $(\mathbf{I}_s(\mathbf{V}))_i$ is the current crossing the dual face \tilde{f}_i corresponding to the node n_i ; the entries of $(\mathbf{I}_s(\mathbf{V}))$ are null for any node not belonging to the catalyst layer. Boundary conditions must be considered in addition along the l_a, l_b lines, Fig. 1; the potential is unknown along the catalyst layer. Symmetry boundary conditions on the pair of lateral sides of D are considered in addition.

III. NUMERICAL RESULTS

We will analyze the potential distribution in the cathodic region of a segmented electrode cathode of a PEM fuel cell, by

¹This model accounts for various factors like local membrane hydration state, reactant and product concentration, temperature, etc. affecting the electrochemical reactions in a fuel cell.

considering a portion D of the periodic current collector structure with the geometry given in Fig. 1. We solved the non-linear system (2) by means of a Newton-Raphson method. As boundary condition we implemented the so called constant voltage operation of the fuel cell, where the potential of the primal nodes on l_a, l_b is imposed as $V_{l_a} = V_{l_b} = 0.695$ V. In the full paper, we will also show the so called constant current operation, where the total current crossing dual faces along l_a, l_b are imposed and consequently the potential V_{l_a}, V_{l_b} of the equipotential interfaces l_a, l_b is computed.

The final potential distribution in $D_{GDL} \cup D_a \cup D_b$ is shown in Fig. 2. The obtained results are in a good agreement with those reported in literature, but obtained by means of a finite difference method, [7].

Fig. 2. Part A): The resulting potential distribution along the catalyst layer is shown. Part B): the resulting overall potential distribution in the 2D region $D_{GDL} \cup D_a \cup D_b$ is depicted.

Abstract — This paper presents a magnetic circuit modeling of closed loop Hall-effect current sensors based on a magnetic equivalent circuit which could be simulated with a circuit type simulator software (PSPICE model). First, the principle of measurement of the closed loop Hall-effect current sensors is presented. Then, the magnetic equivalent circuit (MEC) modeling justified by the engineers' model needs is elaborated. Finally the parameters identification protocol based on 3D Finite-Elements (FE) simulations and simplex optimization method is explained.

I. INTRODUCTION

The closed loop Hall-effect current sensors [1] can measure all kinds of current from DC to several tens of kHz with a galvanic insulation between the primary current and the measuring signal. The current sensor must have a measuring signal directly proportional to the current to be measured. In order to improve current sensors accuracy, frequency bandwidth or magnetic immunity, engineers require specific models able to reproduce signals with a good accuracy in a short time in order to test many improvement ideas. A specific model which can be implemented in circuit-type simulator software has been created in order to help engineers to improve the sensors performances.

II. PRINCIPLE OF MEASUREMENT

The current sensor main parts are represented in Fig. 1.

Fig. 1 : Current sensor main parts

The primary current (I_p) passing through the sensor creates a magnetic flux ϕ . This magnetic flux is concentrated by the magnetic core. The Hall probe placed inside the air-gap of the core provides a voltage proportional to the magnetic flux density. The electronic board converts this voltage into a secondary current. This secondary current is then, at any time,

proportional to the primary current following (1), (N_p, N_s : primary and secondary coil number of turns respectively):

$$N_p I_p = N_s I_s \quad (1)$$

III. MAGNETIC CIRCUIT MODELING

A. Engineers' needs

The electronic board, necessary to create the secondary current proportional to the primary one, contains many electronic components (diodes, resistors, capacitors...). In order to test the whole system (magnetic circuit and electronic board), engineers need a model of the magnetic circuit able to be implemented in a circuit-type simulator software. The magnetic behavior non-linearities (hysteresis and dynamic effects) excludes a linear electric equivalent model (R,L,C model). A magnetic equivalent circuit or reluctance network model offers a good compromise between accuracy and rapidity. The final model must take into account all the phenomena (geometric effects, hysteresis, dynamic effects) that can create signal distortion. These different phenomena occurred by the magnetic circuit can be studied separately.

B. Modeling of "geometric effects"

The air-gap, where the hall probe is placed, induces flux leakages which lead to local saturation of the magnetic circuit. The Fig. 2 shows the results of a 3D finite elements simulation in magnetostatic. It can be seen that the modulus flux density B inside the magnetic circuit is greatly inhomogeneous. This means that there are a lot of flux leakages.

Fig. 2: Flux density modulus inside the magnetic circuit.

The model must take into account these flux leakages, so the magnetic circuit is decomposed into several flux tubes like shown on Fig. 3

Fig. 3: Magnetic equivalent circuit scheme

With:

- $\mathfrak{R}_1, \mathfrak{R}_2, \mathfrak{R}_3$: magnetic circuit flux tubes
- \mathfrak{R}_{leak} : leakage flux tube
- \mathfrak{R}_{ag} : air-gap flux tube
- $N1.I, N2.I, N3.I$: fictitious magnetomotive force sources
- ϕ_1, ϕ_2, ϕ_3 : magnetic fluxes.

After analysis, and in order to represent accurately the geometric effects (flux leakages, air-gap), three specific parameters that can not be identified analytically have to be determined. These three parameters are: α , the angular position of the leakage flux tube, S_{ag} the cross-section of the air-gap flux tube, S_{leak} , the cross-section of the leakage flux tube.

In order to identify these parameters, an optimization algorithm [2] based on the simplex method is used. The criterion used here is the mean quadratic error between the flux density modulus calculated by a 3D FE simulation in magneto static and the flux density modulus calculated by the magnetic equivalent circuit along the mean length of a half of the magnetic circuit. In order to find constant parameters and make a compromise between linear and saturated behavior, two objective functions (OF_1, OF_2) are evaluated. Then, these two objective functions are used to make a single objective function OF so as to:

$$OF = \sqrt{(OF_1)^2 + (OF_2)^2} \quad (2)$$

OF is the simplex optimization algorithm criterion to minimize. Results of the optimization are shown on Fig. 4.

C. Magnetic material dynamic effects modeling

The magnetic material dynamic effects are represented with a differential equation. This model is based on (3).

$$H_{app} - H_{stat}(B) = \gamma \frac{dB}{dt} \quad (3)$$

H_{app} is the applied excitation field, $H_{stat}(B)$ represents a fictitious static excitation field for a given flux density B and γ is a constant coefficient that represents the whole dynamic effects (eddy currents, wall motion). Assumption, limits and rules of use are described in [3]. This model can

easily be introduced in the MEC seen before. γ is determined by comparing simulated and measured hysteresis loops.

Fig. 4: flux density modulus versus position angle for a half magnetic circuit and air-gap. (MEC: Magnetic equivalent circuit, 3DFE: 3 dimensions finite elements, lin: linear, sat: saturated)

IV. RESULTS

After identification of all the parameters, the model is tested without the electronic card (the measuring resistor is directly linked to the secondary coil) for different current amplitudes and frequencies. Fig.5 shows an example for a current of amplitude 800A and frequency 100Hz. The measured primary current is imposed to the simulation, and the measured and simulated secondary currents are in good agreement.

Fig. 5: imposed primary current and secondary current

V. CONCLUSION

In the extended paper, more details about the parameters identification protocol will be given. The present protocol will be applied for different magnetic circuit sizes and different materials.

Study of Three Dimensional Flux Distribution in Nonlinear Core of Power Transformers Based on 3-D FEM Modeling

Mousavi S. A, Faridi M. and Nabaei V.
Azad University of Khodabadeh
Iran-Transfo Co., Zanjan, Iran
ali.sam2006@gmail.com

Abstract— In this study, we examined three dimensional magnetic flux distributions in the case of single and three phase power transformers. The method of flux distribution inside every packet and also between them has been studied. However, total flux which passes through core limbs may be sinusoidal, but local flux density in some regions of core is distorted and has higher additional harmonics along with fundamental one. In this work, local harmonic flux density is identified. The three dimensional, time-stepped edge-based finite element method is used for modeling power transformer cores. Anisotropy and nonlinear of Laminated steel have been considered in this analysis. The accuracy of this method have examined by experimental results.

I. INTRODUCTION

Power transformers have a very important role in transmission of electrical energy in power systems. The quality of core has large effect on transformer performance and efficiency. Therefore, many researches have been done for investigation of flux distribution in core and improving its characteristics [1, 2]. In previous works, studies are performed by experimental method on a scaled sample core [1] or by numerical two dimensional methods [2]. The disadvantage of experimental methods is that by changing core material or its dimensions, the early results will not be valid. In addition, the test sample is a scale of large power transformer cores and thus its results are not completely correct for actual one. In most cases, core cross section tends to be of roughly circular or semi-circular shape. For this purpose, core is made of several packets that have different widths and depths. In numerical two dimensional methods, we can not model this packet design and the core is taken as one packet with rectangular cross section.

In this paper, we modeled single and three phase three-limbs power transformer cores with 3-dimensional geometry (Fig.1). In order for analyzing, we applied 3-dimensional time-stepped edge-based finite element method. Packet design, nonlinear and anisotropy characteristics of laminated steel has been considered in this model. The skin effects in very thin laminated steels which core is made from are completely negligible in power frequency conditions [3].

We examined 2, 3 and 4 limbs single phase and 3 and 5 limbs three phase power transformers and compared them together.

II. FINITE ELEMENT METHOD

Analysis of flux distribution in power transformer cores is a complex electromagnetic problem. Since the core has a three dimensional structure and its medium is anisotropy and nonlinear, therefore, in this paper we used 3-D finite element method (FEM) with edge based vector potential formulation. Inaccuracies in FEM analysis of 3-D magnetic field problems with nodal based continuous vector potential in present inhomogeneous media are shown in [5]. These shortcomings can be eliminated by applying edge element method. In this method, we considered both anisotropy and nonlinear B_H curve.

For arbitrary voltage supply, first total magnetic flux must be pass through the winding is calculated in term of time. Then in each time step a magneto static analysis is done in such a way that total passed flux across winding equals with calculated one in same time. The current flow from windings in each time step is computed by an iterative algorithm.

After doing this analysis in a time period, we could determine the distribution of magnetic flux density in terms of time and place.

Fig. 1. Three dimensional geometry model of a three phase, three limbs power transformer core with $\frac{1}{4}$ symmetry

III. RESULTS

Generally, the flux and loss profiles showed a trend to exhibit the following features:

The magnetic flux in limbs and yokes of each packet has higher density near core window; by increasing flux and reaching to saturation state, the flux distribution tends to take uniform shape in limbs and yokes.

In low flux densities, flux distributions between packets have great variety, but by reaching to saturation state, distribution would be uniform.

For example, flux distribution in low and high average flux densities for a 4-limbs single phase power transformer are shown in Figs. 2 and 3, respectively.

The most flux distortion is observed in T-joint region.

In core types that have return path, the total flux distortion can be seen in return limbs, too.

The detailed findings and results of modeling the commercial power transformers will be presented in our complete article.

We examined 2, 3 and 4 limbs single phase and 3 and 5 limbs three phase power transformers and compared them together. Furthermore, the results of flux distribution obtained from modeling, is compatible with the results of measurement which is reported in [1] for a sample core.

Wideband Equivalent Circuit Model for Automotive Ignition Coil

JIA Jin, YU Ji-hui, WANG Quan-di, ZHENG Ya-li

The Key Laboratory of High Voltage Engineer and Electric New Technology under the State ministry of Education, Chongqing University, Chongqing 400030, China
E-mail:twoj1985-163.com@163.com

Abstract—automotive ignition coil acts as a transient voltage transformer in spark process. A lumped circuit model is proposed in this paper to predict the wideband characteristics of ignition coil. This model separates the winding into individual sections that simulate winding impedance quality. The parameter capacitance and inductance in circuit are derived from Finite Element Method (FEM) analysis. Calculated results are compared with the measured data in frequency and time-domain and the reliability of the presented model in this paper is verified.

1—Steel Lamination; 2—Primary Bobbin ; 3—Secondary Bobbin;
4—Secondary Winding; 5—Primary Winding

Fig.1 Physical model of ignition coil

I. INTRODUCTION

The basic function of an ignition coil is to convert low-voltage DC source into very fast high voltage at the spark plug gap [1]. Due to primary and secondary coil inductance, stray capacitance, core eddy current loss, the ignition coil terminal characteristics become more sophisticate than stationary state.

The objective of this paper is to predict the wideband characteristic of ignition coil. A wideband, lumped equivalent circuit model topology for ignition coil is proposed. And the parameters in the circuit model are calculated using FEM. The measured and the simulated frequency- and time-domain results are presented. These results show that the proposed model accurately predicts the ignition coil terminal responses in the 100Hz to 10MHz frequency range.

II. COMPUTATION MODEL

Ignition coil 2D cross-section is described in the Fig.1 (a). Fig.1 (b) shows a single section in secondary winding, which consists of hundreds of coated copper wires.

Fig.2 shows equivalent circuit model. This model separates the winding into individual sections. Each section of the circuit consists of capacitance C , inductance L and resistance R . Ten sections were used in this paper.

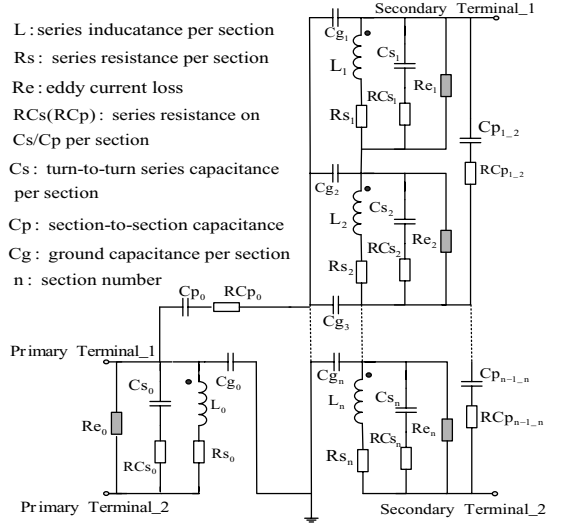

Fig.2 Equivalent circuit model of ignition coil

III. PARAMETER CALCULATION

A. Capacitance

For calculating the ground capacitance C_g and the section-to-section capacitance C_p , simplified solid winding substitutes the virtual winding section, as shown in Fig.3 (a). The capacitance matrix can be obtained from the electrostatic 3D FEM analysis, which is based on (1). Fig.4 (a) shows the 3D meshes of ignition coil.

$$W = \frac{1}{2} \sum_{i=1}^n \sum_{j=1}^n C_{ij} U_i U_j \quad (1)$$

Where W is electrostatic energy; C_{ij} is capacitance between section i and j ; U_i , U_j is voltage to ground of section i , j ; n

is the number of sections. For calculating the turn-to-turn series capacitance C_s , simplified sheet winding substitutes the virtual winding section, as shown in Fig.3 (b). Capacitance matrix is derived from electrostatic 2D FEM analysis. Fig.4 (b) shows the 2D meshes of single section when sheet winding layers number is 20. Then using the matrix data, the capacitance C_s can be calculated with (2).

Fig.3 simplified model of virtual winding

$$C_s(N) = \frac{\sum_i \sum_j ij C_{ij}}{(N-1)^2} \quad (2)$$

Where C_s is turn-to-turn series capacitance; C_{ij} is capacitance between sheet i and j ; N is the number of sheet winding layers.

(a) Fig.4 2D/3D mesh in FEM analysis (b)

B. Inductance

In this work, for converting nonlinear problem to linear, the varying relative permeability μ_r of steel lamination was substituted by the constant and magnetic saturation phenomenon was also ignored. The inductance matrix can be extracted from the magnetostatic 3D FEM analysis, which is based on (3).

$$L_{ij} = N_i N_j \int \vec{B}_i \cdot \vec{H}_j d\Omega \quad (3)$$

L_{ij} is mutual inductance between section i, j ; N_i, N_j is the number of winding turns in section i, j .

Inductance value follows the frequency varying, because of skin effect. Hence, steel lamination $\mu_r=2800$ is adopted for low frequency range, and in this case the inductance matrix is defined as L_L ; $\mu_r=0.001$ is for high frequency range, and the inductance matrix is L_H , as shown in Fig.5.

Fig.5 Inductance Matrix in low-frequency (left) range and high-frequency range (right)

C. Resistance

In circuit model, R_s represents the winding resistance; RC_s/RC_p represents the capacitance dielectric loss and their calculation methods are presented in [2]; R_e represents the steel eddy current loss and its calculation method is proposed in [3].

IV. SIMULATION AND EXPERIMENT

A. Frequency-domain

To invest the secondary winding terminal impedance response from 100Hz to 10MHz, the following simulation cases are studied: Case A-the inductance matrix L_L is adopted as series inductance L; Case B-the inductance matrix L_H is adopted as series inductance L; Case C-ignoring the turn-to-turn series capacitance C_s . As shown in Fig.6, in case A, the simulation matches well with the calculation from 100Hz to 10MHz; and in the other two cases, the simulations only partly agree with measurement.

Fig.6 measured and simulated magnitudes of secondary winding impedance

B. Time-domain

Fig.7 shows the transient voltage test circuit principle. In time-domain test, the above-mentioned case A is performed. The primary winding current and secondary winding voltage are measured and calculated, and the results show a reasonable agreement, as shown in Fig.8

Fig.7 time-domain test circuit principle for ignition coil

Fig.8 measured (upper-part) and calculated (under-part) current of primary winding and voltage of secondary winding

V. CONCLUSION

This paper has presented an equivalent lumped circuit model for predicting wideband characteristics of automotive ignition coil. The main parameters in the circuit are calculated with FEM field analysis. This circuit model was validated by experiment in both frequency and time domains.

Echizen, Fukui 915-8515, Japan

Abstract- In large permanent magnet motors, the permanent magnet in the motor is segmented into parts in order to reduce the eddy current loss in permanent magnet. It is reported that the insulation between sintered Nd-Fe-B magnets is possible only by contacting the segmented permanent magnets without insulation. But the mechanism for such a phenomenon has not been clear. We have already reported that the analysis considering the resistance of the contact part is possible by defining the contact resistance coefficient K . In this paper, the effects of number of segments of magnet, exciting frequency, contact resistance between magnets and the permeance of magnetic circuit on the eddy current loss of a magnet are investigated. It is shown that the property of eddy current loss in a magnet at high frequency is different from that at low frequency, and the tendency is changed by the contact resistance and the permeance (surrounding iron core).

I. INTRODUCTION

It is reported that the eddy current loss of the segmented Nd-Fe-B sintered magnet can be reduced even if magnets are not insulated[1]. We measured the resistance between magnets under various compressive stresses, then, the effect of stress on the contact resistance between magnets is clarified. Moreover, the eddy current analysis is performed using the 3-D finite element method by considering a contact resistance between magnets. But, the examination was limited to one kind of frequency (=10kHz) and a case of six segmented magnet in an open circuit. As the carrier frequency of the inverter used for the control of PM motor is sometimes more than 10 kHz, and the magnet in a motor is surrounded by the iron core, a systematic investigation of the effects of the exciting frequency etc. is required.

In this paper, the effects of the number of segments of magnet, the exciting frequency, the contact resistance between magnets etc. on the eddy current loss are investigated.

II. MEASUREMENT AND EXAMINATION OF CONTACT RESISTANCE

We measured the resistance of the contact part between magnets by putting two magnets in a vice and by impressing a compressive stress. As the length ΔL of the contact part is unknown, the following contact resistance coefficient K is defined:

$$K = \rho^* \Delta L = SR' \quad (1)$$

Fig.1 . Relationship between contact resistance coefficient K and stress.

Fig.2. Analysis model of eddy current loss.

where ρ^* is the resistivity of contact part, S is the cross sectional area of the contact region, R' is the resistance of the contact part. The relationship between K and the stress is shown in Fig.1. The figure denotes that the contact resistance coefficient is decreased with the stress.

III. EFFECT OF SEGMENTS, FREQUENCY AND CONTACT RESISTANCE

The eddy current analysis considering the resistance of the contact part is carried out. Fig.2 shows the examined model. A large magnet (50mm×50mm×10mm) is segmented into n

7. Material Modelling

parts. The magnetic field is impressed in the z-direction. The magnetic flux density is 13.5mT when there is no magnet.

Fig.3 shows the relationship among the eddy current loss, the exciting frequency (10kHz, 40kHz), the number of segments (n=1-6), and the contact resistance (compressive stress) when there is no iron core. The figure denotes that the eddy current loss W_e decreases with the decrease of contact resistance (with the increase of stress) at 40kHz. This is, because most of eddy current flows along the edge of magnet due to the remarkable skin effect, and the length of eddy current path is decreased when the contact resistance is decreased (when the stress is increased) as shown in Fig. 4. On the contrary, the eddy current losses W_e at $n=3-6$ are

Fig.3. Effect of frequency, number of segments and contact resistance on eddy current loss (compressive stress).

Fig.4. Eddy current distribution (40kHz).

increased with the decrease of contact resistance at 10kHz.

(a) 10kHz

This is, because the amplitude of eddy current density at 6MPa is increased compared with that at 0MPa as the

(b) 40kHz

Fig.5 Relationship among W_e , n and contact resistance.

apparent area of magnet is increased due to the decrease of contact resistance. From the above-mentioned results, it can be found that the eddy current loss is not always reduced when the contact resistance is increased (or magnets are insulated).

Fig.5 shows the eddy current loss W_e when iron cores are put in both sides of magnet as shown in Fig.1. As the skin effect is remarkable when iron cores are put, W_e increases with n and has a peak value due to the same reason discussed in the case of 40kHz in Figs. 3 and 4. When n is larger than about eight, W_e at 10kHz is decreased by segmenting the magnet at 10kHz, but W_e at 40kHz is increased by the segmenting. The figure denotes that W_e can be reduced if adjacent segments are connected by the contact resistance. Therefore, the segmented magnet without insulation has an advantage that W_e at a high frequency of more than the carrier frequency can be reduced.

Abstract — these studies will describe the electromagnetic analyses of different configurations of the so called “Integrated Production Umbilical” (IPU), or simply umbilical cables. Modern IPU can have more than 4 independent 3-phase power circuits as well as steel tubes physically inside the same cable. There is no 2-D symmetry for these cable configurations and the 3-D simulations are very undesirable since they can have more than 10 km. The adopted methodology is a combination of 2D-finite element analyses (coupled with electric circuit) and the transposition technique. The cable performance (voltage drops and modulation) will be investigated to determine the appropriate configuration.

I. INTRODUCTION

The oil exploration on offshore platforms represents an activity of high investment, where the risk of fails must be minimized. On the oil exploration process, there are cables composed by hydraulic steel tubes, independent 3-phase power circuits, signal conductors, etc., integrating an “Umbilical Cable” (UC). Nowadays, the new concept of umbilical cables requires more than only one independent power circuit. The power circuits are required to operate in a wide range of voltage and frequency levels, with strong power quality requirements. The UC configuration aspects can affect the magnetic coupling between the UC components derating the ampacity of the UC [1]-[3] and also degraded the power quality on the load terminals. The main objective of the electromagnetic analysis presented in this paper is to calculate mutual coupling effects between power conductors, power shields, metal tubes and armors (metallic parts inside the cable) to determine the terminal voltage at the load terminals. Moreover, an original combined methodology was developed to make the simulations less time consuming than the 3D-model.

The sections are organized as follows. In section II, one presents the main geometric and electrical characteristics of the analyzed configuration of UC. The original methodology is presented in section III. In section IV, partial results are shown.

II. DESCRIPTION OF THE UC’S SYSTEMS

The configuration of the analyzed umbilical cables consists of four 3-phase power circuits (Circuit #1, Circuit #2, Circuit #3 and Circuit #4). Each circuit feeds independently one submerged oil pump. The main electrical characteristics of the variable voltage supplied by the converters (C1, C2, C3 and C4) are: frequency range ($F = 30\text{-}80$ Hz); supply voltage ($V = 1200\text{-}3200$ V); V/F constant; constant current ($I = 280$ A).

Fig. 1. Unifilar diagram of the 3-phase system

Fig. 2. Cross-sections number 1 of the two analyzed UC configurations.

The cross-sections number 1 of the two analyzed UC configurations are shown in Fig. 2. One can see the 4 power circuits on the inner layer (configuration A) and in the outer layer (configuration B) of the cables with their respective phases A (dark grey), B (black) and C (white). Each power conductor has its own copper shield. There are 8 steel tubes in the outer layer (configuration A) and in the inner layer (configuration B) used to transport fluid. Both have an external metallic armor mainly used for mechanical purposes. The outer diameter of both configurations is 280 mm and its length is 10 km.

For better structural resistance, the internal structure of the UC must rotate in relation to the center along its length. In this specific case, the entire inner layer rotates in anticlockwise direction (1 turn every 1000 mm), while the entire outer layer rotates in clockwise direction (1 turn every 1500 mm). As can be seen, these cables have only 3D model. In addition, a configuration C is derived from the configuration A including the rotation of each power circuit in relation to its own center completing one turn every 750 mm. The full paper will evaluate the power quality of the supply voltage at the oil pump terminals for all the three configurations by a developed methodology to represent the 3D characteristics of the UC’s using a combination of 2D finite element analysis and the transposition technique [1],[4].

III. THE COMBINED METHODOLOGY

As indicated in section II, the analyzed cables has no 2D symmetry, once the metallic elements (conductors, shields, tubes and armors) of the UC change their relative position along the cable length, performing an helicoidally path. Therefore, it is not possible to represent the cables performance simulating only one cross section presented in Fig. 2. In order to avoid the use of the 3D models, one has developed a combined methodology using 2D models and the transposition technique.

As described in section II, the inner layer of these UC's completes 1 turn every 1000 mm while its outer layer completes 1 turn every 1500 mm. The Least Common Multiple (LCM) between layer lengths is then 3000 mm. This means that at each 3000 mm, the cable pattern repeats. The concept of transposition is addressed in classical 3-phase high voltage transmission line (TL) theory [4]. More details will be given in the full paper.

IV. PARTIAL RESULTS

The evaluation of the UC performance regarding to the power quality was performed using the methodology described in section III for two configurations: A (the power circuits do not turn around their own centers) and C (the power circuits turn around their own centers). The configuration B will be analyzed in the full paper. The supplied voltage of the circuits consider one of the worst operation conditions considering the modulation criteria: 3 circuits (#1, #2 and #3) were supplied on 80 Hz, while 1 circuit (#4) was supplied on 30 Hz. These two cases were analyzed to verify the impact of circuit rotation on modulation results.

A. Induced Voltage at the Load Terminal

Fig. 3 (a) shows the equipotential lines obtained from the steady-state analysis of the circuits #1, #2 and #3 supplied on 80 Hz, while Fig. 3 (b) shows the other separately analysis of the circuit #4 on 30 Hz, both for the cross section number 1 of 50. These two separately analyses are necessary to analyze the power quality. For each cross section, the real and the imaginary components of terminal voltage in the pump connected to circuit (#4) were kept separately. As in the transposition technique, the average values of real and imaginary components were calculated. The terminal voltage of case A and C obtained by the 2D FE steady-state analysis are discussed below.

In Fig. 4, the average of voltage values is used to compute the power quality characteristics. Moreover, one can verify that the values are almost constant because of the fact that the power circuits do not rotate around their own centers resulting on a fixed relative position between them with almost constant induced voltage. From Fig. 5, one can verify that these values are not constants. The rotation of the power circuits around their own centers results on a variable induced voltage that compensates itself.

Fig. 3. Equipotential lines of magnetic potential obtained in the cross section number 1 of configuration A.

Fig. 4. RMS real components of induced voltage (80 Hz) in phase C of circuit #4 - configuration A

Fig. 5. RMS real components of induced voltage (80 Hz) in phase C of circuit #4 - configuration C

B. Power Quality Analysis

The induced voltage on the oil pump terminal of circuit (#4) by the 80 Hz circuits were computed and compared with its terminal voltage feed on 30 Hz. Configuration A presents the highest modulation values of 7,2 % over the phase C while configuration C only 0,45 %.

The full paper will present more specific results and will include the analysis of the configuration B. This configuration can be built physically in a less complex machine than configuration A and C.

Signal-to-noise ratio analysis of radio frequency coils in low-field MRI systems

Ye Li and Xiaohua Jiang

Department of Electrical Engineering, Tsinghua University, 100084 Beijing, China
jiangxiaohua@mail.tsinghua.edu.cn

Abstract—An approach to analyze signal-to-noise ratio of radio frequency coils in low-field magnetic resonance imaging systems is presented. The integral equation method (IEM) is proposed and used to calculate with high accuracy the coil self-resistance that accounts for much higher percentage of the equivalent noise resistance in low field MRI than that in high field MRI. A two dimensional model is built and the analysis of a simple surface RF coil for a 0.3T permanent MRI system is performed. The results show that the coil self-resistance is comparable with the sample resistance, which indicates the importance of accurate coil self-resistance analysis. With IEM for calculating the coil self-resistance, the coil geometries can be easily optimized to obtain the optimal SNR in the region of view.

I. INTRODUCTION

The performance of radio frequency (RF) coils, which are used to pick up magnetic resonance signal, is significant for imaging quality [1]. The signal-to-noise ratio (SNR) and sensitive distribution of RF coils are the targets to optimize coil structure for better imaging quality and higher imaging speed.

The noise voltage picked up by RF coils is proportional to the equivalent noise resistance, which consists of coil self-resistance, sample resistance and dielectric loss in the sample [2, 3]. In low-field magnetic resonance imaging (MRI) system, the dielectric loss can be reduced remarkably by using distributed tuning capacitors and neglected due to the quasi-static assumption. The equivalent noise resistance is therefore dominant by coil self-resistance and sample resistance, which are closely related to current distribution in the conductor and induced current in the sample respectively.

The finite difference time domain (FDTD) method is a widely used numerical method to calculate RF field distributions, power dissipation and tuning capacitor value of the RF coils in high-field MRI because the sample resistance is much larger than the coil self-resistance at 64MHz and above [4]. However, in low-field situation when the coil self-resistance is comparable with the sample resistance, the accuracy of the current density distribution in the conductor calculated by the FDTD method is limited by the Cartesian grid. Although the finite element method (FEM) can achieve accurate results of RF field distribution in both coil conductor and imaging sample, it is limited by the calculation efficiency when used to optimize coil geometries.

This work proposes an approach to calculate coil SNR in low-field MRI system, in which coil self-resistance is calculated by the integral equation method (IEM) and both coil sensitivity and sample resistance are calculated by the magnetic vector potential. In addition, an optimization design approach to improve the SNR of a RF surface coil is presented

as example. The geometry of the circular coil is optimized to achieve the highest SNR with sensitivity homogeneity constraint in the region of interest.

II. ANALYSIS APPROACH

According to the concept of reception, the SNR of RF coils is defined by the following equation [3]

$$SNR = \omega |M_{xy} \cdot B_I| / \sqrt{4kT\Delta f R_e} \quad (1)$$

where M_{xy} is the magnetization vector, B_I is the magnetic field generated by RF coil, R_e is the equivalent noise resistance, T is the temperature, k is the Boltzmann constant and Δf is the band width. Coil self-resistance and sample resistance are proportional to current density integration and the power absorbed by the sample respectively. Generally,

$$SNR \propto |B_I| / \sqrt{R_{coil} + R_{sample}} \quad (2)$$

where R_{coil} and R_{sample} are coil self-resistance and sample resistance respectively.

The magnetic field B_I and electric field $E(r)$ can be calculated by Biot-Savart's law and magnetic vector potential respectively [5]. Coil self-resistance is estimated by current density in conductor at resonance frequency, which is given by

$$\mathbf{J} = -\sigma \cdot (\partial \mathbf{A} / \partial t + \nabla \cdot \varphi) \quad (3)$$

where \mathbf{J} is the current density, \mathbf{A} is the vector potential and φ is the scalar potential. Since the conductivity of the conductor is much higher than that of the sample, the influence of eddy current in the sample on current density in the conductor is neglected. Under the quasi-static assumption, the variation of current density along current direction is neglected. Thus, the two dimension current density distribution is given by [6]

$$\dot{\mathbf{J}} = -j\sigma\mu f \iint_S \dot{\mathbf{J}} \ln r ds - \dot{J}_0 \quad (4)$$

where σ and μ are the conductivity and the permeability of the conductor respectively, f is the resonance frequency, r respects to the distance between ds , S is the cross section, and $\dot{J}_0 = \sigma \cdot \partial \varphi / \partial z$ is a constant in this case.

This integral equation is solved by numerical method which changes integral equations to matrix equations [6]. The cross section of conductor is discretized on an $M \times N$ grid. Assuming the current density of each cell on the grid is constant, (3) is expressed as following linear integral equations

$$\begin{aligned} \mathbf{J}_i + j\sigma\mu f \iint_S \mathbf{J}_i \ln r ds = -\mathbf{J}_0 \\ \sum_{i=1}^{M \times N} s_i \mathbf{J}_i = \mathbf{I} \end{aligned} \quad (5)$$

where J_i and s_i are current density and area of the i^{th} element respectively, and I is the current in conductor. The above $M \times N + 1$ equations can be represented in the matrix-vector form.

The proximity effect can be analyzed as well as the skin effect by this method. All the cross sections of conductor are meshed by the same way, which is shown in Fig. 4. The scale of integral equations shown in (5) increases to $(M \times N + 1) \times n$, including all the elements in the conductors.

Fig. 1. The cross section mesh for proximity effect analysis

The current density distribution is obtained by solving the above linear equations. AC resistance coefficient k_{ac} is defined as (6) to describe skin effect and proximity effect on coil self-resistance.

$$k_{ac} = R_{ac}/R_{dc} = S \cdot \sum_{i=1}^{M \times N} s_i |\mathbf{J}_i|^2 / I^2 \quad (6)$$

In order to obtain homogeneous images, the sensitivity homogeneity S in the region of interest should be considered as constraint. S is related to the magnetic field generated by RF coil, which is defined as

$$S = 1 - 2 \times (|\mathbf{B}_f|_{\max} - |\mathbf{B}_f|_{\min}) / (|\mathbf{B}_f|_{\max} + |\mathbf{B}_f|_{\min}) \quad (7)$$

where $|\mathbf{B}_f|_{\max}$ and $|\mathbf{B}_f|_{\min}$ are the maximum and minimum magnetic field of the RF coil in the region of interest.

III. EXAMPLES

The imaging sample is human body, which is simplified as a cylinder ($\sigma = 0.5$ S/m and $\mu = \mu_0$) with length $L=15$ cm, diameter $D=30$ cm. The conductor is copper tape with a 1.2 cm width, a 0.018 cm thickness and $\sigma = 5.3 \times 10^8$ S/m. The region of interest is a 2 cm diameter sphere of which the center is 4cm from the right end of the cylinder. The RF coil is a circular surface coil and the gap between the RF coil and the cylinder sample is 1 cm. The geometries of model are shown in Fig. 2. The coil is designed for a 0.3T permanent MRI system of which the resonant frequency is 12.72 MHz.

Fig. 2. The geometries of sample and RF coil

A. Current Density Distribution Analysis

The penetration depth at 12.72 MHz is 0.023 mm. As shown in reference [6], the current density in centre region of conductor is much more uniform than that of edge region. The mesh of the conductor is formed by a non-uniform rectilinear grid with higher densities in the edge region.

The current density distribution is obtained by the IEM. The contour of current density on cross section is shown in Fig. 3.

Fig. 3. Contours of current density.

B. Coil Geometry Optimization

The geometry variable of the surface coil is the radius R shown in Fig. 2, which is optimized to achieve the highest SNR in the region of interest with the homogeneity constraint.

The optimized radius R is 4.0 cm. In this case, the sensitivity homogeneity in the region of interest is 81.7%. The coil self-resistance and the sample resistance are 43.8 m Ω and 45.1 m Ω respectively.

IV. CONCLUSION

In the present paper a method to analyze SNR of RF coils in low-field MRI systems is presented. By using IEM, the calculation efficiency of coil self-resistance analysis is improved with good accuracy. Also, it is relatively easy to combine the proposed approach with the optimization problem to improve coil performance.

The results of the sample analysis show that the coil self-resistance of a surface RF coil for a 0.3T permanent MRI system is comparable with the sample resistance, which indicates the importance of accurate coil self-resistance analysis.

Time Domain Analysis Of Compact Lumped Element Circulators

Robert Stonies, Dirk Schulz
 High Frequency Institute
 Friedrich Wöhler Weg 4, 42277 Dortmund, Germany
 schulz@hft.e-technik.uni-dortmund.de

Abstract — A symmetrical 3-port lumped element circulator is designed by the use of a numerical time domain method. It is shown, that the application of the numerical time domain method is essential for the numerical analysis of very compact circulator devices built by using thin film technology.

The circulator performance is numerically calculated and optimized to some extent, providing valuable information about important device performances. A comparison with measured scattering parameters shows good agreement with the numerical simulation.

I. INTRODUCTION

Nowadays circulators and isolators are very important components in radio frequency and microwave systems due to their unique non-reciprocal characteristics. Their design and principles of operation have been discussed in some detail for many years now. Among the various kinds of realizations the lumped element approach shows the most promising properties for miniaturization.

However, in opposite to most other types of circulators and isolators, to the knowledge of the authors a lumped element circulator will not be examined with numerical methods in detail. One reason may be the difficulties arising from the adverse aspect ratios of the structure features. With the availability of powerful solvers for EM problems this is no longer an obstacle.

The simulation results presented in this paper are obtained from the commercial numerical tool MICROWAVE STUDIO (CST), because the necessary algorithms for gyromagnetic media are included using the finite integration technique, a time domain approach based on solving the integral form of Maxwell's equations by discretization in time and space. Complex media such as ferrites can be included. This is a prerequisite to model the circulators in discussion.

Numerical results are compared with measurements to proof the results. For the experimental setup a hybrid setup is chosen due to the advantage of using a standard industrial process for the production of printed circuit boards to realize the coupling network, which is essential for the device operation.

II. DESIGN CONSIDERATIONS

In opposite to commonly used distributed circulators, lumped element types are independent from the wavelength to some extent. The only prerequisite is that the wavelength is much larger than the element.

For lumped element circulators, a size-reduction of a factor of 5-10 [1] can be achieved with adequate performance. Distributed devices have been examined in detail inter alia by Bosma [2] and Fay [3]. For them it is necessary to satisfy the condition $kR=1.84$ [2], [4] for the normal mode excitation of a ferrite disc with its radius R . k is the wave number within the ferrite [2]. The most interesting part of a lumped element circulator certainly is the magnetic circuit.

II. DEVICE UNDER TEST

Two different technological concepts are used for the time domain simulation and described in the following. The first one is a double sided standard process printed circuit board process with drilled via-holes. The second one is a sequential layer build-up process allowing for a very thin insulation layer between the conductor layers. The device structure under test is shown in Fig. 1.

Fig. 1. Three dimensional view of the device showing the interwoven conductor structure, ports and some additional lumped capacitors

A. Double Sided Standard Process

The substrate materials used for in this case, FR4 glass reinforced epoxy ($140\ \mu\text{m}$) or MylarTM (DuPont) polyester film ($175\ \mu\text{m}$), is drilled ($250\ \mu\text{m}$ diameter) to form the necessary via-holes first. Thin layers of titanium and copper are sputtered on both sides. Furthermore, the vias are activated for later electroplating implicitly. A $25\ \mu\text{m}$ dry film photoresist FP325 (Elga Europe) is laminated on both sides and structured with a MA56 mask aligner (Suess). Electroplating is now used to grow copper into the resist grooves and form the conductors. After electroplating, the resist is stripped and the seed layers are removed through chemical etching.

B. Sequential Layer Build-Up Process

First, the substrate is coated with titanium and copper on one side through sputtering to provide a seed layer for later

electroplating. Then, the FP325 dry film resist is laminated and structured. Copper is electroplated to a height of 15 μm into the grooves. The resist is stripped and the seed layers are etched. Now, a second layer of FP325 is laminated on top. It is structured by the via and feed-line pattern before the surface is completely sputter-coated with titanium and copper again. An additional electroplating process enhances the layer thickness to 15 μm . Finally, AZ-3210 (ALLRESIST), a thick film positive photo resist, is spin-coated onto the sample and structured to protect the later bridges and vias of the top layer from being etched. In contrast to the first example interdigital lumped capacitors are used for matching and tuning.

III. SIMULATION AND OPTIMIZATION

The parasitics appear to influence the characteristics in particular. Especially the crossover capacities are responsible for a significant decrease of the operating frequency. To speed up the calculation, the lumped capacitors may be substituted through idealized capacitors, virtually connected between two mesh points. Once the necessary capacity is evaluated, a separate parametric simulation model including single capacitor model is used to obtain the exact geometries. To be more exact with that capacitors, a full three-dimensional electrodynamic calculation can be performed at the design center frequency. Finally, the geometries of all simulations are combined into one CAD-file and masks are generated. As can be concluded from Fig. 3 and is expected, fringing fields tend to increase the capacity to an amount that does not allow to neglect them. Another interesting observation, already predicted in [7] is, that the magnetic field is not at all homogeneously distributed in the ferrites. It is rather clearly concentrated around the conductors (Fig. 2). The ferrites bulk shows a magnetic field that is less than 10 percent of the field close to the conductor.

Fig. 3. Magnetic field (in a plane) concentrating in the vicinity of conductors, normalized to 1 W input power at 2.5 GHz

IV. VERIFICATION

To verify the calculated performance, the structures are mounted into a jig containing the ferrites and providing the SMA connectors to the interface of a vectorial network analyzer. The dc magnetic field is generated by a current-controlled electromagnet with a slitted yoke.

For the double sided processed structure including drilled vias, Fig. 4 shows a comparison between the calculated and measured performance. It ought to be reminded that the layout for the structure only consists of the isoductor conductors.

No capacitors are included and hence there is only the small parasitic capacity of the line crossings that act as a tuning element for the device. This leads to a much higher

resonance frequency close to the gyromagnetic resonance frequency. This reduces bandwidth and implies higher insertion losses. The inclusion of explicit lumped tuning elements is no problem at all and similar to the sequential layer build up.

Fig. 4. Calculated and measured scattering parameters

For the second structure the scattering parameters are also measured and compared with the calculated ones. In evidence from Fig. 5, the measured data agree well with the data resulting from a numerical calculation but the center frequency is slightly shifted to lower frequencies. The authors assume that the reasons for this shift are inaccuracies in the calculation and in the technological process. First, the ferrite is treated as to be completely homogenous magnetized, which is not true in reality. Magnetostatic calculations show, that the magnetic field is much stronger close to the circumference than it is in the middle of the thin disc. Second, thin layers are represented by one mesh-cell in height to keep the time for calculation short. This may lead to some inaccuracies, especially concerning the field distribution at edges.

Nevertheless, the comparison shows a quite good agreement and with some correction and modifications it will be possible to predict the behaviour of a lumped element circulator with high accuracy by use of numerical calculations.

Abstract — We present an approach to determine a correction factor for core losses due to joints in power transformers. Its determination is carried out by finite element analysis in two dimensions. The influence of two kinds of joints, namely with and without *step-lap*, are investigated, as well as three airgaps. Results are validated by comparison with other authors, and also by experimental data.

I. INTRODUCTION

The determination of core losses in power transformers is usually carried out with the aid of the curve W/kg versus T for a given frequency, provided by the steel manufacturer. This curve includes both hysteresis and eddy current losses.

However, other effects not predicted by those curves, which are mainly due to core manufacturing process, such as burr, localized poor insulated lamination, airgaps due to joints and so on, also give rise to additional, not-predicted losses and local heating in transformer cores. Most of those effects are of difficult estimation, owing to their randomness. Therefore, the estimation of actual core losses is always a troublesome, difficult task.

Manufacturers of power transformers make use of a *building factor* (BF) to correct the calculated core losses. This BF is obtained statistically from historical, experimental data sets, which can lead to either an over or an underestimation of the losses, with resulting cost penalization [1].

This work thus proposes a correction in the BF in order to improve the estimation of the total core losses by means of a *correction factor* (CF). This CF takes into account the increase in the core losses due to the presence of joints in the core of power transformers.

It is well known that core losses in transformer can be considerably reduced by an improved joint design, which can be achieved by an accurate knowledge of the local flux density distribution, both in the corners and in the limbs. Then, the proposed approach to calculate this CF is based on two-dimensional (2D) finite element analysis (FEA). The methodology is outlined in the following sections.

II. TRANSFORMER CORE JOINT CONFIGURATIONS

Two configurations of core transformer joints will be analyzed. Fig. 1 depicts a typical transformer core, in which regions of joints appear dark-grayed. Fig. 2 illustrates the two joint configurations, with and without *step-lap*, used in the analysis.

Fig. 1 A 3-phase transformer core showing regions with joints (in dark gray).

Fig. 2 Transformer core joints: (a) without *step-lap*; (b) with *step-lap*.

III. FEA OF CORE JOINTS

To estimate the increase in no-load core losses due to the core joints, a CF, k_c , has been defined, as follows:

$$k_c = P_{0j} / P_0, \quad (1)$$

where P_{0j} and P_0 stand for losses in cores with and without joints, respectively. These core losses are determined through a FE modeling of the joint regions.

Two FE simulations were carried out with the aid of a trial edition of commercial FE-package for electromagnetic design. By means of a 2D magnetostatic simulation, the package calculates the power losses from the computed flux density distribution in the domain.

In order to overcome the modeling restrictions of this FE-package, the joint regions are modeled as a 2D periodic domain, excited by a hypothetical current source coil.

The 2D FE models are illustrated in Fig. 3. No simplification was adopted in the core model, such as shell elements or stack-homogenization, since no such facilities were available in the package. Therefore, all steel sheets of the laminated stack, as well as their insulations, have been represented in the geometrical model of the core. Two simulations were performed, for the two configurations (with and without joint), to calculate P_0 and P_{0j} .

The magnitude of the current to excite the hypothetical source coil was determined by trial and error, in order to yield, close to the periodic boundaries, the required, typical average values of peak flux density, present in joint-free parts of the core (i.e. limbs and yoke).

Fig. 3 2D FE domains with laminated core (cyan) and source coil (brown) to model the transformer core joints. (a) Without joint. (b) With joint.

The adjusted no-load core loss, including the correction factor, can then be estimated as follows:

$$P_0 = m_{Fe} \cdot \left[\frac{W}{kg} \right] \cdot \left[(F_j \cdot k_c) + (1 - F_j) \right] \quad (2)$$

In (2) the factor F_j was introduced in order to correct the losses only in the joint-parts of the transformer core (see Fig. 1) and is given by the ratio between two areas: the total area of the joint regions (sum of dark-grayed areas in Fig. 1) and total area of transformer core (sum of light- and dark-grayed areas in Fig. 1). The quantities m_{Fe} and $[W/kg]$ stand for the core mass and the core loss density, respectively.

IV. RESULTS

A set of FE simulations were performed with the following values of airgaps and average peak flux densities: 0.5/1.0/1.5 mm and 1.0/1.2/1.4/1.73/1.77 T.

Figs. 4 and 5 show color maps of flux densities in non-step-lap and step-lap joints, respectively, where it can be seen that the latter exhibits a significant reduction in saturated spots, and hence iron losses, as expected. These results were obtained with a 1.73T flux density and a 1.5mm airgap.

Fig. 4. Color map of flux-density distribution in a *non-step-lap* joint (1.5mm airgap, 1.73 T).

Fig. 5. Color map of flux density distribution in *step-lap* joint (1.5-mm airgap).

A comparison of the computed CFs for joints without and with step-lap is presented in Fig. 6.

Fig. 6. CF determined by FEA for joints without (V1) and with (V2) *step-lap*.

These results are in accordance with other authors [1],[4]-[5], since they confirm the reduction in the CF yielded by the step-lap joint with respect to that without step-lap.

The methodology was applied in the transformers of a manufacturer data set. The newly estimated core losses, with the proposed correction, led to a better agreement with the measured losses than those adjusted by the original, conventional BF.

V. CONCLUSION

A correction factor was proposed to account for the increase in no-load transformer core losses due to core joints, thereby improving its estimation. This more accurate adjustment was accomplished by applying a 2D FEA of a reduced, equivalent model of core joint region. The effectiveness of *step-lap* joints in reducing core losses was confirmed, when compared to *non-step-lap* joints, although the latter proved to be less sensitive to variations in the airgap. Additional experimental verification and results are intended to be presented in an extended version of this digest.

Effects of a remanent magnetization on the detection signals of the metal loss in Magnetic Flux Leakage type NDT

Kang Seo, Gwan Soo Park and Jae Min Kim

School of Electrical Engineering, Pusan National University, Busan 609-735, South Korea

E-mail: kalam@pusan.ac.kr

Abstract—Because of a strong magnetic field in magnetic flux type NDT system, the object itself is magnetized so that it shows a hysteresis characteristics during the sensing, which might cause a distortion of the defect signals. In this research, the magnetization characteristics of a pipeline in the magnetic flux leakage type non-destructive testing are analyzed. Effects of a magnetic hysteresis of a pipeline are analyzed. Magnetic flux density due to a remanent magnetization of gas pipeline is computed and verified by real measurement.

Index Terms—magnetic flux leakage, magnetic sensor, non destructive testing, nonlinear finite element analysis

I. INTRODUCTION

The magnetic flux leakage type non-destructive testing system is widely used to detect metal losses of the underground pipe in gas pipelines [1]. In the system, the sensor modules are consisted of permanent magnet, magnetic yoke and Hall sensors to detect the metal loss, corrosion defect and any other damages of the gas pipeline. The object pipeline is magnetically saturated by a magnetic system with permanent magnet and yokes as in Fig. 1. Hall sensors detect the stray leakage fields in the metal loss region.

In the system, a magnetization level is designed to be high enough to saturate the pipeline in order to increase the sensitivities of the systems [2]-[3]. So, in most cases, pipes are to have remanent magnetizations that have distorted the sensing signals to reveal the metal losses [4]-[6]. To detect the defects precisely, the sensing signals need to be compensated to eliminate the distortions coming from the media hysteresis. In this paper, the magnetizations of the pipeline in MFL type NDT are analyzed by 3 dimensional finite element analysis and the distortions of the sensing signals are compared with measurement.

Fig. 1 Diagram of a MFL type NDT

II. MAGNETIZATION IN MFL TYPE NDT

The relations between magnetic field intensity H , magnetic flux density B and magnetization M of the magnetic material could be represented as follows,

$$B = \mu_0(H + M') \quad (1)$$

$$B = \nabla \times A \quad (2)$$

$$\nabla \times H = J \quad (3)$$

The main source of the magnetic field in this system is permanent magnet so the magnetization M' is represented by the sum of reversible component (χH) and irreversible component (M) as in (4).

$$M' = \chi H + M \quad (4)$$

The magnetic field in this case is represented as follows,

$$H = \nu B - \nu_r M \quad (5)$$

where $\nu = 1/\mu$, $\mu = \mu_0 \mu_r$, $\nu_r = 1/\mu_r$, $\mu_r = 1 + \chi$.

From substituting these equations into (1) and (3), Coulomb gauge and vector relation gives

$$\nabla \times (\nu \nabla \times A) = J + \nu_r \nabla \times M \quad (6)$$

$$-(\nabla \cdot \nu \nabla) A = J + \nu_r \nabla \times M \quad (7)$$

In this equation, M is not constant in hysteresis problems. The classical Preisach modeling [3] is adopted in this system.

$$M(t) = \iint_{u,v} P(u,v) \cdot H(t) du dv \quad (8)$$

where $P(u,v)$ is Preisach density function. To solve the hysteresis problem, this modeling is solved with finite element solution simultaneously. Finite element analysis gives the final matrix equation as follows,

$$[K_v] \{A\} = \{f\} + \{f_m\} \quad (9)$$

In this equation, $[K_v]$ includes the geometry and material constant information whereas $\{f_m\}$ includes the magnetic hysteresis characteristics of the materials. The iterative algorithm to solve the scalar Preisach modeling is included in the computations.

III. HYSTERESIS EFFECTS ON THE SENSING SIGNALS

To measure this, we made a measuring coil in the pipeline as in Fig. 2. The magnetization level of the pipeline could be measured from the flux linked in the coil. As the PIG passing again, the remanent magnetization level becomes decreased as in Fig. 3. Fig. 4 shows the decrease of the sensing signals of a defect $2t \times 2t \times 0.8t$. The remanent magnetic field according to the remnant magnetization of the object could be summarized as in Fig. 5. So, the compensating data as a function of pigging events are successfully obtained. For the exact estimation of the defects, the sensing signals needs to be corrected by using this data according to the numbers of sensing events.

Fig. 2 Search coil for the measurement of remanent magnetic flux

Fig. 3 Remanent magnetization according to the pigging events

Fig. 4 Decrease of sensing signals according to the pigging events

Fig. 5 Remanent magnetic fields according to the pigging numbers

IV. CONCLUSIONS

In MFL type NDT system, a magnetization level is designed to be high enough to saturate the pipeline in order to increase the leakage field under the defect region. So, in most cases, pipeline is to have remanent magnetizations according to the movement of the PIG so that the sensing signals are distorted to reveal the metal losses. In this research, the dynamic characteristics of magnetization in MFL type NDT system are analyzed. Effects of a remanent magnetization is computed by using 3 dimensional finite element analysis including hysteresis characteristics. The results show that the effects of axial components of magnetization are increasing the MFL signals. In case of re-magnetization, the magnitudes of magnetization level become increased because of magnetic hysteresis, which are agreed well with measurement. So, it is necessary to include the magnetic hysteresis of the pipeline for the precise analysis of the MFL type NDT.

Abstract — This paper investigates the effect of an adaptive mesh refinement strategy for the force computation in Micro Electro Mechanical Systems (MEMS). First, the error is estimated in the whole domain and then the refinement is applied in specific regions of the system. The results given by the refinement are compared with those of a reference problem issued from a system with a fine mesh.

I. INTRODUCTION

Micro Electro Mechanical Systems (MEMS) consist mostly of movable and fixed parts subjected to an electric potential difference to create an electrostatic force. Thus, to describe such systems, an electro-mechanical model can be useful [1]. In the case of a weak coupling between electrostatic and mechanical models, the coupling term is the electrostatic force which must be determined with accuracy. To this purpose, the finite element method (FEM) is a useful tool but it requires a suitable mesh construction, especially for high field gradient regions.

In this paper, the electrostatic force involved in a simple MEMS structure is computed for different positions of the movable part. The approach consists in an adaptive mesh refinement strategy. This one is based on the error due to the discontinuity of the normal component of the electrical flux density when using the scalar electric potential formulation in the FEM. As a result, the refined mesh will have higher granularity where it is needed.

A common MEMS actuator is the *linear comb drive* that consists of interlocking teeth on which a voltage is applied. To study this type of actuator, a unit cell, i.e. a segment representative of the entire system, is defined.

First, we present the FE formulation. Then, we introduce the chosen error estimator. Some results are presented for the studied device.

II. MATHEMATICAL MODEL

Considering an electrostatic problem with free charge region, the distribution of the electric field in a domain D of boundary Γ is given by the Maxwell’s equations such as,

$$\operatorname{div} \mathbf{D} = 0 \quad \text{with } \mathbf{D} \cdot \mathbf{n} = 0 \quad \text{on } \Gamma_D \quad (1)$$

$$\operatorname{curl} \mathbf{E} = 0 \quad \text{with } \mathbf{E} \times \mathbf{n} = 0 \quad \text{on } \Gamma_E \quad (2)$$

with \mathbf{E} the electric field, \mathbf{D} the electric flux density and Γ_D , Γ_E complementary boundaries of the studied domain D . The electric behavior law of the material is given by,

$$\mathbf{D} = \varepsilon \mathbf{E} \quad (3)$$

with ε the electric permittivity. To solve the problem constituted by the relationship (2), the scalar electric

potential (φ) formulation can be used and the electric field can be written such as,

$$\mathbf{E} = -\operatorname{grad} \varphi - \nabla \operatorname{grad} \alpha \quad \text{with } \varphi=0 \quad \text{on } \Gamma_E \quad (4)$$

where φ is the scalar electric potential and α a scalar function defined in order to take into account the imposed voltage V [2]. In the case of numerical discretization, Whitney’s elements can be used to discretize the potential φ and the function α in the nodal element space.

Using equations (1), (3) and (4), the weak form of the scalar potential formulation is written as,

$$\int_D \varepsilon \operatorname{grad} \varphi \operatorname{grad} \varphi' dD = -V \int_D \varepsilon \operatorname{grad} \alpha \operatorname{grad} \varphi' dD \quad (5)$$

with φ' a test function verifying the same boundary condition as the potential φ . Using the Galerkin’s method, the interpolation functions are used as test function in (5).

III. ADAPTIVE MESH REFINEMENT

In this formulation, the electric field \mathbf{E} obtained by the FEM has a continuous tangential component on the whole domain as it is derived from the gradient of the scalar potential φ . The electric flux density \mathbf{D} is continuous in each element but its normal component continuity at the interface between elements is not verified. In fact, these discontinuities of boundary conditions between elements are due to the FEM approximation of the scalar potential. The evaluation of the numerical error due to this unphysical discontinuity is used as criterion for the mesh refinement.

Let f be a facet of an element of the mesh. On each facet f an error ε_f is defined such that,

$$\varepsilon_f = (\Phi_f^+ - \Phi_f^-)^2 \quad (6)$$

where Φ_f^+ and Φ_f^- are the fluxes of \mathbf{D} calculated from, respectively, both elements associated to the facet f . Then, the error associated to an element e of the mesh is obtained by summing the errors calculated on its facets,

$$\varepsilon_e = \sum_{f \in e} \varepsilon_f \quad (7)$$

At this point, an error distribution map can be defined for the studied domain. Using this error distribution, one can use a mesh refinement tool according to an error criterion defined by the user.

In our case, we used HOMARD® which is a mesh refiner from EDF R&D [3]. It is based on the refinement, and eventually the unrefinement, of meshes by cutting the elements. The criterion of the refinement has been fixed such that the elements with an error greater than the average

error are refined while the others remain untouched. The refinement can be done either in the whole domain or in a chosen part of the domain.

IV. APPLICATION

The application chosen to emphasize the presented approach is a unit cell of an electrostatically actuated MEMS comb drive [4]. The geometry of the studied system is depicted in Fig. 1. Its dimensions are $L=10\ \mu\text{m}$, $g=1\ \mu\text{m}$, $b=1\ \mu\text{m}$, $t=2\ \mu\text{m}$, $ts=0.5\ \mu\text{m}$, $gs=1\ \mu\text{m}$, $Ls=20\ \mu\text{m}$.

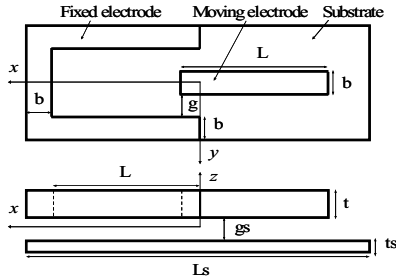

Fig. 1: Geometry of the studied system

A voltage of 30V is applied between the fixed and the moving electrodes, leading to an attractive electrostatic force in the x direction. First, a reference system is considered, which consists in solving the problem with 3D-FEM using a very fine mesh (~ 300000 elements, Fig. 2).

Fig. 2: Reference meshes for positions $0\ \mu\text{m}$ (a) and $5\ \mu\text{m}$ (b)

Then, starting from an initial coarse mesh, the same problem is solved and the mesh is refined according to the calculated error distribution using the previously mentioned criterion. The mesh size for several positions and refinement steps are given in Table I.

TABLE I
MESH SIZE FOR THREE POSITIONS AND REFINEMENT STEPS

Refinement step	Number of elements		
	Position $0\ \mu\text{m}$	Position $1\ \mu\text{m}$	Position $2\ \mu\text{m}$
Initial mesh	21349	20644	20708
1	52298	52576	52007
2	64896	69126	65028
3	95054	100937	96484

In this study, the error was considered on the whole domain and the refinement was applied in a region surrounding the movable part. The meshes for two refinement steps are shown in Fig. 3. The electrostatic force is computed using a method based on the virtual work principle.

Fig. 3: Initial (a) and final refined (b) mesh for position $5\ \mu\text{m}$

In Fig. 4, we present a comparison between the results obtained by the reference system and after 1, 2 and 3 refinement steps for the coarse mesh. At step 2, the results are already in good agreement with the reference.

Fig. 4: Force comparison between the reference and refinement

The relative error between the forces obtained from the reference, the coarse mesh and its last step refinement are given in Fig. 5.

Fig. 5: Relative error for the force calculation

The results obtained with the average error criterion and the refinement in a specific part of the domain, give satisfactory results. Nevertheless, the accuracy can be further improved. In the extended version, other error estimation techniques and refinement strategies will be presented.

A Methodology for Applying Three Dimensional Constrained Delaunay Tetrahedralization Algorithms on MRI Medical Images

Feras AbuTalib and Dennis Giannacopoulos
Department of Electrical and Computer Engineering, McGill University
3480 University Street, Montreal (QC), H3A 2A7, Canada
feras.abutalib@mail.mcgill.ca, dennis.giannacopoulos@mcgill.ca

Abstract— This paper addresses the problem of producing three-dimensional constrained Delaunay tetrahedral meshes from sequential two dimensional MRI medical image slices. The approach is to generate the volumetric meshes of the scanned organs as a result of several low-level tasks: image segmentation, connected component extraction, isosurfacing, image smoothing, mesh decimation and constrained Delaunay tetrahedralization. The proposed methodology produces a portable application that can be easily adapted, evaluated, and extended by the researchers. Experimental results are presented to validate the new approach and characterize its performance.

I. INTRODUCTION

Finite element (FE) analysis of MRI medical data depends heavily on the quality of the mesh representation of the scanned organs. Most medical applications available in the market today are commercial and very expensive. Moreover, they are designed for specific hardware architectures that limit their portability [1]. This paper proposes an architecture that can be used to transfer the medical images into meshes that can be utilized by FE software such as ANSYS, and NASTRAN. A set of different quantitative measures is also compiled in order to be able to evaluate the implementations of such applications. The paper also presents experimental test results that illustrate how the different operations performed during the process can affect the quality of the final mesh.

II. THE SYSTEM ARCHITECTURE

The functional features of the proposed system are: (1) ability to process MRI images in their native format; (2) capability of providing the various image processing services needed during the various steps to generate the mesh such as the segmentation, isosurface creation, smoothing, and decimation techniques; and, (3) ability to generate volume adaptive Delaunay meshes when seeded with an initial surface mesh. The non-functional features include: (1) performance (the proposed system is designed to maximize speed while minimizing the memory as much as possible); (2) usability; (3) expandability; and, (4) portability.

The approach to build the proposed system is to integrate the minimum number of developed compatible open-source software components/libraries of which each would be able to achieve a sub-set of the functional requirements while not breaking the overall non-functional requirement. Fig 1. shows the various steps needed in this process and the chosen components/libraries needed to accomplish each task.

The overall functionalities are achieved by combining the different software libraries and components together after defining the interfaces between the different components as shown in Fig 2.

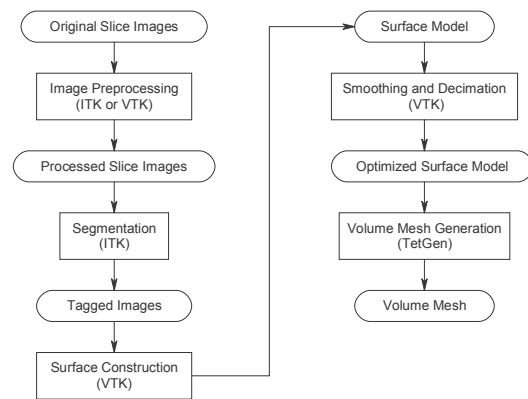

Fig. 1: The proposed object design process with the data flow

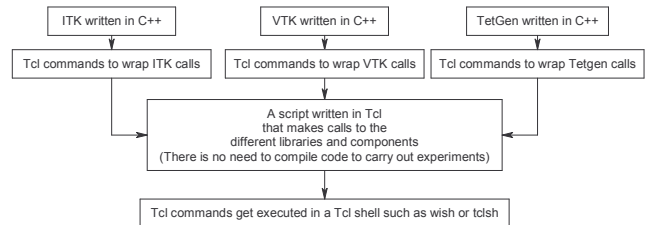

Fig. 2: The proposed interfaces used between the software components.

III. EXPERIMENTAL SETUP

This section provides a set of criteria which can be employed to compare and evaluate the experimental results of such systems. These can be summarized into three categories: (A) geometric mesh quality measures; (B) mesh surface approximation measures; and, (C) performance measures.

A. Geometric Mesh Quality Measures

It is well known that the accuracy and efficiency of the FE method can be directly affected by very poor quality elements [2]. Geometric mesh quality measures evaluate the shape of the produced tetrahedra based on purely geometric characteristics. Most of these measures are usually presented in the form of quantities such as volume, edge lengths and radii of the spheres associated with the tetrahedral elements.

Both α and β_{Baker} measures are considered among the most commonly used measures [2].

$$\alpha = \frac{3R_i}{R_c} \quad (1)$$

$$\beta_{Baker} = 2\sqrt{6} \frac{R_i}{l_{max}} \quad (2)$$

R_i is the radius of the insphere inscribed in a tetrahedron such that each face of the tetrahedron is tangent to the sphere, R_c is the circumsphere radius of the sphere passing through all four vertices of the tetrahedron, and l_{max} is the length of the largest edge in a tetrahedron. Both ratios achieve a value of one for equilateral tetrahedra [3]. Elements having a lower value considered poorer quality.

B. Mesh Surface Approximation Measures

One of the most important properties of a tetrahedral mesh is that it must completely fill the region being simulated. In the proposed methodology, this heavily depends on the surface approximation of the anatomical object. The quality of the surface approximation can be evaluated using the Hausdorff distance mean error $d_m(S, S')$ [4] between the approximated surface (S') and the original surface (S).

$$d_m(S, S') = \frac{1}{|S|} \iint_{p \in S} d(p, S') dS \quad (3)$$

$|S|$ donates the area of the surface S and $d(p, S')$ is the distance between a surface S' and a point p belonging to surface S and it can be computed as

$$d(p, S') = \min_{p' \in S'} \|p - p'\|_2 \quad (4)$$

C. Mesh Performance Measures

Performance measures include both the modeling time and the memory needed during the process. Also, the mesh produced from such systems should lead to as few computations as possible in a finite element simulation. Both the bad quality and the large number of the mesh elements can negatively affect the execution time of a FE simulation. The number of the mesh elements should be small enough to keep the computation time reasonable [5]; however, the number of elements cannot be very small as this would lead to mesh elements with large sizes. Mesh elements with large sizes are reported to produce less accurate FE results than the smaller ones [6]. Therefore, in order to evaluate the performance of such systems, the system should report the time needed for the various tasks to be executed, the number of mesh elements that were generated, the sizes of these elements, and the memory needed during the process.

IV. EXPERIMENTAL RESULTS

Mesh quality is a pre-requisite for successful FE analysis. The implementation of the proposed architecture and the measures described above were utilized to study the affect of some individual operations executed during the process to

transform the medical images into volumetric meshes. The experimental results are summarized qualitatively in Table 1.

TABLE I
SUMMARY OF THE EXPERIMENTAL RESULTS

1) Effect of the Decimation Operation	
a) Decimation Reduction Rate Effect	By changing this factor, there was low impact on the geometric measures. The impact was clearer on the performance measures as higher reduction rates caused better performance. However, the rate of improvement slowed down with higher reduction rate because of the restriction to maintain the topology of the object.
b) Different Decimation Implementation	Similar results were obtained as in 1a. The algorithm used had less restriction in maintaining the topology and more performance was achieved with higher reduction rate.
2) Effect of the Smoother Operation	
a) Effect of the Weight Factor of the Smoother Operation	By increasing the value of this factor, there was a clear positive change in the geometric measures. There was improvement in the performance measures as well.
b) Effect of the Number of Iterations of the Smoother Operation	Similar results were obtained as in 2a which suggests that both parameters have similar effect on the quality of the final mesh.
c) Combined Effect of Both Parameters of the Smoother	Achieved very similar results as in 2a but by using only half the values used in 2a and 2b.
3) Effect of Adding a New Operation	
The operation added was applying the Gaussian Smooth on the initial nodes before the surface construction operation. By introducing this new pre-processing operation in the middle of the tasks, it was possible to get improvement in the performance measures. There was no clear change introduced in the geometric measures for the final mesh though.	

Quantitative results corresponding to the experiments summarized in Table I will be presented in the long version paper along with detailed descriptions of the MRI data used. Full details of the proposed architecture as well as the novel features of the low-level operations described will also be presented at the conference and in the long version paper.

A very interesting possible future work is to extend the current design and implementation to support parallelism. Both VTK and ITK software components can be utilized to provide a parallel solution; however, TetGen component doesn't support parallelism and therefore it is possible to be modified or replaced with a different component.

Abstract— This paper describes calculation of copper losses in resistance spot welding transformer (RSW) windings with two different methods, Dowell method and finite element method. The advantage of Dowell method, as an analytical method is inclusion of proximity effect influence in calculations and possibility of further use in determining of minimal copper losses by an optimization algorithm. The second part of the research gives a comparison between analytical results, numerical results and experimentally obtained ones. The main objective of this research is to evaluate the agreement between analytical and numerical results and to compare them with experimental results. It has also been proven that Dowell method is applicable on this particular type of transformer.

I. INTRODUCTION

This paper describes resistance spot welding (RSW) transformer and numerical, analytical and experimental analysis of copper losses in the windings. An algorithm to achieve minimal copper losses in windings by proper conductors design is fully described in the full paper. The real RSW transformer consists of two laminated iron cores, four layers of primary turns and two layers of secondary turns. Primary winding consists of four layers with total number of turns 55. Secondary winding consists of two layers and each one has a single turn. Primary winding of RSW transformer is supplied by a pulse width modulated voltage, which gives characteristic pulse form of primary current with a peak value 100 A. Secondary current is 55 times higher and it retains a pulse form. Due to the rectifier mounted onto the secondary windings of RSW transformer, only one secondary layer (turn) is active during each half of a primary current period. At the load side (rectifier output) first half of a period gives 5500 A and the second as well. Together, two secondary turns give 11000 A of DC peak value current at rectifier output. Nominal power at 80% duty cycle is 75 kVA.

II. NUMERICAL MODEL

Numerical model is based on finite element method [1]. Modelling, magnetic transient analysis and post-processing are carried out with programme package Maxwell3D.

It has already been mentioned in introduction that during each half of a period of primary current only one secondary layer (turn) is active. It means that number of total active layers in one half of a period equals five. Number of layers and turns is significant for Dowell method [2].

Each primary and secondary turn is separately modelled, which contributes to the preciseness of the numerical model. Transient analysis is necessary to obtain instantaneous power time behaviour and determine copper losses in each time instant. Instantaneous losses time behaviour enables calculation of average copper losses. Minimal average copper losses can represent an objective function and winding's dimensions can be optimization parameters. It is possible to create a parametric numerical model and apply an optimization algorithm in the case of numerical calculation. Numerical calculation of copper losses is based on current density calculation, which is determined with Helmholtz equation (1):

$$\nabla^2 \mathbf{J} - j\omega\mu_0\sigma\eta\mathbf{J} = 0, \quad (1)$$

where \mathbf{J} is current density vector, j is defined as $j = \sqrt{-1}$, ω represents angular frequency, μ_0 is permeability of free space, σ is electrical conductivity and η is conductor spacing factor, respectively.

III. DOWELL METHOD

The magnetic field strength in the vicinity of the transformer winding can be easily determined by using MMF (magneto motive force) diagrams [3]. These diagrams are constructed by application of Ampere's law, following the closed paths of the magnetic field lines which pass near the winding conductors. Dowell method is generally based on Fourier analysis of current and MMF diagrams. Fourier analysis is used to include the influence of higher harmonics from primary and secondary current, while MMF diagrams determine magnetic field strength. For this particular case, MMF diagrams are non-symmetric functions. The construction of the MMF diagram for the first half-period of the primary and secondary current is shown in Fig. 1. Total copper losses, without DC losses, according to Dowell method are given by the following expression (2):

$$\sum_{n=1}^{harm.layers} \sum_{k=1} P_{nk} = \sum_{n=1}^{harm.layers} \sum_{k=1} I_{nk}^2 R \varphi_n \left[\left(2m_k^2 - 2m_k + 1 \right) G_1(\varphi_n) - 4m_k (m_k - 1) G_2(\varphi_n) \right], \quad (2)$$

where n signifies the n^{th} harmonic, k is the layer number in transformer windings, $harm$ is total number of harmonics, $layers$ is total number of layers, P_{nk} is copper loss caused by the n^{th} harmonic in the k^{th} winding layer, I_{nk} is Fourier coefficient obtained from Fourier analysis of the primary or secondary current, R is ohmic resistance at the given operation temperature, φ_n is obtained from conductor spacing factor and skin depth at the given frequency, m_k represents real part of the magnetic field ratio and $G_1(\varphi_n)$, $G_2(\varphi_n)$ are expressions containing trigonometric and hyperbolic functions. The last two are obtained from the solution for the current density from relevant Helmholtz equation (1). Factors φ_n and m_k refer to proximity effect.

Fig. 1. MMF diagram for the first half period of primary and secondary current

It is necessary to note that Dowell method encompasses copper losses caused by higher harmonics and skin effect.

IV. RESULTS

Results are obtained with analytical calculations (Dowell method) and finite element method in Maxwell3D. Numerically calculated copper losses vary from analytical ones for approximately 10%. Table 1 contains results for only one case of dimension of windings and the differences between numerical, analytical and experimental results for this particular case are minor. Note that only preliminary experimental results are given here due to the space limit. More completed experimental, numerical and analytical results will be presented in the full paper. For now, analytical results distinguish from existing experimental results for approximately 8%.

Finite element method results strongly depend on accuracy of the numerical model and time discretization. Instantaneous power time behaviour (Fig. 2) contains irregular increases of values because of the questionable accuracy of the finite element method.

TABLE I
SUMMARY OF DATA AND SOME OBTAINED RESULTS

Physical Quantity	Value
Primary Current Peak Value	100 A
Secondary Current Peak Value	11000 A
Primary Winding Temperature	130°C
Secondary Winding Temperature	50°C
Primary Winding Electrical Conductivity	$38 \cdot 10^6$ S/m
Secondary Winding Electrical Conductivity	$56 \cdot 10^6$ S/m
Nominal Power	75 kVA
Copper Losses Obtained Numerically	2.058 kW
Copper Losses Obtained With Dowell Method	2.154 kW
Copper Losses Obtained With Measurements	2.326 kW

Fig. 2. Instantaneous power time behaviour for primary layer width 3 mm and secondary layer width 12 mm obtained with Maxwell3D

According to Fig. 2, total average copper losses, calculated with finite element method, given in Table 1, are obtained with (3):

$$P = \frac{1}{t} \int_0^t p(\tau) d\tau = \frac{1}{2 \cdot 10^{-3}} \int_0^{2 \cdot 10^{-3}} p(\tau) d\tau, \quad (3)$$

where $p(\tau)$ is instantaneous power and t is time interval (in this case $t = 2$ ms).

V. CONCLUSION

The objective of this research is to analyze copper losses in RSW transformer windings. Three different methods are used to obtain results. Analytical approach (Dowell method) gives results, which are very close to so far experimentally obtained values, while numerical approach gives less accurate results.

Abstract— As China's economy continued to grow, the electromagnetic influence on oil/gas pipeline near transmission line becomes increasingly prominent. In this paper, firstly, the transient simulation of the currents along ground wire and tower is performed by EMTP when the lightning strikes the tower of the transmission line. The results show that the currents along the ground wire and tower dramatically decrease and can be ignored after 5 spans (about 2 km). Secondly, based on the method of moment, the coating stress voltage on the oil/gas pipeline parallel to or across the transmission line is investigated and the approximate expression for the crossing situation is obtained, which involves the lightning current, pipeline type, earth resistivity and the distance between the pipeline and tower grounding structure. Eventually, with the lightning electrical strengths of different coatings, the safety distances between the pipeline and tower grounding structure for different lightning current peaks are suggested.

I. INTRODUCTION

With the fast development of economy in China, energy demand is gradually pressing and the power transmission lines and oil/gas pipelines are in the construction of rapid development. Ultra High Voltage (UHV) and West-East gas projects are the national key projects in recent years. Because of the similarity of transmission path selectivity in the power industry and oil/gas industry, the situations of parallelism, oblique approach and crossing between the transmission lines and pipelines have frequently happened. Therefore, the electromagnetic influence on oil/gas pipelines near the transmission lines becomes increasingly prominent [1].

The pipelines are subject to interference arising from three parts, capacitive, inductive and resistive coupling. Capacitive coupling only affects the aboveground pipeline since it has both a capacitance to the transmission line and to earth. And the pipeline buried below ground is shielded by the ground and cannot be affected by capacitive coupling. Inductive coupling is caused by the time-varying magnetic field produced by the transmission line currents. The induced voltage at the pipeline ends will vary as a function of length of parallelism, earth resistivity, distance between the pipeline and transmission line, and so on. Aerial and underground pipelines are both affected by inductive coupling. Resistive coupling between the transmission line and pipeline is only relevant during the grounding fault and lightning strike when significant level of current flows into the earth. And this will raise the potential of the tower base and of the neighboring soil with regard to the remote earth, and result in a considerable stress voltage across the coating of the pipeline, which can lead to arcing that damages the coating, or even the

pipeline itself. When the lightning strikes the transmission line, both the inductive and resistive coupling will take place and put the pipeline at severe risk.

The electromagnetic influence on the underground pipeline near transmission line is chiefly concerned with the personal safety, pipeline safety, alternating current (ac) corrosion of pipeline and normally operating of pipeline cathodic protection system. Some research work has been carried out and the limits of electromagnetic influence are released in [2]-[4]. These studies mainly focus on the inductive and resistive coupling modeling during the normally operating and ground fault of the transmission line. The switching and lightning transient induced voltages on the aerial and buried pipelines are simulated and some conclusions are obtained in [5].

In this paper, firstly, the transient simulation of the currents along ground wire and tower is performed by EMTP when the lightning strikes the tower of the transmission line. Secondly, based on the method of moment (MoM) [6], the coating stress voltage on the pipeline parallel to or across the transmission line is investigated and the approximate expression for the crossing situation is put forward. Finally, with the lightning electrical strengths of different coatings, the safety distances between the pipeline and tower grounding structure can be obtained for different lightning current peaks.

II. LIGHTNING CURRENTS ALONG GROUND WIRE AND TOWER

In this section, the transient simulation of the currents along ground wire (shield wire) and tower is carried out making use of EMTP when the lightning strikes the tower of the transmission line, which involves different voltage levels (330kV, 500kV, 750kV and 1000kV), different configurations of the transmission line (horizontal-single-circuit, triangular-single-circuit and vertical-double-circuit) and different earth resistivity (100Ωm, 500Ωm, 1000Ωm and 2000Ωm). The detailed results are not listed here. As illustrated in Fig.1, the EMTP simulation model includes 24-span ground wires and 25-base towers, which is symmetrical with regard to the lightning point. The ground wires are symmetrically numbered from 1 to 12 while the towers are from 0 to 12, where the No.0 tower represents the location of lightning current injection. During the simulation, the lightning current is with the amplitude of 100kA, waveform of 2.6/50μs and wave impedance of 250Ω. The tower is modeled as the transmission line with single wave impedance, the grounding impedance of the tower takes the lightning impulse impedance, and the ground wires are modeled as the overhead transmission line. One thing worthy of note is that both the so-

called back-flashover toward phase conductors and the spark discharge of the grounding conductors of the tower are not involved when the lightning strikes the tower of the transmission line.

Based on the above simulations, the conclusions can be listed as follows: (1) the currents along the ground wires dramatically decrease, i.e. 20%-25% of the intruding lightning current peak for the 1st span, 10%-15% for the 2nd span, 5%-10% for the 3rd span, and the currents can be ignored after the 5th span; (2) the currents along the towers dramatically decrease, i.e. 80%-90% of the intruding lightning current peak for the No.0 base where the lightning current is injected, 15%-20% for the 1st base, 5%-10% for the 2nd base, and the currents can be ignored after the 3rd base; (3) the currents along the ground wire and tower slightly depend on the voltage levels and configurations of the transmission line, namely, the height of tower is not very important during the simulation; (4) the higher the earth resistivity, the greater the lightning impulse impedance of the tower grounding structure, the higher the current along the ground wire, and the lower the current along the tower. In general, the earth resistivity has little effect on the lightning current distribution of the ground wire and tower. These conclusions turn out contrary to those of the ground fault of the transmission line.

As a result, for the situation of parallelism or oblique approach between the transmission line and pipeline, both the inductive and resistive coupling are considered, and the simplified transmission line model is suggested, which only includes 5 spans on each side of the lightning current injection point (10 spans in total). While for the situation of crossing, only the resistive coupling of the current in the earth through two towers adjacent to the pipeline is considered and the inductive coupling of the current along the overhead ground wire is ignored during the simulation.

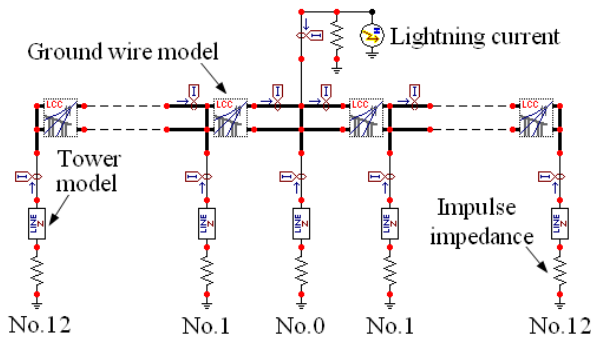

Fig. 1. Simulation model for EMTP

Fig. 2. Simulation model for the method of moment

III. COATING STRESS VOLTAGE FOR PARALLELISM

As shown in Fig.2, the simulation model for the method of moment includes 10-span ground wires and 11-base towers. Both the two ground wires of the 1000kV double-circuit ac transmission line and the tower grounding structure shown in Fig.3 are modeled by the thin conductors according to the actual size of the configuration. The tower is approximately modeled by 4 vertical thin conductors. The underground pipeline is modeled by the hollow conductors with insulation coating. Combined the method of moment with the Fourier transform, the transient coating stress voltage along the pipeline parallel to transmission line is investigated for different approach distances.

Fig. 3. Configuration of the pipeline and tower grounding structure

IV. COATING STRESS VOLTAGE FOR CROSSING

In this section, the proposed method is applied to the evaluation of the coating stress voltage along the pipeline across transmission line shown in Fig.3 and the corresponding approximate expression is put forward, which involves the lightning current, pipeline type, earth resistivity and the distance between the pipeline and tower grounding structure. Finally, with the lightning electrical strengths of different coatings, the safety distances between the pipeline and tower grounding structure for different lightning current peaks are suggested.

Abstract — This paper deals with the development of analysis method in a synchronous reluctance motor (SynRM) using finite element method (FEM) coupled electromagnetic field of Preisach model, which is presented to represent the additional thermal source due to hysteresis loss, & thermal field. The focus of this paper is the thermal analysis relative to hysteresis loss and copper loss in a SynRM.

I. INTRODUCTION

Issues such as efficiency and torque/ampere are important in evaluating the performance of an electric machine.

Such characteristics depend mostly upon the losses behavior of the machine and therefore the study of heating problems of electric machines and the prediction of temperature rises of magnetic core, teeth, insulation, conductor etc. are necessary for sophisticated design, yet extremely complex.

Accurate solution is important to maintain design integrity, assure high performance and optimize costs.

For this purpose, it is essential that the temperature distribution and its gradient in the electric machines are predicted more accurately.

The heat losses of SynRM mainly consist of the Joule effect resulting from copper winding and the hysteresis loss of magnetic materials.

The heat generated by copper windings could be obtained from the results of a general process used in the heat transfer analysis method [1].

However hysteresis component in the internal thermal source have traditionally been obtained by analytical techniques, with many simplifying assumptions with respect to geometry and manufacturer material data.

The Preisach model is now generally accepted to be a powerful hysteresis model, and is therefore intensively studied [2]-[4].

With the advent of Preisach model, numerical technique for modeling the additional thermal source J_m in the magnetic material can be obtained.

In this paper, a finite element analysis coupling electromagnetic field of Preisach model & thermal field for a SynRM are presented and dynamic characteristic analyses are performed under the effect of Joule and hysteresis loss.

The focus of this paper is the development of thermal analysis method in a SynRM for Joule and hysteresis loss.

II. FINITE ELEMENT METHOD COUPLED ELECTROMAGNETIC FIELD OF PREISACH MODEL & THERMAL FIELD

A. Governing Equation of SynRM in Electromagnetic Field

When the moving coordinate system is used, the governing equation in 2D is given as follows:

$$\frac{\partial}{\partial x} \nu_0 \left(\frac{\partial A_z}{\partial x} \right) + \frac{\partial}{\partial y} \nu_0 \left(\frac{\partial A_z}{\partial y} \right) = -J_z - J_m \quad (1)$$

$$J_m = \nu_0 \left(\frac{\partial M_y}{\partial x} - \frac{\partial M_x}{\partial y} \right) \quad (2)$$

Where, A_z : z component of magnetic vector potential
 J_z : current density, ν_0 : magnetic resistivity

B. System Matrix

The circuit equation is written as:

$$\{V\} = [R]\{I\} + [L_0] \frac{d}{dt} \{I\} + \{E\} \quad (3)$$

Where, $\{E\}$: E.M.F. vector in the winding, $\{V\}$: supplying voltage vector, $\{I\}$: phase current vector, $[L_0]$: leakage inductance

To solve (1), we used the Galerkin finite element method. For the time differentiation in (3), a time stepping method is used with backward difference formula. Coupling (1), (2) and (3), the system matrix is given as follows:

$$\begin{aligned} & \left[\begin{array}{cc} \nu_0[S] & -[N] \\ [0] & [R] \end{array} \right] + \frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \begin{Bmatrix} \{A\} \\ \{I\} \end{Bmatrix}_t \\ & = \frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \begin{Bmatrix} \{A\} \\ \{I\} \end{Bmatrix}_{t-\Delta t} + \begin{Bmatrix} \{M\} \\ \{V\} \end{Bmatrix}_t \end{aligned} \quad (4)$$

Where, $[LG]$ is coefficient matrix related to emf, the magnetization $\{M\}$ is calculated by preisach modeling [5].

C. Finite element formulation in thermal field

In the thermal field, the finite element model corresponding to variational formulation of the heat conduction problem with convective boundary conditions and thermal sources, for typical element, is given by the

following matrix equation.

$$[M^e] \frac{d}{dt} [T^e] + ([S^e] + [H^e] + [G^e]) [T^e] = [F^e] + [F_m^e] + [P^e] + [R^e] \quad (5)$$

where,

$\frac{d}{dt} [T^e]$: time derivative temperature vector, $[M^e]$:

thermal capacity matrix, $[S^e]$: thermal conductivity matrix ,

$[H^e]$: convection matrix, $[G^e]$: resistivity temperature dependency matrix , $[T^e]$: temperature vector, $[F^e]$:

Heating sources vector due to the copper winding, $[F_m^e]$:

Heating sources vector due to hysteresis of materials, $[P^e]$:

convective vector, $[R^e]$: Boundary vector

$$[M^e] = \rho c \Delta \frac{1}{2} \begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix}, [S_{ij}^e] = \frac{k}{4\Delta} (c_i c_j + d_i d_j)$$

$$[H^e] = \frac{h_{ij} l_{ij}}{6} \begin{bmatrix} 2 & 1 & 0 \\ 1 & 2 & 0 \\ 0 & 0 & 0 \end{bmatrix} + \frac{h_{jk} l_{jk}}{6} \begin{bmatrix} 0 & 0 & 0 \\ 0 & 2 & 1 \\ 0 & 1 & 2 \end{bmatrix} + \frac{h_{ki} l_{ki}}{6} \begin{bmatrix} 2 & 0 & 1 \\ 0 & 0 & 0 \\ 1 & 0 & 2 \end{bmatrix}$$

$$[G^e] = -\rho_0 \alpha l^2 \Delta \frac{1}{12} \begin{bmatrix} 2 & 1 & 1 \\ 1 & 2 & 1 \\ 1 & 1 & 2 \end{bmatrix},$$

$$[F^e] = \frac{\rho_0 J_0^2 (1 - \alpha T_0) \Delta}{3} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}, [F_m^e] = \frac{\rho_0 J_m^2 (1 - \alpha T_0) \Delta}{3} \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}$$

$$[P^e] = \frac{h_{ij} l_{ij} T_f}{2} \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix} + \frac{h_{jk} l_{jk} T_f}{2} \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix} + \frac{h_{kj} l_{ki} T_f}{2} \begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}$$

$$[R^e] = \frac{l_{ij} T_0}{2} \begin{bmatrix} 1 \\ 1 \\ 0 \end{bmatrix} + \frac{l_{jk} T_0}{2} \begin{bmatrix} 0 \\ 1 \\ 1 \end{bmatrix} + \frac{l_{ki} T_0}{2} \begin{bmatrix} 1 \\ 0 \\ 1 \end{bmatrix}$$

Where

ρ_0 : electric resistivity at T_0 temperature [$\Omega \cdot m$], α : linear expansion coefficient [$1/K$], T_f : undisturbed fluid temperature [K], l : length between node [m]

The convective heat transfer coefficient is calculated from the following experimental expression [5].

$$h = h_f = h_n (1 + 1.3 \sqrt{v_f})$$

Where

h_f : forced convective heat transfer coefficient [$W/(m^2 \cdot K)$]

h_n : natural convective heat transfer coefficient [$W/(m^2 \cdot K)$]

v_f : average fluid velocity [m/s]

III. SIMULATION AND DISCUSSION

Fig.1 is the flow chart of transient thermal analysis of a SynRM using coupled electromagnetic of Preisach model & thermal finite element method taking into account the rotation.

Current density J_0 and equivalent magnetizing current density J_m , which were calculated previously in electromagnetic field, are used as a heating source of thermal field. The variation of stator resistance and conductivity, which are caused by temperature rise, are returned to electromagnetic field. Fig.2 represents the isothermal line of analysis model.

Through the proposed method, the characteristics of variable thermal analysis will be observed for a SynRM in next extended version

Abstract — This paper proposes a novel preconditioning based on the incomplete Cholesky (IC) factorization and the concept of the explicit error correction (EEC) method for finite element electromagnetic field analyses: A - ϕ block IC preconditioning. The A method using the proposed method has the same convergence characteristic as the A - ϕ method with block IC preconditioning. The effectiveness of the proposed method is investigated in high-frequency and quasi-static field analyses comparing conventional preconditioning.

I. INTRODUCTION

In electromagnetic field analyses by the edge-based finite-element method (FEM), it is well known that the A - ϕ method has an advantage over the A method in convergence characteristic of iterative solvers such as the incomplete Cholesky conjugate gradient (ICCG) method [1]. The A method is superior to the A - ϕ method in terms of the number of unknowns. However, the improvement of the condition number is more significant and therefore the A - ϕ method is much faster than the A method.

On the other hand, the explicit error correction (EEC) method and the implicit error correction (IEC) method were proposed as the novel frameworks for linear iterative solvers [2][3]. For example, the A - ϕ method can be regarded as an implicit error correction with the redundant unknowns ϕ . If the EEC method attains nearly the same convergence property as the IEC method by appropriately devising the auxiliary matrix, the EEC method is generally superior to the IEC method in terms of computational costs. This feature is noticeable in the case of the multigrid method which executes error correction at multiple levels [4]. These imply the possibility that the convergence characteristic of the A method can be improved by the concept of the EEC method. In fact, the folded preconditioning, which has a strong relationship to the EEC and IEC methods, especially in the case of folded Gauss-Seidel preconditioner, has been proposed [5].

In this paper, from a different perspective, we develop the novel preconditioning for the A method based on the IC factorization by using the concept of the EEC method. The application of the IC smoother to the ordinary EEC procedure cannot derive the effective preconditioning because the preconditioner becomes nonsymmetric and cannot treat the off-diagonal blocks of the coefficient matrix obtained from the A - ϕ method, which represents the relationship between A and ϕ . Because preconditioning only needs the approximate solution, we propose omitting the off-diagonal blocks in the EEC procedure, which results in the novel preconditioning: the A - ϕ block IC preconditioning. We clarify the relationship

between the proposed method and the folded preconditioning. To investigate the effectiveness of the proposed method, we compare the performance of the standard ICCG method, the folded ICCG method and the A - ϕ block ICCG method.

II. A - ϕ BLOCK IC PRECONDITIONING

A. EEC Method for the A method

Consider solving the following linear system of equations derived from the A method

$$K\mathbf{x} = \mathbf{b}. \quad (1)$$

Here, K is the coefficient matrix, \mathbf{x} is the unknown vector, and \mathbf{b} is the right-hand-side vector. Similarly, the linear system derived from the A - ϕ method is given by

$$\begin{pmatrix} K & KG \\ G^T K & G^T KG \end{pmatrix} \begin{Bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \end{Bmatrix} = \begin{Bmatrix} \mathbf{b} \\ G^T \mathbf{b} \end{Bmatrix}, \quad (2)$$

where G is the discrete gradient operator. The procedure of the EEC method corresponding to (2) is as follows [3]:

- (i) Update the approximate solution $\tilde{\mathbf{x}}$ by a sweep for (1).
- (ii) Compute vector \mathbf{p} by solving $G^T KG \mathbf{p} = G^T (\mathbf{b} - K\tilde{\mathbf{x}})$.
- (iii) Update the approximate solution by $\tilde{\mathbf{x}} \leftarrow \tilde{\mathbf{x}} + G\mathbf{p}$.

The above procedure can also be used as the preconditioning.

B. A - ϕ Block IC Preconditioning

In order to develop the effective preconditioning for the A method which has nearly the same convergence characteristic as the A - ϕ method, we use the IC smoother for a sweep in the EEC procedure. The preconditioning for (1) with the IC smoother in the EEC procedure can be written as follows.

$$M^{-1} = \left((L_1 L_1^T)^{-1} + G (L_2 L_2^T)^{-1} G^T (I - K (L_1 L_1^T)^{-1}) \right). \quad (3)$$

where M indicates the preconditioner, the superscript T means transpose, and the lower triangular matrix L_1 and L_2 are given by (4) by using IC factorization

$$\begin{pmatrix} K & KG \\ G^T K & G^T KG \end{pmatrix} \approx \begin{pmatrix} L_1 & O \\ L_3 & L_2 \end{pmatrix} \begin{pmatrix} L_1 & O \\ L_3 & L_2 \end{pmatrix}^T. \quad (4)$$

The preconditioning (3) is nonsymmetric and the effective preconditioner cannot be derived if a post sweep is added to the EEC procedure. Preconditioning generally needs only the approximate solution. Additionally, (3) does not include the off-diagonal block L_3 . Therefore, we propose omitting the off-diagonal blocks KG and $G^T K$ in (2) when the EEC procedure is used as the preconditioning. In this case, the step (ii) is modified as

- (ii)' Compute vector \mathbf{p} by solving $G^T KG \mathbf{p} = G^T \mathbf{b}$.

This modification derives the novel preconditioner as follows:

$$M^{-1} = (L_1 L_1^T)^{-1} + G(L_2 L_2^T)^{-1} G^T. \quad (5)$$

We term this method the A - ϕ block IC preconditioning because it only treats the diagonal blocks in (2).

C. Relationship between A - ϕ Block IC and Folded IC

The folded IC preconditioner for (1) is given by

$$M^{-1} = L_1^{-T} L_1^{-1} + (G - L_1^{-T} L_3^T) L_2^{-T} L_2^{-1} (G^T - L_3 L_1^{-1}). \quad (6)$$

Preconditioner (5) can be derived from (6) by regarding L_3 as zero matrix, which indicates the A - ϕ block IC is a special case of the folded IC. For any preconditioned Krylov subspace (KS) method for a redundant linear system of equations, a mathematically equivalent KS method for the redundancy-reduced linear system of equations can be constructed by using the folded preconditioner [5]. Thus, the CG method preconditioned by the A - ϕ block IC for the A method is mathematically equivalent to the CG method preconditioned by the block IC for the A - ϕ method. The convergence characteristic of the A - ϕ block ICCG method for the A method can be deteriorated slightly compared with the standard ICCG method for the A - ϕ method because of the omission of the off-diagonal blocks. However, the optimal acceleration factor [6] of two diagonal blocks of (5) can be decided independently, which leads to the compensation for the deterioration. Furthermore, the operation counts for one iteration step and memory requirement can be reduced because of the decrease of the number of unknowns. Therefore, the total performance of the A - ϕ block ICCG method for the A method is expected to be superior to the standard ICCG method for the A - ϕ method.

III. NUMERICAL EXAMPLES

A. Rectangular-Iris Coupled Circular-Waveguide Filter

The performance of the proposed method is examined in the high-frequency electromagnetic field analysis of the rectangular-iris coupled circular-waveguide filter shown in Fig. 1(a). The quarter part of the whole model is analyzed because of the symmetry. The convergence criterion for the iterative solvers is set to 10^{-8} and computations are executed on a Xeon X5472 with 8 GB RAM.

Table I shows the computational results obtained from 4 kinds of methods. The convergence characteristic of the folded ICCG method for the A method is almost the same as that of the standard ICCG method for the A - ϕ method, and the folded ICCG method has better performance. Meanwhile, the application of the A - ϕ block IC preconditioner does not deteriorate the convergence property due to the appropriate acceleration factors which vary by block. Thus, the proposed method can reduce the elapsed time by about 47 % and 37 % compared with the standard ICCG method and the folded ICCG method, respectively. From the above results, the effectiveness of the proposed method can be confirmed with respect to both elapsed time and memory requirement.

B. Surface Permanent Magnet Motor

The effectiveness of the proposed method is investigated in the nonlinear eddy-current analysis of the surface permanent magnet (SPM) motor shown in Fig. 1 (b). The one-

eighth part of the whole model is analyzed because of the symmetry and periodicity. To model the laminated iron core, the homogenization method is utilized. Table II shows the computational results at the first time step. The number of nonlinear iterations is 12 in all the cases. In eddy-current problems, the region where ϕ is defined is small compared with high-frequency problems. However, even in the case of eddy-current analyses of the practical electric machine, the A - ϕ block IC preconditioning is fairly effective.

More numerical results and detailed discussion about the proposed method will be included in the full paper.

Abstract—A robust formulation for the computation of combined resistive, capacitive and inductive effects in time-harmonic low frequency applications has been introduced in [1]. The Galerkin discretization with conforming finite elements leads to a sparse system matrix. Large jumps in the material coefficients may cause severe ill-conditioning of the matrix. In this paper we investigate how *operator preconditioning* can be used to construct an efficient preconditioner. The approach can be treated with almost linear complexity by making use of *hierarchical matrices*.

I. INTRODUCTION

Finite element based discretization of time-harmonic full Maxwell or eddy current problems in realistic industrial applications requires a huge number of degrees of freedom (d.o.f.) in order to guarantee sufficient precision. Thus, the application of iterative solvers is desirable. It is often realized by employing algebraic multigrid methods, see [2] and [3]. A novel alternative is preconditioners that are based on *hierarchical matrices*. This yields a robust method even in the presence of large jumps in the material coefficients [4].

II. ROBUST FULL MAXWELL AT LOW FREQUENCIES

If neither capacitive nor inductive effects can be neglected in a low frequency application then quasi-static models cannot be used and the solution of the full Maxwell's equations is necessary. An example is shown in figure 1. We consider the case where field computation is confined to an artificially bounded domain $\Omega \subset \mathbb{R}^3$ of simple topology. Inside Ω there are ohmic conductors occupying the region Ω_c , and the non-conducting region is $\Omega_e := \Omega \setminus \overline{\Omega_c}$. Note that the non-conducting domain may not only consist of air, but also of other parts like the high-permeable core in figure 1. Voltage boundary conditions are imposed at the contacts at $\partial\Omega \cap \partial\Omega_c$. The stationary limit $\omega \rightarrow 0$ of the full Maxwell's equations has been addressed in [1]. There it has been described how standard potential based formulations of full Maxwell lack stability at low frequencies. A robust formulation can be achieved by coupling Gauss' law in the non-conductive domain Ω_e . This extra condition has to be balanced by an extra unknown that results from the non-direct splitting of the electric scalar potential φ into two parts $\varphi = \tilde{\varphi} + \psi$, with $\psi = \text{constant}$ in Ω_e . The final stable formulation

Fig. 1. Arrangement of an inductively coupled capacitor. A time-harmonic voltage-drop of 1 V / 50 Hz is imposed at the contacts. The conductors are made of copper and have cylindrical shape with diameter of 2.5 cm. The core is a non-conductor with relative permeability of 2000.

in strong form is given by:

$$\begin{aligned} \operatorname{curl} \frac{1}{\mu} \operatorname{curl} \mathbf{A} - (\omega^2 \epsilon - i\omega\sigma) \mathbf{A} \\ + (i\omega\epsilon + \sigma) \operatorname{grad}(\tilde{\varphi} + \psi) = 0 \quad \text{in } \Omega, \\ \operatorname{div}(\epsilon \mathbf{A}) = 0 \quad \text{in } \Omega, \\ \operatorname{div}(\epsilon \operatorname{grad}(\tilde{\varphi} + \psi)) = 0 \quad \text{in } \Omega_e. \end{aligned} \quad (1)$$

Herein μ , ϵ , σ are the material coefficients and ω is the angular frequency. The matrix \mathbf{M} that results from Galerkin discretization of the system (1) with conformal finite elements is singular. This becomes obvious by applying the divergence on the first equation, because of the linear dependency of the resulting equations in the non-conducting domain. An iterative preconditioned BiCGstab succeeded in solving the unsymmetric system. A preliminary preconditioner \mathbf{P}_p was obtained by applying the direct solver Pardiso [5] to (1) after setting $\omega \leftarrow \max\{\omega, 1 \text{ Hz}\}$, $\sigma(\mathbf{x}) \leftarrow \max\{\sigma(\mathbf{x}), 10 \Omega \text{ m}^{-1}\}$. This measure removes the linear dependence of the equations and regularizes the system. Nevertheless, this procedure provides a good approximation of (1), because of the continuity with respect to frequency and conductivity. Fig. 2 shows the results of the computation on a mesh that consists of 250,000 curved tetrahedral first order finite elements.

III. OPERATOR PRECONDITIONING

An alternative preconditioner for \mathbf{M} can be derived by using the idea of operator preconditioning that has been introduced in [6, Sect. 3]. It makes use of the stability of the variational problem related to (1) with respect to suitably chosen norms on

Fig. 2. Simulation results of the arrangement described in figure 1. The upper left illustration shows the real part of the electric potential in [V], the upper right picture shows the rms-value of the magnetic induction in [T], the lower left picture shows the rms-value of the current density in [A/m²], and the lower right picture shows the rms-value of the electric field in [V/m].

the function spaces. The inverse of the operator inducing these norms will then furnish a preconditioner which is robust with respect to discretization parameters. In the concrete setting of (1) the novel preconditioner is given by inverting a finite element discretization of

$$\mathbf{P} := \begin{pmatrix} \operatorname{curl} \frac{1}{\mu} \operatorname{curl} \mathbf{A} + \omega \sigma \mathbf{A} & 0 & 0 \\ 0 & \Delta \tilde{\varphi} & 0 \\ 0 & 0 & \Delta \psi \end{pmatrix}, \quad (2)$$

with \mathbf{A} , φ functions on Ω , and ψ supported in Ω_e . In (2) we also impose lower bounds for frequency and conductivity, that is, we set $\omega \leftarrow \max\{\omega, 1 \text{ Hz}\}$, $\sigma(\mathbf{x}) \leftarrow \max\{\sigma(\mathbf{x}), 10 \Omega \text{ m}^{-1}\}$. First tests with a direct solver applied to \mathbf{P} demonstrated strongly improved efficiency of a preconditioned BiCGstab iteration, see table I. The computations were carried out on a 4 core 2,5 GHz / 16 GB RAM Intel Xeon.

Number of complex d.o.f.	Time old min	Memory old GB	Time new min	Memory new GB
199 000	4.2	6.0	0.6	1.4
405 000	16.8	15.3	1.4	3.3
708 000	-	-	3.3	6.3
1 074 000	-	-	7.0	10.4
1 564 000	-	-	10.6	15.1

TABLE I

TOTAL MEMORY AND TIME CONSUMPTION FOR THE COMPUTATION OF THE PROBLEM OF FIGURE 1 WITH OLD \mathbf{P}_p AND NEW PRECONDITIONER \mathbf{P} .

Note that each block of the block-diagonal matrix \mathbf{P} is real, symmetric and positive definite. This is a great advantage compared to other preconditioners. Memory and time consumption of the applied direct solver Pardiso could drastically be reduced by using a Cholesky decomposition.

IV. HIERARCHICAL MATRICES (\mathcal{H} -MATRICES)

We have to overcome the fill-in problems of direct solvers if the problem size is further enlarged. Fast summation

methods have considerably attracted attention during the last two decades. The introduction of *hierarchical matrices* (\mathcal{H} -matrices) [7], [8] has paved the way to methods which have almost linear complexity and which are robust; see also [9]. Their efficiency is gained from representing sub-blocks from an appropriate matrix partition P by low-rank matrices; see Fig. 3. The set of hierarchical matrices on the partition P and

Fig. 3. A hierarchical matrix with its rank distribution.

blockwise rank k is defined as

$$\mathcal{H}(P, k) = \{A \in \mathbb{C}^{M \times N} : \operatorname{rank} A_b \leq k \text{ for all } b \in P\}.$$

The elements of this set can be stored with logarithmic-linear complexity and hence provide data-sparse representations of fully populated matrices. Additionally, exploiting the hierarchical structure of the partition, an approximate algebra can be defined which is based on divide-and-conquer versions of the usual block operations. These approximate operations also have logarithmic-linear complexity and can be used to define substitutes for higher level matrix operations such as inversion and LU factorization. Our aim is to construct approximate preconditioners for (1) by computing \mathcal{H} -matrix approximations to the factors of the Cholesky decomposition of (2). This has not yet been implemented, but will be accomplished and presented at the conference.

Abstract—In the forward problem of multi-layer medium magnetic induction tomography and geological electromagnetic field, the integration including dual Bessel function should be calculated. Because of the serious oscillation and slow decay of the product term, it is difficult to use ordinary numerical integration method. This paper provide a hybrid numerical integration algorithm, which divide the integral interval $[0, \infty)$ into two regions: $[0, \lambda_0)$ and $[\lambda_0, \infty)$. In $[0, \lambda_0)$, the integration can be calculated through Gauss-Legendre numerical integral method, while in $[\lambda_0, \infty)$, we convert the integration into Fourier transform and calculate it by polygonal approximation algorithm. Finally, add the two results. This algorithm is proved to have better convergence characteristic and higher precision.

Index Terms—hybrid numerical integration, Gauss-Legendre method, polygonal approximation

I. Introduction

In the forward problem of magnetic induction tomography and geological electromagnetic field, the integration including dual-Bessel function of the following form should be calculated:

$$\int_0^{\infty} F(\lambda) \cdot J_1(\lambda\rho) \cdot J_1(\lambda\rho') \cdot d\lambda \quad (1)$$

where $\rho > 0$, $\rho' > 0$, $F(\lambda)$ is the kernel function. $J_1(\lambda\rho), J_1(\lambda\rho')$ are the first order Bessel functions of first kind. It is also called as Hankel transform.

Due to the serious oscillation and slow decay of the dual Bessel function product term (as shown in Fig.1), it is difficult to use ordinary numerical integration method. Referring to the research of Chave^[1] and Huajun^[2], a new numerical integration algorithm is introduced.

Fig.1. The plot of two one-order and first kind Bessel functions multiplying

II. Algorithm Description

According to the gradually changed attenuation characteristic of Bessel function, the integral interval $[0, \infty)$ can be divided into two regions: $[0, \lambda_0)$ and $[\lambda_0, \infty)$. In these two regions, the integration be calculated by different methods. The result is the sum of the two results.

A. Integration in Region $[0, \lambda_0)$

First, find the distribution of zero points for the dual Bessel function product term in this interval. Then, use Gauss-Legendre integral method between the adjacent two zeros in turns. We get 5 zero points of five-order Legendre polynomials as the Gauss points in $[-1, 1]$. Arbitrary integral interval $[a, b]$ could be converted into interval $[-1, 1]$ by coordinate transform^[3].

B. Integration in region $[\lambda_0, \infty)$

The Hankel transform can be written as fourier transformation using the mass-argument approximate expression of Bessel function, and calculated by polygonal approximation algorithm. The mass-argument approximate expression of one-order Bessel function is:

$$J_1(x) \approx \sqrt{\frac{2}{\pi x}} \cos\left(x - \frac{3\pi}{4}\right) \quad (x \rightarrow \infty) \quad (2)$$

Taking (2) into (1), substituting the integral region with $[\lambda_0, \infty)$ yields:

$$\begin{aligned} & \int_{\lambda_0}^{\infty} F(\lambda) \cdot J_1(\lambda\rho) J_1(\lambda\rho') \cdot d\lambda = \\ & \int_{\lambda_0}^{\infty} F(\lambda) \cdot \frac{-\sin[\lambda(\rho+\rho')]}{\pi\lambda\sqrt{\rho \cdot \rho'}} \cdot d\lambda \quad (3) \\ & + \int_{\lambda_0}^{\infty} F(\lambda) \cdot \frac{-\cos[\lambda(\rho-\rho')]}{\pi\lambda\sqrt{\rho \cdot \rho'}} \cdot d\lambda \end{aligned}$$

The Hankel transform has been convert into the sum of two fourier transforms. Polygonal approximation algorithm is employed to calculate these two fourier transforms:

$$\begin{aligned} & \int_a^b F(\lambda) \cdot \cos(\lambda\rho) d\lambda = \frac{1}{\rho} F(\lambda) \sin(\lambda\rho) \Big|_{\lambda=a}^b \\ & + \frac{1}{\rho^2} \sum_{i=0}^n \frac{F(\lambda_{i+1}) - F(\lambda_i)}{\lambda_{i+1} - \lambda_i} [\cos(\lambda_{i+1} \cdot \rho) - \cos(\lambda_i \cdot \rho)] \end{aligned} \quad (4)$$

$$\begin{aligned} & \int_a^b F(\lambda) \cdot \sin(\lambda\rho) d\lambda = -\frac{1}{\rho} F(\lambda) \cos(\lambda\rho) \Big|_{\lambda=a}^b \\ & + \frac{1}{\rho^2} \sum_{i=0}^n \frac{F(\lambda_{i+1}) - F(\lambda_i)}{\lambda_{i+1} - \lambda_i} [\sin(\lambda_{i+1} \cdot \rho) - \sin(\lambda_i \cdot \rho)] \end{aligned} \quad (5)$$

Notes that, the integrating region of Polygonal approximation algorithm is finite, namely, $[a, b]$. But the integrating region in expression(3) is infinite: $[\lambda_0, \infty)$, the infinite interval should be truncated according to the convergence characteristic of $F(\lambda)$ at infinity.

III. Experiment of the test function

We used the following expression as the test function.

$$F(x) = \int_0^{\infty} \lambda \cdot e^{-\lambda^2 x^2} \cdot J_1(\lambda\rho) \cdot J_1(\lambda\rho') \cdot d\lambda \quad (6)$$

This integration has an analytical solution:

$$f(x) = \frac{1}{2x^2} e^{-\frac{\rho_1^2 + \rho_2^2}{4x^2}} \cdot I_1\left(\frac{\rho_1 \cdot \rho_2}{2x^2}\right) \quad (7)$$

where I_1 is the first kind of one-order modified Bessel function.

The result of the numerical algorithm and the analytical solution are drawn in the Fig.2:

Fig.2. Comparison between function analytical solution and numerical solution

As Fig.2 shown, we can see that the numerical solutions are coincide with the analytical ones.

IV. Conclusion

The algorithm solves the problem of numerical integration of Hankel transform. The calculation of the test function shows that this algorithm has better convergence characteristic, higher precision and efficiency. The algorithm can be used in the solution of the forward problem in magnetic inductive imaging and geological electromagnetism exploration.

Abstract — In contrast to the standard algebraic multigrid, the Wavelet-based Algebraic Multigrid method relies more strongly on the smoothing method because the coarse spaces are chosen a priori. So, it is very important to develop new smoother methods, especially for those cases where the classical Gauss-Seidel smoothing method does not give good results. This paper proposes a new multilevel smoothing approach based on projection technique. The proposed smoothing method was applied to smoothing the error in a linear systems issued from finite element solutions of the elliptic equation and the results compared with those obtained from the Gauss-Seidel method.

I. INTRODUCTION

THE WAVELET-BASED Algebraic Multigrid method (WAMG) was proposed for the solution of linear systems issued from Finite Element applications in Electromagnetic Field problems [1]. In this method an incomplete discrete wavelet transform is applied in order to generate an approximation of the original matrix in each level of a multiresolution process. The same approach is also used to transfer the vectors between the different grids in the multigrid scheme. In contrast to the standard algebraic multigrid, that uses some simple relaxation scheme and enforces the interaction between the smoother and the coarse-grid correction by choosing the coarser levels and the transfer operators appropriately [2],[3], the WAMG relies more strongly on the smoothing method because the coarse spaces are chosen a priori. So, the WAMG selects a suitable smoothing method to ensure an accurate error representation in the coarsest level.

In face of this, it is very important to develop new smoothing methods that are suitable for the case where the classical Gauss-Seidel smoothing method does not give good results as, for example, for the global systems resulting from FEM–BEM formulations which the common smoother types do not work properly [4].

This paper proposes a new multilevel smoothing approach based on projection techniques which search an approximation in the high frequency subspace created by the high-pass filters in the discrete wavelet transform.

II. THE REQUIREMENTS OVER THE SMOOTHER IN WAMG

In order to analyze the requirements over the smoothing methods in WAMG, we have to understand the DWT behavior and the effects of the use of this technique in the algebraic multigrid context.

Usually in the literature, the discrete wavelet transform is

defined using the concept of filter bank [5]. In such cases low-pass and high-pass filters are chosen to obtain the low frequency and the high frequency terms of the input signal, respectively. In this procedure, if the discrete input signal $x = \{x[n]\}_{n \in \mathbb{Z}}$ is sufficiently smooth then the high frequency terms are close to zero and the output low frequency component will be a good approximation of the signal.

To better understand the effects of this technique in the WAMG context, we will suppose that there are only two grids: the original grid and a coarse grid.

The WAMG method uses only the low-pass filters to produce an approximation of the original coefficient matrix. This approximation will represent the system of equation in the coarse grid and it will be used to solve the residual equation on the coarse grid. Then, the residual equation solution is used in the correction of the error in the original grid.

As the WAMG coarse grid is created by the low-pass filters, the coarse grid error correction will only be accurate if the error is smooth. The fact that the error is smooth means that the high frequency components become small after a few stationary iterative iterations whereas the low frequency components hardly change [2]. Therefore, the smoothing method should be able to remove or, at least, to lessen the high frequency components of the error.

III. THE PROPOSED MULTILEVEL SMOOTHER METHOD

In a projection process an approximation for the solution of a linear system is extracted from a subspace \mathcal{K} which is the subspace of candidate approximations, or search subspace. If m is the dimension of \mathcal{K} , then the residual vector $b - Ax$ is constrained to be orthogonal to m linearly independent vectors in order to obtain such an approximation. This orthogonal condition defines another subspace \mathcal{L} , of dimension m , called the subspace of constraints [6].

Mathematically, if we know an initial guess, $x_0 \in \mathcal{K}$, the approximate solutions can be defined as

$$\tilde{x} = x_0 + \delta, \quad \delta \in \mathcal{K} \quad (1)$$

$$(r_0 - A\delta, w) = 0, \quad \forall w \in \mathcal{L} \quad (2)$$

in which $r_0 = b - Ax_0$.

As an ideal smoother should remove the high frequency error component it is interesting that this smoother search an approximation to the linear system solution in a high frequency subspace.

In other hand, the multiresolution analysis in discrete wavelet transform decompose the original grid (space) V in two subspaces V_1 and W_1 such that

$$V_1 = \text{span} \{ \phi(2^{-1}x - k) \}_{k \in \mathbb{Z}}, \quad (3)$$

$$W_1 = \text{span} \{ \psi(2^{-1}x - k) \}_{k \in \mathbb{Z}}, \quad (4)$$

and

$$V_1 \oplus W_1 \quad (5)$$

where ϕ and ψ are the scaling and wavelets function, respectively. Therefore, we can develop a smoothing method based on a projection approach with,

$$\mathcal{K} = \mathcal{L} = W_1 \quad (6)$$

which will search the approximations to the solution in the high frequency subspace W_1 . As result the obtained error should be smooth in the sense of the Discrete Wavelet Transform.

In a matrix representation, denoting by $W = [w_1, \dots, w_m]$ an $n \times m$ matrix whose column-vectors form a basis of W_1 , a two-level smoothing method based on projection technique can be represented by the following algorithm:

Algorithm: Two-level smoothing method

1. Get the current approximation x_i
2. $r^h = b - Ax_i$
3. $r^{2h} = W^T r^h$
4. $e^{2h} = (W^T AW)^{-1} r^{2h}$
5. $x_{i+1} = x_i + We^{2h}$
6. Return x_{i+1}

The recursion of this two-level process produces a new multilevel smoothing method which has shown to be efficient in smoothing the high frequency error.

IV. DESCRIPTION OF THE TEST PROBLEM

In order to analyze the efficiency of the proposed smoother the method was applied to smoothing the error in the linear systems with 5041 rows and 56911 nonzero elements, issued from finite element solutions of the elliptic equation.

For analyzing the smoothing method behavior we assume that the exact solution \bar{x} is known,

$$\bar{x}_i = \sin(2i \times 200\pi / n) + \sin(2i \times 600\pi / n) + \sin(2i \times 1200\pi / n) \quad i=1, \dots, 5041, \text{ and we use it to supply the right hand side vector } b.$$

The error is analyzed after one, two and three smoother iterations. As in the WAMG context is supposed to there is no predefined geometric grids the error is analyzed in an algebraic sense, in which an error is smooth if it is slow to converge with respect to the smoothing method [2]. The classical Gauss-Seidel was used for comparison.

V. RESULTS

The error after one, two and three smoothing iterations are shown in Fig. 1. As a zero initial guess was adopted the initial error is equal to the exact solution \bar{x} .

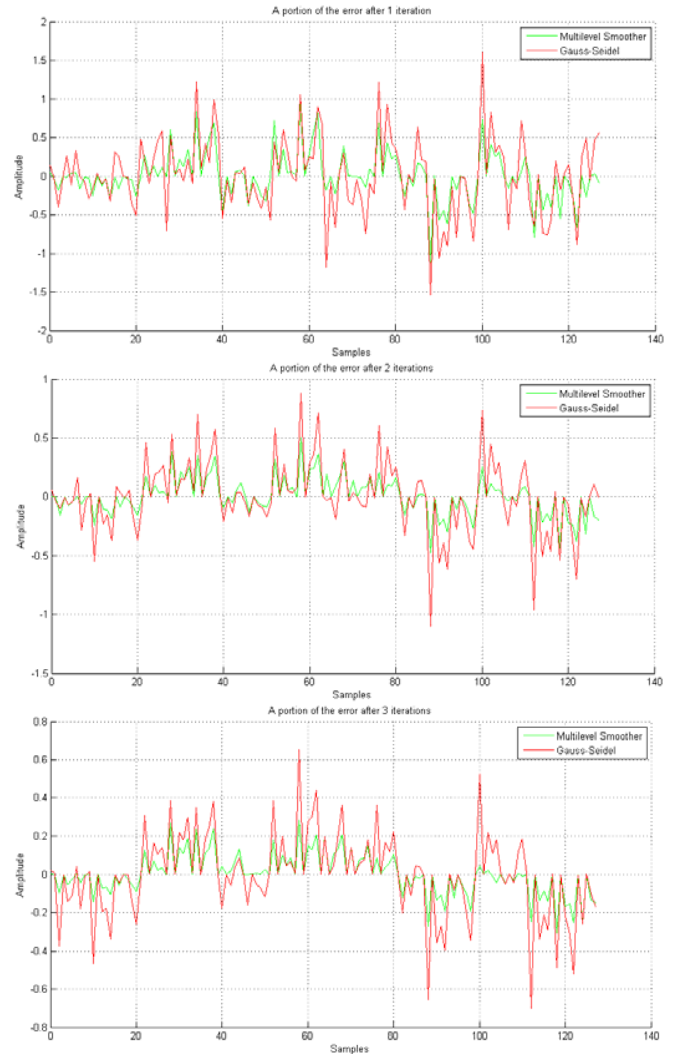

Fig. 1. A portion of the error after one (top), two (middle) and three smoothing iterations

VI. CONCLUSIONS

The proposed method seems to be very efficient in smoothing the high frequency error. The results in Fig. 1 show that the errors produced by the multilevel approach appear less oscillatory than those created by the classical Gauss-Seidel method in the three first iterations.

Abstract—This work shows the use of a hybrid numerical technique to fully analyze circularly symmetric omnidirectional antennas fed by coaxial horn. Mode Matching technique is employed to analyze the interior region of the coaxial horn. The Electric and Magnetic Field Equations (EFIE/HFIE) are employed to related the horn aperture fields and the induced currents on the reflectors and outer surfaces of the feed. Method of Moments (MoM) is used to solve the Field Integral Equations. The analysis yields the accurate prediction of the antenna radiation pattern and return loss at the feed connector. Due to the numerical efficiency of the scheme, the analysis can be associated with optimization methods to design the feed horn in order to minimize the antenna return loss.

I. INTRODUCTION

Last-mile broadband access has been considered as an alternative wireless technology to attend the growing interest on high-speed Internet access, as it can show lower costs, rapid deployment, and lower maintenance when compared with cable technologies. For the antenna in the hub station, compact single and dual reflector omnidirectional antennas have been considered [1,2]. The reflector surfaces are bodies of revolution obtained by rotating the generating curves about a symmetry axis, as illustrated in Figure 1 for dual reflector systems. The vertical polarization is obtained by employing a coaxial TEM feed horn, placed on the central opening of the main reflector, as indicated in Figure 1.

Figure 1 - Circular symmetric reflector surfaces.

Besides the control of the radiation pattern in the elevation plane and the reduction of the return loss at the feed input, the design of the reflector these omnidirectional antennas has to provide compact configurations to make them attractive.

However, the design for compact geometries implies on diminishing the distance between the elements and increasing the coupling effects between feed and reflectors. In order to estimate electrical performance of these compact omnidirectional antennas, a full-wave stepped-waveguide model and MoM/HFIE method are combined to analyse both the fields in the interior region and the contributions of the induced currents on the reflector, subreflector, and the exterior wall of the feed horn [3,4]. The interaction is accurately analysed by using the EFIE on the exterior surfaces of the coaxial horn. The equivalence currents principle is introduced to formulate the HFIE on the radiating aperture which combines the interior field transition problem with the exterior radiation. The procedure is similar to those described in [3,4] and applied in the electromagnetic analysis of conical feed horns excited by the TE₁₁ mode. Here, the procedure is adapted to include the reflectors and a coaxial feed horn excited by the TEM mode. As a consequence of the TEM mode excitation, only the TEM and TM modes are considered at the transition region, as the TE mode do not couple with the TEM excitation.. The application of the analysis technique yields the antenna radiation pattern as well as the antenna return loss at the end of the N-type connector. The numerical scheme is particularly efficient in the optimization of the antenna feed horn.

II. ANTENNA ANALYSIS

The analysis is separated in two parts. First, the horn is represented as series of stepped coaxial waveguides sections and Mode Matching is performed by rigorously enforcing the boundary conditions at each step. It results a scattering matrix [S] for the entire transition region:

$$\begin{bmatrix} b^C \\ b^A \end{bmatrix} = \begin{bmatrix} S_{11} & S_{12} \\ S_{21} & S_{22} \end{bmatrix} \begin{bmatrix} a^C \\ a^A \end{bmatrix} \quad (1)$$

The scattering matrix relates the reflected modes at the two extremes of the transition region. In (1), the vectors $[a^C]$ and $[a^A]$ contain the amplitudes of incident modes at the region 'C' and 'A', respectively, whereas the vectors $[b^C]$ and $[b^A]$ contain the amplitudes of reflected modes at the connector 'C' and aperture 'A', respectively (see Figure 2). The matrix [S] depends on the geometrical parameters and on the wavelength as well as the number of modes considered to ensure continuity of the electric and magnetic throughout the transition region. Part of the power of the modes reaching the

aperture, region A, is radiated into the space while the rest is reflected back into the horn.

Figure 2 - Horn represented as series of stepped coaxial waveguides sections

In the second part of the analysis scheme, to calculate the radiate fields and the amplitude of the reflected modes $[b^A]$, MoM is employed to solve the EFIE and MFIE, as described in [4]. To apply the above strategy, an equivalent to the actual electromagnetic problem is defined by replacing the feed radiating aperture by a sheet of perfect conductor with an equivalent magnetic current density

$$\vec{M}([a^A], [b^A]) = -\sum_{l=1}^{N_M} (a_l^A + b_l^A) (\hat{n} \times \vec{e}_l^A) \quad (2)$$

where \hat{n} is the unit vector normal to the aperture, \vec{e}_l^A is the electric field of the modes internal to the aperture and N_M is the number of modes used in the expansion. The magnetic current density \vec{M} radiates into the space and induces an electric surface current \vec{J} on the metallic wall of the equivalent problem, as described in Figure 3. These currents ensure the continuity of the tangential magnetic field across the aperture and zero tangential electric field on the metallic surface at the aperture and reflectors:

$$\begin{aligned} \hat{n} \times [\vec{E}^S(\vec{J}) + \vec{E}^S(\vec{M})] &= 0 \\ \hat{n} \times [\vec{H}^S(\vec{J}) + \vec{H}^S(\vec{M})] &= \hat{n} \times \vec{H}^A \end{aligned} \quad (3)$$

where \vec{E}^S and \vec{H}^S are electromagnetic field scattered by the currents \vec{M} and \vec{J} .

Figure 4 - Surface currents outside the feed horn

To apply the MoM solution, the current densities \vec{M} and \vec{J} are expanded by sub sectional roof-top patch modes \vec{P}_j^J and \vec{P}_k^M respectively. In this way, a conversion matrix is introduced to transform the roof-top patch modes into eigenmodes of the aperture fields. By testing the EFIE with \vec{P}_i^J and the HFIE with $\hat{n} \times \vec{e}_i^A$, it leads to two systems of matrix

equations. By combining them with (1), it is possible to define a relation between the vector $[a^C]$ and the vectors $[b^C]$, $[a^A]$ and $[b^A]$.

III. RESULTS

The analysis algorithm was applied to calculate the antenna radiation pattern and the antenna return loss of a dual reflector omnidirectional system. The antenna is generated by an axis displaced confocal conics of ADE type where the parameters are described in [2]. The antenna radiation pattern and return loss are depicted in Figures 4 and 5 (dotted line), respectively. In order to minimize the peak of the antenna return loss over the operation band (7.5-10.0 GHz), the analysis was embedded in an optimization scheme to shape the feed horn profile. The results after the shaping are show by the lull line in Figure 3, where can e observed a 2 dB reductio in the peak. As the shaping may modify the feed radiation pattern, Figure 4 shows the antenna radiation pattern after optimization (full line). Measured results will be available for comparison.

Mixed Fault Diagnosis of Squirrel Cage Induction Motor by Winding Function Approach

Daesuk Joo

Kyungil Woo

Pukyong National University, Yongdang-Dong, Nam-Gu, Busan, South Korea
cogging@pknu.ac.kr

Abstract — This paper studies on the mixed fault diagnosis of 3-phase squirrel cage induction motor with the broken rotor bar and rotor static eccentricity at steady state. The fault model is presented by the winding function approach and the coupled magnetic circuit theory. Fast Fourier transform of the stator current is used to diagnose faults. Individual and mixed fault characteristic caused by the broken rotor bar and the rotor static eccentricity are analyzed. From the individual fault analysis result it is shown that there are sidebands due to the broken rotor bar and the rotor static eccentricity respectively. Examination of the mixed fault analysis result shows that one fault characteristic made by the broken rotor bar does not affect the other fault characteristic cause by the rotor static eccentricity.

I. INTRODUCTION

The induction motor is the most important one because of its simplicity, low cost and ease of operation. Asymmetrical operation of the induction motor results in poor efficiency which eventually leads to the failure of the motor. The analysis of the induction motor is important for diagnose failures in the motor. The conventional d-q model of the induction motor is based on the assumption that distribution of the stator windings is sinusoidal. This implies that the harmonics of the winding distribution are neglected in the analysis of the motor. This model is not suitable for motor analysis and simulation under rotor eccentricity or the broken rotor bars. However a model based on the winding function theory is more convenient for such conditions.

This paper focuses on the mixed fault analysis of 3-phase squirrel cage induction motor with the rotor static eccentricity and the broken rotor bars at steady state. The fault model is presented by the winding function theory and the coupled magnetic circuit method. Self and mutual inductances for the induction motor are calculated by using the winding function theory. The stator current is obtained by means of the coupled magnetic circuit method and Park's transformation. Individual and mixed fault characteristic caused by the broken rotor bar and the rotor static eccentricity are analyzed. The analysis results are identified by the special frequency component obtained by the spectrum analysis of the stator current.

II. MODELING OF INDUCTION MACHINES

The voltage equations of m -phase induction machine with n rotor bars for the stator loops in vector-matrix form can be written as

$$V_s = R_s I_s + \frac{d\Lambda_s}{dt} \quad (1)$$

$$\Lambda_s = L_{ss} I_s + L_{sr} I_r \quad (2)$$

where V_s is the stator voltage matrix, R_s is an m dimensional diagonal matrix consisting of resistances of each stator phase, I_s is the stator current matrix, Λ_s is the stator flux linkage matrix, L_{ss} is the $(m \times m)$ matrix of stator inductance, L_{sr} is an $(m \times n)$ matrix comprised of the mutual inductances between the stator phases and the rotor loops, and I_r is the rotor current matrix.

The voltage equations for the rotor loops are

$$V_r = R_r I_r + \frac{d\Lambda_r}{dt} \quad (3)$$

$$\Lambda_r = L_{rs} I_s + L_{rr} I_r \quad (4)$$

where V_r is the rotor voltage matrix. In case of a cage rotor, the rotor loop voltages, $V_r = 0$. R_r is n symmetric matrix consisting of resistances of each rotor bar, Λ_r is the rotor flux linkage matrix, L_{rs} is a $(n \times m)$ matrix consisting of the mutual inductances between the rotor loops and the stator phases, and L_{rr} is $(n \times n)$ matrix of rotor inductances.

III. CALCULATION OF INDUCTANCES

The winding function is defined by

$$N(\phi) = n(\phi) - \frac{1}{2\pi} \int_0^{2\pi} n(\phi) d\phi \quad (5)$$

The function $n(\phi)$ is called the turns function. The second term is clearly the average value of the turns function.

Fig. 1 shows an important example of continuous winding distribution and such a winding is said to be uniformly distributed. Here, the N_t turns are assumed to be uniformly distributed over β radians. The function $n(\phi)$ is

$$n(\phi) = \frac{N_t}{\beta} \phi \quad (6)$$

where $\phi_1 - \frac{\beta}{2} \leq \phi \leq \phi_1 + \frac{\beta}{2}$. Hence, $n(\phi)$ changes linearly over this region. The other quantity changes same manner. The turns function $n(\phi)$ remains fixed at $N_t/2$ until reaches ϕ_2 at which point negative turns start being enclosed.

According to winding function theory, the calculation of winding inductance between any two windings "A" and "B" in any electric machine can be computed by

$$L_{AB}(\theta_r) = \mu_0 \ell \int_0^{2\pi} r(\theta_r, \phi) \frac{N_A(\theta_r, \phi) \cdot N_B(\theta_r, \phi)}{g_e(\theta_r, \phi)} d\phi \quad (7)$$

where θ_r is the angular position of the rotor with respect to some stator reference, ϕ is a particular position along the stator inner surface, g_e is effective air-gap function, ℓ is the length of the stack, and r is the average radius of the air-gap.

The term $N_A(\theta_r, \phi)$ and $N_B(\theta_r, \phi)$ are called the winding function.

Fig. 1. Winding function, $n(\phi)$ changes linearly over the slot

Fig. 2. Winding function of phase "a" not considering effect of slot width

Fig. 3. Winding function of phase "a" considering effect of slot width

Fig. 2 shows the winding function of the phase "a" not considering the slot width of the induction motor. In this figure, it is shown that the distribution of current over a slot pitch has been neglected in the computation of the winding function. Fig. 3 shows the winding function of phase "a" considering the slot width. As the width of the slot increases, the winding function changes linearly across the slot.

The specific machine studied in this paper is a three-phase, 1-hp, 60-Hz, 4-pole, 380-V induction motor. The motor has 36 stator slots and 44 rotor bars with one coils per stator phase.

IV. SIMULATION RESULTS

Motor current signature analysis is a noninvasive, on-line monitoring technique for the diagnosis of problems in induction motors.

Fig. 4 is a fast Fourier transform(FFT) zoom current spectra for 3 broken rotor bars. In Fig. 4, Fig. 5 and Fig. 6 a solid line and a dashed line represent a faulty motor and a healthy motor respectively. The motor was operating at full-load slip of 0.05, and the predicted twice slip frequency sideband " $(1-2s)f$ " for a supply frequency of 60 Hz are ± 6 Hz. As in Fig. 4 there is sideband at -6 Hz around the supply frequency by broken rotor bar. This is referred to as a twice slip frequency due to broken rotor bars.

Fig. 5 is a FFT zoom current spectra for 50% rotor static eccentricity. In this figure there is only a frequency components " $\pm f_{ec}$ " which are a function of rotor eccentricity.

Fig. 6 is a FFT zoom current spectra for 3 broken rotor bars and 50% rotor static eccentricity. In this figure there are

sideband and frequency component together. From these result, we know that one fault characteristic made by the broken rotor bars does not affect the other fault characteristic cause by the rotor static eccentricity.

Fig. 4. FFT zoom stator current spectra for 3 broken rotor bars.

Fig. 5. FFT zoom stator spectra for 50% rotor static eccentricity.

Fig. 6. FFT zoom stator spectra for 3 broken rotor bars and 50% rotor static eccentricity.

Simple Parallelization Strategy for Mesh Refinement Algorithms

Thiago E. A. Macêdo, Adriano C. Lisboa, and Renato C. Mesquita
 Department of Electrical Engineering, Universidade Federal de Minas Gerais
 Av. Antônio Carlos 6627, 31270-901, Brazil
 th.emmanuel@gmail.com, adriano@cpdee.ufmg.br

Abstract—This paper presents a simple implementation strategy for parallelizing mesh refinement algorithms that, besides performance improvements, requires only a few changes in the refinement algorithm. Furthermore, its fundamental structure allows a generic implementation for reusable code. It is applied and further analyzed in the instance of a Delaunay refinement algorithm for curved complexes.

I. INTRODUCTION

The clock frequency of processors seems to have reached an upper bound. This achievement has put parallelization as an ever so important way to speed up computational applications. A new programming paradigm has come up: algorithms must allow parallel processing.

Parallelizing an algorithm may require great changes, or even be impractical. A parallelization strategy that is less intrusive in the sequential algorithm may be considered preferable. Common strategies to parallelize a mesh refinement algorithm include a fine grain parallel cavity expansion, a medium grain parallel expansion of multiple cavities, and a coarse grain parallel refinement of geometry subregions [1]. A fine granularity must consider specific algorithm behavior, and it is justified only when the cavity inclusion predicate is computationally expensive. At coarser granularity levels, it is possible to develop strategies that are less dependent on a specific refinement algorithm. This paper proposes a simple medium grain implementation pattern.

The proposed strategy is used to parallelize a Delaunay refinement algorithm for curved complexes [2]. Despite the unique cavity expansion and remeshing of this refinement algorithm, the parallelization strategy can be implemented seamlessly.

II. IMPLEMENTATION PATTERN

The implementation pattern considers a refinement algorithm that takes an element from the refinement queue, marks up extra elements to be remeshed (cavity expansion algorithm), remeshes the cavity, and finally updates the refinement queue. The refinement queue contains full identification of elements that must be refined according to some refinement criteria. The parallelization strategy requires the following interventions in the mesh generation algorithm:

- the refinement algorithm is embedded in a thread;

This work was supported by FAPEMIG under grant 13180, Brazil.

- the refinement queue becomes a global refinement queue whose access is protected;
- the cavity expansion algorithm must detect and treat cavity conflicts;
- the selection of an element to refine is only taken from the global refinement queue when the thread's local refinement queue is empty.

Two extra data structures are used in the implementation pattern. The first one is a local refinement queue for each thread with elements that must exclusively be refined by its thread. The second one is a localizing vector where threads mark up elements of their cavity, and query to detect conflicts. The localizing vector is indexed by element identification numbers, and contains the respective owner thread. The following subsections describes the behavior of the implementation pattern. Further details will be given in the final paper.

A. Non-conflicting Cavity Expansion

Each thread selects an element to refine and start expanding its cavity from it (see Fig. 1). A thread marks up an element with their identification number in the localizing vector as soon as the cavity membership is verified. After completing its cavity expansion, a thread remeshes the cavity and updates the global refinement queue: cavity elements are removed from the queue, and new elements that do not satisfy the refinement criteria are inserted into the queue. Before selecting another element to refine, the thread unmarks its cavity elements in the localizing vector and clears its cavity.

Fig. 1. Threads 0 and 1 concurrently expand their cavities marking up member elements in the localizing vector. The cavity expansion starts from the bold border element. They are non-conflicting since no neighbor of one cavity belongs to the other cavity.

B. Handling Conflicts

The cavity expansion goes through neighbor elements. Before testing the membership of a neighbor element, a thread

checks, in the localizing vector, whether the element has already been marked up by another thread. If so, a conflict is confirmed. The conflicted thread then unmarks all its cavity elements and pushes the start cavity element identification into the local refinement queue of the conflicting thread, as shown in Fig. 2. Using local refinement queues avoids another conflict with the same thread when starting from the same element. The conflicted thread takes another element to refine, and the conflicting thread continues its cavity expansion.

Fig. 2. Threads 0 and 1 concurrently expand their cavities marking up member elements in the localizing vector (left). The cavity expansion starts from the bold border element. Thread 0 detects a conflict with thread 1, then unmarks all elements of its cavity and pushes its start element identification into thread 1 local refinement queue (right). Thread 1 continues its cavity expansion.

Each thread checks, in the localizing vector, whether the start element of its cavity, which is taken from a refinement queue, has already been marked up by another thread. If so, a conflict is confirmed. In this case, the thread can simply discard the refinement element, since it will be removed by the conflicting thread after reshaping its cavity. The conflicted thread takes another element to refine, and the conflicting thread continues its cavity expansion.

C. Synchronization

To avoid inconsistencies with multiple threads changing, at the same time, the global refinement queue or the localizing vector, a binary semaphore for each data structure guarantees exclusive access. The synchronization on the global refinement queue is trivial: a thread claims the exclusive access to the queue through its respective semaphore, and releases it after changing it. The synchronization on the localizing vector deserves some remarks.

When a thread detects a conflict, it owns the exclusive access to the localizing vector. At this time, it unmarks all elements of its cavity, and also pushes the start element into the conflicting thread local refinement queue, before releasing the access. The conflicting thread would have to own the semaphore to detect a conflict with the same thread, so that it always continues expanding its cavity without realizing what happened. Furthermore, the conflicting thread only access its local refinement queue after unmarking elements of its cavity. That is why local refinement queues do not need their own semaphores to guarantee exclusive access.

D. Preventing Conflicts

The local refinement queues were introduced to handle conflicts. However, delegating elements to be refined by a specific

thread can be used to prevent conflicts in a more general sense. For instance, if it is possible to define disconnected refinement locations for each thread, then elements to be refined from one location can be pushed into the local refinement queue of a specific thread. Notice that it does not matter the strategy used to assign an element to a thread, and that intermediate strategies are also possible, where unassigned elements are obviously pushed into the global refinement queue. However, if a thread becomes allowed to assign an element to another one, the exclusive access to local refinement queues must be guaranteed. Preventing conflicts imbues features of a coarse grain parallelization.

III. INSTANTIATION

This section describes the instantiation of the parallelization strategy for a Delaunay refinement algorithm for curved geometries.

The cavity expansion comes from an extension of the Bowyer-Watson algorithm, which may contain simplices of different dimensions. Fortunately, the parallelization strategy does not depend on expansion rules. It only interferes where new cavity simplices are identified. Notice that neighbor simplices can also be lower dimensional.

The refinement queues in Delaunay refinement algorithms are usually actually priority queues, in order to reduce the output mesh cardinality. However, only the exclusive access guaranteed by a semaphore is required by the parallelization strategy, which is independent on how elements to be refined are removed/pushed from/into the queues.

It is possible to detect conflicts a priori and to efficiently determine non-conflicting sets of elements to be refined for Delaunay refinement algorithms [3], [4]. Although, they have not been tested on curved geometry constraints.

Timings and practical behavior of the parallel Delaunay refinement algorithm for curved geometries, with and without strategies for preventing conflicts, will be shown in the final paper. Further details of the instantiation will also be included.

IV. CONCLUSION

This paper presents a simple and general parallelization strategy for mesh refinement algorithms. The parallelization is typically medium grain, but allows to introduce features of coarse grain ones by preventing conflicts.

Abstract — When the magnetic field analyses of architectural components, in which magnetic materials are distributed complicatedly, are carried out, huge efforts toward the modelling are required. In this paper, a homogeneous technique is applied to the magnetic field analysis of the architectural components in order to reduce the effort and computer costs. The suitable region, where the homogeneous technique is applied, is investigated in the analysis of magnetic disturbance of a building model. Moreover, the effectiveness is shown in the analysis of the shielding performance of an open-type magnetically shielded room for MRI. It is shown that the homogeneous technique should be applied to not only the magnetic materials with complicated structure but also the air region surrounding them.

I. INTRODUCTION

For example, when the magnetic disturbance due to buildings is calculated by the magnetic field analysis with the finite element method (FEM) [1, 2], huge efforts toward modelling complicatedly distributed magnetic materials in buildings are required. Moreover, the huge memory requirements and CPU time are also required due to large number of the finite elements. Recently, the homogeneous technique, in which the complicatedly distributed magnetic materials are replaced to the homogeneous body with the equivalent permeability, was proposed [3]. In this technique, the equivalent permeability is determined so that the energy of homogeneous body is equal to be that in the region of distributed magnetic materials.

In this paper, the technique is applied to the magnetic field analysis of architectural components, in which magnetic materials are distributed complicatedly. First, the suitable region, where the homogeneous technique is applied, is investigated in the calculation of the magnetic disturbance of a simple building model. Next, the technique is applied to the analysis of the shielding performance of an open-type magnetically shielded room (MSR) [4] with square cylinders made of magnetic materials for a magnetic resonance imaging (MRI) in order to investigate the effectiveness.

II. HOMOGENEOUS TECHNIQUE

The homogeneous technique [3] using a simple building model composed of only iron bars shown in Fig. 1 used in this paper is described. In the homogeneous technique, the iron bars distributed complicatedly in the building are replaced to the homogeneous body with equivalent permeability μ_h . The subscript h denotes the value for the homogeneous model. The equivalent permeability μ_h is determined by using the cell model which is a part of building as shown in Fig. 2. For example, the x -component μ_{hx} of μ_h is determined so that the energy of the homogeneous body is equal to be that of the cell model obtained by FEM as the following equation, in the case

the same average flux density B_x is applied in the x -direction for both models;

$$\sum_{ie=1}^{ne} \frac{B^{(ie)^2} \cdot V^{(ie)}}{2 \mu^{(ie)}} = \frac{B_x^2 \cdot V_h}{2 \mu_{hx}} \quad (1)$$

where left and right hand side correspond to energies of cell and homogeneous models, respectively. The superscript ie denotes the value for each element in cell model. ne and V are the number of elements and the volume, respectively.

Fig. 1. A simple building model (1/8 region).

Fig. 2. Homogeneous technique.

III. ANALYSIS OF MAGNETIC DISTURBANCE DUE TO BUILDING

The magnetic disturbance due to the simple building model shown in Fig. 1, when the uniform flux density $B_{ox} = 1 \mu\text{T}$ is applied in the x -direction, is analyzed by the homogeneous techniques with the following treatments:

Method 1: One homogeneous model determined by the cell model shown in Fig. 2 (a) is applied to the whole region of buildings.

Method 2: The homogeneous model determined by the different cell model is applied on the side of building because the shape configuration of cell model shown in Fig. 2(a) is different from that on the side of the real model.

Method 3: The homogeneous model determined by the cell model adding that of Method 2 to the air region is applied on the side of building.

Fig. 3 shows the distributions of the magnetic disturbances ΔB_x ($\Delta B_x = B_{cx} - B_{ox}$, B_{cx} : the flux density obtained from calculation), obtained from the calculation using the real model and the several homogeneous techniques, on the line s-t which exists on the position between iron bars and the line s'-t' which exists at the position on the extension line of the iron bar, shown in Fig. 1. In the homogeneous techniques, the ΔB_x 's on the lines s-t and s'-t' are almost the same, whereas the ΔB_x on the line s'-t' becomes larger than that on the line s-t in the real model because the flux concentrates near the iron bar. The results obtained from the homogeneous techniques should be close to the average values of those on lines s-t and s'-t' in the real model. However, the results obtained from Methods 1 and 2 are close to that on the line s'-t' in the real model. This is because the flux distribution in the air region near the building becomes uniform and the increase of the energy due to the concentration of the flux density near the iron bar can not be taking into account in Methods 1 and 2. On the other hand, the result obtained from Method 3 becomes appropriate. As a conclusion, the homogeneous technique should be applied to not only the magnetic materials but also the air region surrounding them.

Fig. 3. Distributions of magnetic disturbance ΔB_x on lines s-t and s'-t'.

IV. ANALYSIS OF OPEN TYPE OF MSR FOR MRI

The homogeneous technique is also applied to the analysis of the shielding performance for an open-type MSR with the square cylinders made of magnetic material for MRI [4] shown in Fig. 4. The enlarged view of the square cylinder is shown in Fig. 5. The square cylinder is divided into two parts by the large slit in order to obtain the higher shielding performance.

Two homogeneous techniques are examined: one is that each magnetic cylinder is replaced to the homogeneous body (Method A). The other is that both magnetic cylinders including the slit are replaced to the homogeneous body (Method B).

Fig. 6 shows the distributions of the leakage flux densities on the line L shown in Fig. 4, obtained from the real model and the homogeneous techniques. The flux distribution

obtained from Method A is much different from that of the real model. This is because the increase of the energy due to the non-uniformity of the flux distribution in the slit can not be represented in Method A. The result obtained from Method B is in good agreement with that of the real model.

The homogeneous technique is effective for the magnetic field analyses of architectural components when the cell model including air region near the magnetic material is used.

Fig. 4. Open-type MSR and MRI model (1/4 region).

Abstract—An adaptive mesh for the finite element method is problem dependent and, hence, unlikely to be defined a priori in complex problems. The usual strategy to reach it is starting with a coarse mesh and then solving the problem to define where the mesh must be refined according to an error estimation. This process goes on iteratively until a given accuracy is met. Under this procedure, pre-discretization of curved parts of the geometry clearly seems to be inefficient. This paper highlights improvements and challenges when a finite element method is coupled with a Delaunay refinement algorithm for curved geometries.

I. INTRODUCTION

DELAUNAY refinement algorithms were first developed for meshing piecewise linear complexes [1], [2], [3], [4], and they were mainly motivated by the finite element method. They already enjoy good theoretical guarantees in quality, size and grading for arbitrary bidimensional piecewise linear complexes. Unfortunately, for higher dimensional inputs, they still lack meaningful theoretical guarantees, specially when considering small input dihedral angles. Fortunately, Delaunay refinement algorithms perform better in practice than in theory.

The Ruppert's Delaunay refinement algorithm has been extended [5], [6] to deal with curved bidimensional geometries. This extension carries out all theoretical guarantees of Ruppert's algorithm, except size optimality that must be further analyzed for curved geometries. Recently, Cheng et al. [7], [8] have proposed a new Delaunay refinement algorithm to cope with curved tridimensional geometries, based on a Delaunay criterion over manifolds [3], [9]. Despite its ability to mesh a large class of geometries, its queries on curved surfaces are very complex and time consuming. This paper is based on a simpler and faster, though less general, Delaunay refinement algorithm for curved geometries [10].

II. DELAUNAY REFINEMENT FOR CURVED COMPLEXES

The Delaunay refinement algorithm for curved complexes used in this paper [10] extends the fundamental ideas of Ruppert refinement and Bowyer-Watson incremental insertion algorithms. Every strongly Delaunay simplex is part of a Delaunay simplicial complex. Hence, pre-defined circumscribed balls of conforming simplices do not enclose any other vertex throughout the refinement. If any of them is encroached by

the insertion point, the insertion point is projected on the respective piece, just like as in Ruppert algorithm. The new simplices created by connecting the new vertex to the cavity boundary, just like as in Bowyer-Watson algorithm, will have empty circumscribed balls as long as the cavity simplices are all those encroached by the projected insertion point. However, for curved pieces, the empty circumscribed balls may not be the pre-defined ones, so that some vertices may have to be removed to ensure that. The creation of the initial mesh is also changed. Homeomorphic simplices are created from lower to higher dimensions. Lower dimensional simplices are guaranteed, by refinement until they become strongly Delaunay, to be part of connected higher dimensional meshes. In this process, an input constraint piece only defines its own parametric space. All boundary or constraint information comes from lower dimensional connected simplices.

III. FINITE ELEMENT METHOD ON CURVED GEOMETRIES

Throughout this section, the improvements and challenges of coupling finite element method and Delaunay refinement for curved geometries will be highlighted in a simple electromagnetic analysis of a micromotor [11], whose geometry is shown in Fig. 1.

Fig. 1. Point and line constraints of the micromotor geometry.

The first and most notable improvement when using Delaunay refinement for curved geometries is the efficient use of coarse meshes, as the one shown in Fig. 2, and, naturally, fine meshes. An adaptive strategy could start with such a

This work was supported by FAPEMIG under grant 13180, Brazil.

coarse mesh and then refine it wherever needed, without recreating the mesh after re-discretizing curves and surfaces as an ordinary Delaunay refinement algorithm for piecewise linear complexes would do.

Fig. 2. Coarse mesh for the micromotor (dielectric board and air meshes are shown separately to ease visualization).

When the Delaunay refinement algorithm can handle curved geometries, it becomes clear what is mesh generation, and what is modeling, because no intermediate steps are needed to create linear approximations of curved pieces. For instance, the mesh generator itself truly refined the coarse mesh, shown in Fig. 2, into a finer mesh with better geometry representation, as shown in Fig. 3. During this refinement, new vertices were inserted into curves and surfaces as needed.

Fig. 3. Refinement of the coarse mesh for the micromotor (dielectric board and air meshes are shown separately to ease visualization).

The refinement timing difference, between the Delaunay refinement for curved geometries used in this paper and one for piecewise linear complexes, comes almost exclusively from the computation of the point on piece that is equidistant to the vertices of a conforming simplex. Whenever this computation is fast (e.g. pieces are spheres, cylinders), or vertices are rarely

inserted on curved pieces (e.g. uniform refinement), the timing difference is negligible.

Unfortunately, the Delaunay refinement for curved geometries used in this paper requires strongly Delaunay simplices conforming the input pieces, unique point on piece that is equidistant to the vertices of a conforming simplex, and that each curved piece is entirely contained in the circumscribed balls of its conforming simplices. These requirements must be satisfied throughout the refinement since the initial mesh. In order to meet them, either artificial features could be inserted into the input geometry, or more complex approaches [7], [8] could be used to generate the initial mesh. Both result in a higher computation cost and in a finer initial mesh.

Another challenging open problem in Delaunay refinement for tri or higher dimensional curved geometries, is the treatment of small input dihedral angles. Slivers can still be removed in practice with a refinement criterion on minimum (typically 15°) or maximum (typically 165°) dihedral angle, although without any theoretical guarantee.

More details about the tetrahedral mesh quality and grading, and refinement timing, will be given in the final paper, as well as electromagnetic solutions of the micromotor problem.

IV. CONCLUSION

The Delaunay refinement for curved geometries has shown to be very competitive when some requirements on the initial mesh are verified. However, it is still a great challenge to cope with small input dihedral angles and with arbitrarily complex curved geometries. Its application to finite element method seems to be rather promising, specially as a key feature in adaptive and efficient mesh generation.

Abstract—Finite element simulation can be directly affected by mesh quality. The accuracy of finite element calculations is dependent upon of the mesh quality. Previously, we have introduced a novel approach to the construction of high-quality, isotropic tetrahedral meshes from segmented medical imaging data. This article proposes an experimental evaluation of the impact of our tetrahedral meshes on electromagnetic and thermal simulations with finite elements.

I. INTRODUCTION

In this paper, we show the impact of the geometrical modelling on the numerical simulation of electromagnetic and thermic phenomena in the human body exposed to radiofrequency field. We present the electromagnetic [1] and thermal Finite Element Models (FEM). The time harmonic formulation is directly written in term of total electric field \mathbf{E} (1). It is obtained by applying the Galerkin method to the wave equation. Coupling to a first order Engquist-Majda Absorbing Boundary Conditions (ABC) taking into account the open boundary:

$$-\int_{\mathcal{V}} \nabla W \times \nabla \times \mathbf{E} \cdot d\mathbf{v} - \int_{\mathcal{V}} W k_0^2 \varepsilon_t^* \mathbf{E} \cdot d\mathbf{v} + \int_{\mathcal{V}} W g_{ABC}(\mathbf{E}) \cdot d\mathbf{s} = -j\omega\mu_0 \int_{\mathcal{T}} \mathbf{J}_e \cdot d\mathbf{v} \quad (1)$$

with $g_{ABC}(\mathbf{E}) = jk_0 \mathbf{E}_t$, where \mathbf{E}_t is the tangential field, k_0 is the propagation constant of the electromagnetic field, W the weight function, ε_t^* the tissue complex permittivity values and \mathbf{J}_e the electric current density. Space discretization is performed using incomplete first order edge elements.

Temperature calculation is based on the solution of the instationary Pennes bio-heat equation (2) with \mathbf{E} as source term.

$$\rho C \frac{\delta T}{\delta t} = \nabla \cdot (k \nabla T) - C_b \omega_b (T - T_a) + \frac{1}{2} \sigma |\mathbf{E}|^2 + Q_m \quad (2)$$

with ρ , the tissue density, C the specific heat of the tissue, k the thermal conductivity, ω_b the blood flow, C_b the specific heat of the blood, T_a the temperature of the arteries, σ the electrical conductivity and Q_m the amount of heat produced by metabolism. Thermal modelling is carried out with classic nodal FEM. We use conjugate gradient solver with various preconditioning techniques: diagonal, SSOR and Gauss.

II. TETRAHEDRAL MESHES GENERATION

A. State of the Art

There are basically three approaches for tetrahedral meshing: greedy approaches, Delaunay-based methods and hierar-

Fig. 1. Meshing process: the segmented "Visible Human" Male Dataset (a), tridimensional discrete set (b), tetrahedral meshing (c) of (b) with our approach.

chical decomposition approaches. The greedy approaches start from a boundary and move a front from the boundary towards the empty space within the domain. Delaunay approaches generate triangulations using Delaunay criteria. Unfortunately, in 3D and higher dimensions, the Delaunay property alone is insufficient to guarantee well-shaped elements. Finally, hierarchical decomposition approaches recursively subdivide the cube containing the geometric model until the desired resolution is reached. Elements that lie outside the meshing domain, and the elements inside the domain are split into tetrahedra. Most of the previously cited approaches share a common point: they take an input surface and enrich it with new vertices to generate the tetrahedra. This can be problematic around the objects boundaries, as the vertices of the input surface can be an important constraint for the resulting mesh, and induce tetrahedra with bad aspect ratio.

B. The Proposed Approach

We have proposed a novel tetrahedral mesh generation algorithm in [2]. Our algorithm directly processes voxels of segmented volumes coming from Tomographic Scanners or Magnetic Resonance Images (MRI) (Fig. 1). No polygonal input surface is needed. Our approach provides a robust mesh design tool for discrete data that can accommodate requirements on the final budget of vertices and on the mesh gradation, for arbitrary domain complexity.

C. Tetrahedra Quality Measure

In our case, the ideal isotropic tetrahedral element is the equilateral tetrahedron. An important parameter in this study

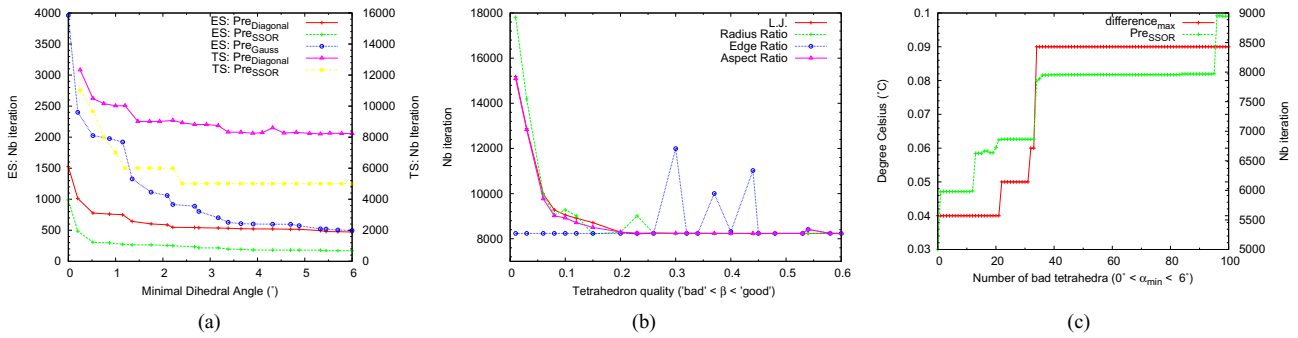

Fig. 2. Effect of the tetrahedral quality: (a) on the electromagnetic and thermal simulations, respectively ES and TS, for several preconditioning techniques; (b) on the thermal simulation for several quality criteria; (c) on the difference between the thermal problem simulation and the analytical solution.

is the choice of the quality criterion. Several quality measures are available in the literature. In this paper, we use five quality criteria : The first criterion is the Minimal Dihedral Angle (MDA) α_{min} of a tetrahedron, which has a maximal value of $\arccos(1/3) = 70,5^\circ$, for a regular tetrahedron. Table I tabulates several quality measures for tetrahedral elements quality evaluation.

Criteria	MDA	L.J.	Radius ratio	Edge ratio	Aspect ratio
Formula	α_{min}	$\frac{12\sqrt[3]{9V^2}}{\sum l_{i,j}^2}$	$3\frac{r_{in}}{r_{out}}$	$\frac{l_{min}}{l_{max}}$	$\frac{12}{\sqrt{6}}\frac{3V}{l_{max}\sum A_i}$

TABLE I
QUALITY MEASUREMENT FACTORS

In this Table I, l is the length of the edges, A the areas of the faces of a tetrahedron, r_{in} the radius of its inscribed sphere, r_{out} the radius of its circumscribed sphere and V its volume. The criterion L.J. is cited in [3]. The criteria are normalized between 0 and 1 (excepted MDA), where 0 denotes a bad element and 1 an equilateral tetrahedron.

III. EFFECT OF THE TETRAHEDRAL QUALITY

A. Theoretical Impact

The quality of geometric discretization is crucial for the effectiveness of these applications [4]. Coarse discretization and poor shape of the elements can introduce incorrect results and numerical errors. Degenerate elements with small volumes and small dihedral angles may lead to large local errors of the solution. Small dihedral angles can have a negative effect on the condition number of the stiffness matrix and large dihedral angles cause large interpolation errors. The worst impact results in an unsolvable system of equations.

B. Numerical Impact

The calculations are realized on a spherical geometry generated by our approach. The minimal dihedral angle is of 16.31° . Figure 2.a shows the impact of the addition of a single bad tetrahedron on the electromagnetic (incident wave at 433 MHz) and thermal (temporal model for convection transfer heat) simulations for several preconditioning techniques. Figure 2.b presents the impact of the addition of a bad tetrahedron on the thermal simulation for several quality criteria. Figure 2.c shows the difference between the thermal problem simulation and the analytical solution [5] when several bad elements are

Fig. 3. Influence of the poor quality elements on the condition number for the thermal simulation.

added. The condition number for a positive definite matrix is defined by the ratio of the maximum eigenvalue to the minimum eigenvalue. Figure 3 shows the condition number and the number of iterations are highly correlated.

IV. DISCUSSION AND CONCLUSIONS

Certain geometrical quality measures are not adapted to evaluate the shape of an element. As an example, a bad-quality tetrahedron has a too great radius-edge ratio and a sliver has a good radius-edge ratio but nearly zero volume (slivers). The radius-edge ratio is not a proper measure for slivers. We have shown in a practical way the impact of the quality of tetrahedral meshes on electromagnetic and thermal finite element models. Our results clearly show that the FEM accuracy can be directly affected by mesh quality. Experimental findings suggest dramatic run time reductions using our high-quality mesher. According to this study, we chose the criteria based on the MDA and cited in [3] for the evaluation and the optimization of our mesh generation algorithm.

Parallel Computing of Magnetic Field for Rotating Machines on PC Cluster

Tomohito Nakano¹, Yoshihiro Kawase¹ and Tadashi Yamaguchi¹

¹Department of Information Science, Gifu University, Gifu 501-1193, Japan E-mail: nakan@fem.info.gifu-u.ac.jp

Abstract—We have developed a parallel computation method of the magnetic field for rotating machines by using the 3-D FEM with edge elements, which can run on PC clusters. In the developed method, the block ICCG method is adopted as the linear solver. The performance of the developed method running on a PC cluster is quantitatively clarified.

I. INTRODUCTION

From the viewpoint of the fields of the industrial applications, the parallel computing of the magnetic field for practical rotating machines on a reasonable PC cluster is desired.

We have developed a parallel computing method of the three-dimensional finite element method (3-D FEM) with the edge elements for PC clusters in which the block ICCG method is adopted as the linear solver [1].

In this paper, we describe the outline of developed method and the performance of the developed method running on a PC cluster.

II. DOMAIN DECOMPOSITION METHOD

In the parallel computing, the domain decomposition method (DDM) is adopted. Using the DDM, the analyzed domain is divided into multiple subdomains, and the subdomains are calculated in parallel while doing appropriate data communications between those subdomains.

Fig. 1 illustrates the DDM for FEM with edge elements. This figure shows that one domain is divided in two subdomains.

The number of edges in each subdomain is almost the same to split the CPU power into subdomains evenly. The divided domain has the overlap elements. By using the overlap elements, the data communication between subdomains becomes unnecessary when the element coefficient matrix is created.

The overlap element has two kinds of edges, one is called ‘boundary edges’ and another is called ‘external edges’. In Fig. 1 (b), the boundary edges are drawn as the bold lines (edge 7 in *Subomain I*, and edges 8 and 9 in *Subdomain II*), and the external edges are drawn as the dotted lines (edges 8 and 9 in *Subdomain I*, and edge 7 in *Subdomain II*). The boundary edge in one subdomain is the external edge in another subdomain.

III. BLOCK ICCG METHOD

In the ICCG method, the calculation in the forward and backward substitutions occupies around 50% of the total computing time. Therefore, these calculations should be parallelized in order to compute efficiently.

The block ICCG method is one of the parallel processing techniques of the ICCG method [2]. Fig. 2 shows the coefficient matrix and vectors of Fig. 1 in the block ICCG method. The external edges in each subdomain are ignored in calculation of the IC decomposition in the block ICCG method to calculate the forward and backward substitutions in parallel.

Fig. 3 shows the algorithm of block ICCG method. The upper subscripts k is the iteration count, the lower subscripts n is the subdomain number, and N is the number of subdomains. The communications are required in the calculation of inner product in line (a) and in the matrix-vector product in line (b). Other calculations in the method can be independently carried out in each subdomain.

IV. NUMERICAL RESULTS AND DISCUSSION

A. Fundamental Equation of Magnetic Field

The fundamental equation of magnetic field is given by the magnetic vector potential \mathbf{A} as follows:

$$\text{rot}(\nu \text{rot} \mathbf{A}) = \nu_0 \text{rot} \mathbf{M} + \mathbf{J}_0 + \mathbf{J}_e \quad (1)$$

where ν is the reluctivity, ν_0 is the reluctivity of the vacuum, \mathbf{M} is the magnetization of permanent magnet, \mathbf{J}_0 is the exciting current density, \mathbf{J}_e is the eddy current density.

B. System configuration of PC cluster

The PC cluster used in this study is composed of 16 PCs that have an Intel Core 2 Duo processor (2.66GHz) and 4GB memory. Each PC is connected by the 1 gigabit local area network. Because the PC cluster system has the distributed memory, not only speed-up but also a very large-scale analysis can be performed.

C. Analyzed Model

Fig. 4 shows the analyzed model of a motor for Blu-ray disc drive. In order to understand the analyzed model easily, the motor case is shown in only 1/3 region. The number of the unknown variables of this model is 19,430,514.

In the full paper, other rotating machines are also studied.

D. Performance of Proposed Method

Fig. 5 shows the contour of flux density. The contour agrees completely with that calculated on a single PC.

Table I shows the performance evaluation of the developed method. The performance of a single PC, which has the Intel Xeon processor (3.0GHz) and 16 GB memory, is also shown in order to evaluate the influence of the number of CPU on the iterations of CG. The elapsed time is evaluated in

one time step. This calculation requires about 144 hours on a single PC. However, using the PC cluster, the calculation has been done in about 9 hours. The increase of CG iterations is due to the ignored non-zero entries in the block ICCG. It is expected that the convergence of CG becomes worse as the number of CPU becomes large. The convergence of Newton-Raphson method doesn't depend on the number of CPU.

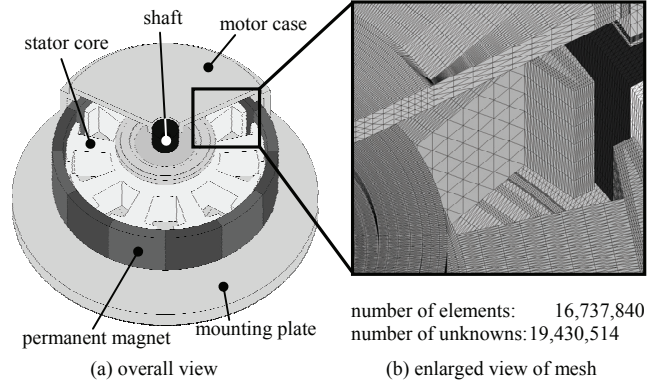

Fig. 4. Analyzed model

Fig. 5. Contour of flux density

TABLE I
PERFORMANCE EVALUATION OF THE DEVELOPED METHOD

number of CPU	elapsed time (hours)	iterations of CG	iterations of Newton-Raphson
1 ^{*1}	144.1	111,279	21
16 ^{*2}	8.8	144,114	21

^{*1}Computer used Intel Xeon (3.00GHz) PC.

^{*2}Computer used Intel Core2 Duo (2.66GHz) PC.

V. CONCLUSION

We have developed a parallel computation method of the magnetic field for rotating machines by using the 3-D FEM with edge elements, which can run on PC clusters. The very large-scale analysis can be performed by the PC cluster that has a distributed memory.

In the full paper, other practical rotating machines are also computed on the PC cluster system.

Abstract—A local error estimator used for *a posteriori* h-type finite element mesh refinement is presented in eddy current testing with separated T-R probes. The proposed technique combines the solutions obtained by feeding alternatively the source and the measurer. The obtained results are compared to the Ligurian approach.

I. INTRODUCTION

EDDY current testing (ECT) is widely used to check the integrity of conducting parts. The finite element method (FEM) is well fitted to the modelling of this kind of problems due to its large flexibility which allows to deal with complex probe and part configurations. However it requires much attention to get a reliable result. In most case, the signal variations in ECT due to a flaw are very low. In this context, the quality of the mesh for a finite element simulation is crucial. Creating a such mesh is delicate and requires expertise from the user. In particular, a user of a finite element software must pay attention to have a sufficient number of elements in the skin depth of the part, in the vicinity of the probe and of the flaw, etc. . . . To obtain accurate result, a slolution is to use a mesh adaptation. In [1] the authors proposed an adaptive mesh refinement procedure in ECT with double fonction probe: a single coil that is used to induce the eddy currents and sense changes in the test material. This procedure does not require deep expertise from the user about the mesh construction. Furthermore, only the required regions are refined to improve the results in an automatic way.

In this paper we are interesting in mesh adaptation in ECT problems with separated T-R probes (Transmitter and Receiver probes). The last ones are constituted at least from two coils, one (Transmitter :T-coil) is used to generate the source field and the other (Receiver: R-coil) is used to sense changes in the test material. The application of a mesh refinement procedure using a “standard” approach like the Ligurian [1] [2] for example, leads to refine the mesh around the T-coil whereas the refinement mesh in the vicinity of the R-coil is ignored. Consequently, inaccuracies in the response calculation of the probe can be induced. In this context, an error estimator for T-R separated probes is developed and compared to the Ligurian approach.

II. DESCRIPTION OF THE PROBLEM

Fig. 1 shows an ECT arrangement. It includes a probe constituted of two coils and a conducting material Ω_c in which exists a flaw.

Fig. 1. ECT configuration

The ECT problem can be solved by FEM using either a magnetic formulation in terms of the combined vector-scalar potentials $\mathbf{t} - \phi$ where, \mathbf{t} is the electric vector potential and ϕ is the magnetic scalar potential, or an electric formulation in terms of $\mathbf{a} - \psi$ where \mathbf{a} and ψ are the magnetic vector potential and a time primitive of the electric scalar potential, respectively [3].

Considering a sinusoidal excitation, the transimpedance Z_{21} of the probe is calculated from Φ_{21} the flux in the R-coil due to I_1 the T-coil current and is obtained as:

$$Z_{21} = j\omega \frac{\Phi_{21}}{I_1} \quad (1)$$

where $j = \sqrt{-1}$ and ω denotes the pulsation.

A. Error estimators

Two error estimators are studied in this part. Both are based on the minimization of the error in the respect of the magnetic constitutive law which describes the relationship between \mathbf{B} and \mathbf{H} , where \mathbf{B} and \mathbf{H} are determined by the $\mathbf{a} - \psi$ and $\mathbf{t} - \phi$ formulations, respectively. Indeed, the magnetic formulation strongly verifies the Ampere law whereas the electric formulation strongly verifies the Faraday law. It follows that the errors appear in the way of a nonrespect of the constitutive laws. A two criteria for error estimation in harmonic linear case are presented in the following.

1) *1st approach*: This error estimator is called Ligurian. It corresponds to a magnetic energy characterizing the difference between the two formulation results [4]. For an element k of the mesh, the magnetic Ligurian estimator is given by the following equation:

$$\lambda_k(\mathbf{H}, \mathbf{B}) = \int_{\Omega_k} \frac{1}{2\mu_k} \|\mu_k \mathbf{H} - \mathbf{B}\|^2 d\Omega_k \quad (2)$$

where \mathbf{B} is the complex magnetic induction field obtained by the electric formulation $\mathbf{a} - \psi$ and \mathbf{H} the complex magnetic field obtained by the magnetic formulation $\mathbf{t} - \phi$.

Experiences have shown that the application of the mesh adaptation procedure using the Ligurian as error estimator leads to refine the mesh around the T-coil and in the skin depth of the conducting material whereas the mesh in the vicinity of the R-coil is not refined. This can introduces inaccuracy in the calculation of probe transimpedance (equation 1). To overcome this effect, an error estimator is developed in what follow.

2) *2nd approach*: The idea is based on the Lorentz-reciprocity relation in the calculation of the separated T-R probe response [5]. It involves the product of fields obtained by feeding alternatively the T-R coils. When the R-coil is fed and T-coil is turned off, two admissible solutions \mathbf{B}_R and \mathbf{H}_R are obtained by using the two dual formulations $\mathbf{a} - \psi$ and $\mathbf{t} - \phi$ respectively. Vice-versa, when the T-coil is fed and the R-coil is turned off, we get two admissible solutions \mathbf{B}_T and \mathbf{H}_T by the two formulations. Let's define an error estimator such as:

$$\lambda_k^{TR} = \sqrt{\lambda_k(\mathbf{H}_T, \mathbf{B}_T) \lambda_k(\mathbf{H}_R, \mathbf{B}_R)} \quad (3)$$

The criterion (3) allows to locate simultaneously the errors in the mesh around the T-R coils which can lead to have a good accuracy on the response of the probe.

III. NUMERICAL EXAMPLE

It consists in two identical circular air-cored coil (inner radius of 6.15 mm, outer radius of 12.4 mm, lift-off of 0.88 mm, thickness of 6.15 mm and 3790 turns) which are placed on an unflawed aluminum alloy plate (12.22 mm thick) with a conductivity of 30.6 MS/m. The frequency is of 900 Hz. Fig. 2 presents the initial mesh for the considered configuration. The distance between the two coils is of 24.8 mm.

Fig. 2. Initial mesh

An iterative procedure of mesh refinement is applied using the two error estimators described above.

Fig. 3 shows the imaginary and real parts of the transimpedance of the probe versus the iterations number.

Fig. 3. Imaginary and real parts of the probe transimpedance

IV. CONCLUSION

It can be observed that the results obtained by using the second approach are effectively better than those obtained by the Ligurian approach : the results converge quickly to each others for the second approach than the first one. More details will be presented in the final paper (about accuracy, computation time and the response of the probe in presence of a thin crack [6] ...).

Demagnetized Permanent-Magnet Fault Recognition in Synchronous Motors

Bashir Mahdi Ebrahimi and Jawad Faiz

University of Tehran

Faculty of Engineering, Campus #2, University of Tehran, Kargar Shomali, Tehran, Iran, P.O. Box 14395-515

ebrahimibm@ut.ac.ir

Abstract — In this paper, a novel approach is demonstrated to detect demagnetization of permanent-magnet in synchronous motors. For this, an efficient criterion is introduced based on processing of developed torque using time series data mining method. This criterion function can be utilized to diagnose demagnetization fault occurrence and determine its percentage precisely. Meanwhile, impacts of load variation on the proposed criterion are investigated. Then the ability of the proposed criterion for the demagnetization fault detection and estimation of its severity is evaluated. For this, the relation between the nominated criterion and demagnetization percentage is computed by mutual information criterion. So, the percentage of the demagnetization is predicted using a support vector machine (SVM) as the classifier. The classification results illustrate that the proposed criterion can recognize fault percentage accurately. Finally, a white Gaussian noise is added to the simulated torque and robustness of the proposed criterion is analyzed with respect to the noise variance. Since, the accuracy of the calculated torque from modeled motor, has considerable impacts on precise fault recognition, time stepping finite element method (TSFEM) is used to model the healthy and faulty PMSM.

I. INTRODUCTION

Protection and maintenance of permanent magnet synchronous motors (PMSMs) as efficient motors in different industries are necessary. Faults in PMSMs are classified into three parts: magnetic, electrical and mechanical faults. Due to having access to the stator of the motor, detection of electrical fault in faulty PM is much easier in magnetic or mechanical faults [1]-[2]. Albeit lots of researches have been published to investigate impacts of demagnetization in PMSMs [3], there are a few documents which introduce an approach to detect this fault precisely [2]. A comprehensive fault recognition approach includes punctual modeling of faulty motor, selection of an appropriate signal for processing and a proper index. Proposed approach in this paper is illustrated in Fig. 1.

II. MODELING OF FAULTY PMSM USING FINITE ELEMENT

According to Fig. 1, exact model of faulty PMSM is the first stage of any reliable fault recognition algorithm. Therefore, in developed model practical conditions of the faulty motor should be considered. Modeling methods which are based on the magnetic field computation and regard different aspects of the machine can be selected as an efficacious manner to evaluate required signals and parameters for processing and feature extraction. In this paper, healthy and faulty PMSM under demagnetization is modeled using TSFEM. In this modeling, geometrical complexities of all parts of the motor including stator, rotor and shaft are included. Moreover, spatial distribution of the stator windings,

non-uniform air-gap, physical conditions of the stator conductors, rotor, shaft and air-gap, and non-linearity of the core materials are taken into account. Three-phase sinusoidal voltage applied to the terminals of the motor is the input. The transient equations of the external circuit and circuit elements are combined with the magnetic field equations. In addition, the motion equations are combined with the magnetic field equations in the FEM in which the motion equations are combined with these equations. Solving the set of equations gives the stator phase currents, magnetic flux density distribution, torque and speed as required variables for analyzing, processing and feature extraction (see Fig. 1). Fig. 2 depicts the magnetic flux density distribution of the healthy and faulty motor under partial demagnetization of a PM. It depicts that the demagnetization distorts magnetic flux density wave forms. Distortion of magnetic flux density makes asymmetrical the torque profile. Fig. 3 demonstrates developed torque of the healthy and faulty motor. Fig. 3, represents that demagnetization causes torque ripples to increase. Since the variation rate of the faulty motor torque is considerable, time series data mining method (TSDM) is utilized for torque signal processing and feature extracting for demagnetization fault diagnosis.

III. TIME SERIES DATA MINING METHOD

TSDM attitude is employed to elicit efficacious criterion functions from the torque signal produced by the TSFEM. Based soundly in dynamical systems theory, the TSDM method reveals hidden patterns in time series data [4]. In this paper, time series data is time domain torque profile. A process called time-delay embedding is used to transform the torque profile into reconstructed state spaces, also called phase-spaces. Nominated the torque time series, $T_{em} = \{T(k), k=1, \dots, M\}$, where k is a time index, M is the number of observations, a two dimensional (2-D) phase-space is generated by plotting $T(k-10)$ on the x - y plane's abscissa and $T(k)$ on the ordinate. Then, $\Delta T = T(k) - T(k-1)$ which is calculated by applying the time delay embedding process to the time series of the torque profile. Fig. 4 presents the phase-space of the torque first difference time series for the healthy and faulty motor.

IV. INTRODUCING A NOVEL CRITERION FUNCTION FOR DEMAGNETIZATION FAULT DIAGNOSIS

Radius of geration around the center of mass [5] of the points in the phase-space mass is proposed as an efficient criterion for demagnetization fault detection. It should be noted that

Fig. 1. Algorithm for static eccentricity fault diagnosis in a PMSM

each point in the phase-space is given a unit mass. The radius of gyration R_g is computed as follows [4]:

$$R_g = \sqrt{\frac{\sum_{k=1+l}^M d(k)^2}{M-l}} \quad (1)$$

Where l is the time lag of the phase space, M is the number of observations and the distance $d(k)$ between the center of mass and the k^{th} point in the phase space is as follows:

$$d(k)^2 = (x(k) - \mu_0)^2 + (x(k-l) - \mu_l)^2 \quad (2)$$

where μ_0 and μ_l , the centers of mass for their respective dimensions, are as follows:

$$\mu_n = \frac{\sum_{k=1+l}^{M-l+n} x(k)}{M-l} \quad (3)$$

Where $x(k)$ is the time series observations at time index k . It is noticeable that $d(k)$ is the distance of the k^{th} phase-space "point" from the center of mass of the phase-space "points". Table I. shows the evaluated R_g for different partial and full demagnetization of one PM in the motor. Referring to Table I exposes that demagnetization occurrence causes to rise the R_g which can be utilized as a proper criterion for precise demagnetization fault diagnosis.

Fig. 2. Magnetic flux density distribution in PMSM air gap, (a) healthy and (b) with 25% demagnetization of one PM

Fig. 3. Time variation of the developed torque (a) healthy and (b) faulty motor with 25% demagnetization of one PM

Fig. 4. Torque first difference phase-space, (a) Healthy, (b) 25% demagnetized and (c) full demagnetized

Meanwhile, it illustrates that develops of the demagnetization increases the R_g which can be employed to determine the percentage of the demagnetization. Estimation of the demagnetization percentage is so important to predict motor performance and fixing necessity.

TABLE I.
RADIUS OF GERATION FOR DIFFERENT PERCENTAGE OF DEMAGNETIZATION

Operating Mode	Radius of Geration
Healthy	0.25
25% Demagnetization	0.61
50% Demagnetization	0.86
75% Demagnetization	1.24
100% Demagnetization	2.82

Induction motor analysis using optimal torque predictor and massive conductor approach

Sławomir Stepień

Poznan University of Technology
 Chair of Computer Engineering
 Piotrowo 3a, 60-965 Poznan, Poland
 Slawomir.Stepien@put.poznan.pl

Abstract — This research presents a method for the simulation of the magneto – mechanical system dynamics taking motion and eddy currents into account. The major contribution of this work leans on the coupling the field – motion problem considering windings as current forced massive conductors, rotor motion with two conductive materials and the torque calculated by the modified Maxwell stress tensor method and predicted by special stochastic algorithm. 3D model of the device is analyzed by time stepping finite element method. Mechanical motion of the rotor is determined by solving second order motion equation. Both magnetic and mechanical equations are coupled in iterative solving process. Presented method is verified by solving TEAM Workshop Problem 30.

I. INTRODUCTION

The improvement of numerical methods in the numerical analysis of electromechanical systems deals with development of the modeling techniques. In case of the analysis of field – motion coupled problems, beside field or motion mathematical description and numerical implementation, also coupling effects should be precisely determined [3-6,8]. That is why researchers pay special attention to obtain the best force or torque numerical approach and construct most optimal predictors. This is the necessary condition to construct useful model for analysis devices such as electromagnetic actuators, AC motors, permanent magnet DC or BLDC drives, etc [2,4,8].

This paper presents a consistent numerical method to analyze the AC induction motor described in TEAM Workshop Problem 30 [1], i.e., time – stepping finite – element analysis of the magnetic field considering motor windings as massive conductors and time – stepping model of the mechanical motion considering modified Maxwell stress tensor method combined with optimal torque predictor [9].

II. THE MODEL

The model of the problem is described by magnetic vector potential \mathbf{A} and electric scalar potential V [7]. The problem is defined in three regions: Ω_c^i - conducting region of immovable conductor, Ω_c^m - conducting region of movable conductor and Ω_n - non-conducting region. The alternating current flows by the massive conductor generates magnetic field rotation in region Ω_n and eddy current in movable conductor Ω_c^m .

Fig. 1. Model of induction motor part

The total current $i(t)$ is connected to the boundary surfaces of immovable massive conductor. The boundary value problem will be described widely in full paper.

The magnetic torque is calculated using modified Maxwell stress tensor method. The global torque is determined from surface stresses combination caused by electromagnetic field. In case of the presented problem, the electromagnetic torque is calculated by the relationship:

$$T \approx r \times \sum_k P_{12,k} \Delta S_{2,k}, \quad (1)$$

and is evaluated along a surface placed in the airgap between rotor and immovable massive conductor.

Fig. 2. Illustration of the torque calculation

Fig. 2 shows stress tensors P and radius r used to determine global torque. As a new contribution, the obtained torque value in each time step of the calculation is combined with optimal predictor [9]:

$$\hat{T}(t + \Delta t) = -\alpha_1 c \hat{T}(t) + \alpha_2 (c + 1) T(t) + \alpha_3 \Delta t \frac{dT(t)}{dt}. \quad (2)$$

where T is a torque value obtained from Maxwell stress tensor, \hat{T} is a prediction of T . The term $\frac{dT(t)}{dt}$ is obtained from spline cubic approximation of $T(t)$. The predictor (2) minimizes value of the expectation $E[T(t) - \hat{T}(t)]^2$. A new predicted value $\hat{T}(t + \Delta t)$ is used to solve numerically the mechanical motion equation

$$J \frac{d\omega}{dt} = \hat{T} \quad (3)$$

where ω is an angular velocity and J is a inertia of the rotor. In the full article will be presented wide description of adopted prediction technique.

III. NUMERICAL EXPERIMENT

To demonstrate the effectiveness of the method, a single phase induction motor is tested. The motor geometry and its excitation is detailed in description of the TEAM Problem 30 [1]. There is examined 3D problem in which the eddy currents in the rotor composed of two different materials are induced by time harmonic current on the massive windings and rotation of the rotor.

Fig. 3. The mesh of analyzed motor

The massive conductors are excited current 2045,175 A at 60 Hz. The rotor is made from aluminum and steel, so for the experiment purpose, assumed following specific gravity values: 2700 kgm^{-3} and 7800 kgm^{-3} . The presented model has been tested with initial torque $\hat{T}(0) = 10^{-5} \text{ Nm}$, considering dynamic characteristics: speed and torque-speed relationship.

Fig. 4. Speed profile of the rotor

Fig. 5. Torque – speed relationship of AC motor

Fig. 4 shows the computed angular speed profile. In steady state the speed is about 360 rad/s, in accordance to the field rotating speed.

Fig. 5 shows the torque - speed mechanical characteristic. Obtained curve during computations in comparison with [1] shows good agreement and usefulness of presented model.

IV. CONCLUSION

A method of analysis of the AC motors including the massive conductors approach and optimal torque predictor is presented. This method, thanks to adopted predictor technique, allows an exact analysis of electrical machines dynamics. Also the windings can be successfully represented as massive conductors with known prescribed currents for the very low frequency analysis. The comparison of simulated results and results given in description [1] shows a good agreement.

FD-TD Calculations of SAR Validated Through Measurements

Ana de Oliveira Rodrigues, Juliano Junio Viana,
Alisson Henrique Quemel de Souza, Eduardo Aparecido dos Santos

Abstract—This paper presents the validation of Copacabana v1.0, a Java based software that calculates Specific Absorption Rate (SAR) using the Finite-Difference Time-Domain method (FD-TD). Measurements were performed at the Laboratório de Absorção e Dosimetria (LAD) of the Centro de Pesquisa e Desenvolvimento em Telecomunicações (CPqD) using a DASY4 system. The half-wavelength dipole was validated by comparing the field of this dipole with measurements and analytical solutions. SAR calculation was validated using a three-dimensional model described in international standards [3]. It is concluded that the software Copacabana v1.0 was validated for SAR calculations with maximum error of 14%.

keywords — SAR, FD-TD, measurements

I. INTRODUCTION

The Specific Absorption Rate (SAR) must be measured to evaluate the thermal effect of high frequency electromagnetic fields in the human body. SAR indicates the energy or power absorbed by one mass unity, usually expressed in Watts per kilogram of biological tissue (W/kg), and is proportional to the peak value of the electric field $|E_0|$ irradiated by the source, and tissue density (ρ [Kg/m³]) and conductivity (σ [S/m]). SAR calculated using Eq.(1) [3]. SAR is usually an indication of the temperature rise in the tissue induced by the electromagnetic field.

$$SAR = \frac{\sigma |E_0|^2}{2\rho} [W/kg] \quad (1)$$

Simulation software is necessary to calculate the SAR that will be obtained by equipment under development to guarantee that "spatial peak SAR values (should not exceed) 1.6 W/kg, as averaged over any 1 g of tissue (defined as a tissue volume in the shape of a cube)"[2]. Direct measurements allow certification of equipment developed. This work presents a software, Copacabana v.1.0, developed to calculate SAR in three-dimensional (3D) models, using the Finite-Difference Time-Domain (FD-TD) Method, and validation of the software through direct measurements.

II. METHODS

A. FD-TD Calculations

Copacabana v1.0. is a Java based software that implements the Finite-Difference Time-Domain Method (FD-TD) [7] in 3D with Mur boundary conditions [5]. These boundary conditions present expected error of 10%. The software calculates peak value of electric field, peak SAR, SAR for 1g and SAR for 10g in each point of the domain.

Fig. 1. "Flat Phantom" (adapted from [3]).

Fig. 2. Measurements: Dipole in Air and Flat Phantom

The model developed, shown in Fig.1, was a "flat phantom" [3] for 1.8GHz. The model is composed of 119, 122 and 89 cubes with 2mm side in x, y and z directions (total of 1,292,102 cubes). Simulation was run for 1,000 time steps of 2ps. The model tissues are: air around the phantom ($\epsilon_R = 1, \sigma = 0$); a 2mm plastic shell ($\epsilon_R = 3.7, \sigma = 0$); and the internal liquid ($\epsilon_R = 40, \sigma = 1.40$).

The source was modeled as a half wavelength dipole, with a radiated power (P_r) of 1W.

B. Measurements

All measurements were performed in the Laboratório de Absorção e Dosimetria (LAD) do Centro de Pesquisa e Desenvolvimento em Telecomunicações (CPqD). Fig2 shows the dipole in air and the "flat phantom", filled with a liquid with $\epsilon_R = 38, 11$ and $\sigma = 1, 43$. Expected error of measurements is 25%.

III. RESULTS

A. Dipole in Air

The electromagnetic field irradiated by a half wavelength dipole in air were obtained through analytical solution [1], measurements, and FD-TD simulations using Copacabana v.1.0. The RMS value of the electric field ($|E|$) in air were calculated and measured for a 2D plane of 12cm using a 2mm grid. Fig.3 shows the results.

As the analytical solution is provided for the far field, it can be observed that its values are not compatible with the measurements and simulation in the near field points (0,02m to 0,08m). Measurements show a better agreement to the results of the simulation in these points than the analytical solution.

Fig. 3. Results of electric field calculated with analytical solution from Balanis [1], measurements and calculated with FD-TD. Vertical bars show simulation (10%) and measurement (25%) expected errors.

Fig. 4. Left: Average SAR calculation using [4]. Right: Average SAR calculation using [6]. Figure adapted from [6]

TABLE I
FD-TD CALCULATIONS OF SAR

Method	Peak SAR [W/kg]	SAR 1g [W/kg]	SAR 10g [W/kg]
Standard [3]	69.5	38.1	19.8
FD-TD [4] (error)	50.8 (27%)	32.8 (14%)	17.0 (13%)
FD-TD [6] (error)	50.8 (27%)	33.0 (14%)	17.8 (8%)

B. SAR

1) *FD-TD Calculation*: SAR averaged in 1g and 10g were calculated using Copacabana v.1.0 in the "flat phantom" described. Two different methods were used, presented in Fig.4. In [4], the 1g averaged cube is centered in the material and contains the peak SAR value. In [6], the peak SAR value is considered in the centre of the cube, and air cubes are not considered. Results are shown in Table I. These results are compared to those presented in international standards [3].

The percentual error in Peak SAR is relatively high (27%). However, this value is directly dependent of the cell size used in the simulations. A smaller grid will necessarily result in a higher peak SAR value. SAR averaged in 1g and 10g, on the other hand, are similar for [3] and both methods, with a maximum error of 14% for [4] and [6]. The method described in [4] requires that either all cubes are calculated, which is a large burden computationally, or that the user indicates the point where the cube must be calculated. The method described in [6], on the other hand, presents the advantage of being model independent, because it does not require the knowledge of where the peak SAR occurs. The calculation can be performed using ever increasing cube sizes until the 1g or 10g SAR is achieved. This algorithm can be automatic and does not require user intervention.

2) *Measurements*: Peak SAR, SAR 1g and SAR 10g were measured inside the phantom shown in Fig.2. Measurements were performed in a cube with sides of 3cm, divided in a 2mm x 2mm x 6mm

TABLE II
MEASUREMENTS OF SAR

SAR 16dBm [W/kg]			SAR 1W [W/kg]		
Máx	1g	10g	Máx	1g	10g
1.68	1.50	0.787	41.33	36.91	19.37

Fig. 5. SAR results from international standard [3], measurements and FD-TD calculations using [4] and [6]. Vertical bars show simulation (10%) and measurement (25%) expected errors.

grid. Table II presents SAR measurements for the maximum power irradiated of 16.09dBm (40.64mW), then normalized to 1W.

IV. CONCLUSIONS

This work presented the comparison of SAR calculated by Copacabana v.1.0 Java based software with measurements. The electric field of a dipole in air was calculated was compared to measurements and analytical solution, presenting a good agreement. Fig.5 resumes the results obtained for peak SAR, SAR 1g and SAR 10g in the international standard [3], measurements and FD-TD simulations. Peak SAR shows an error of 27%, a significant difference that is due to differences in cell size. SAR 1g and SAR 10g, that do not depend on cell size, present error of 14%. It is concluded that the Copacabana v.1.0 software was validated for SAR calculations using FD-TD, with a maximum error of 14%.

Abstract — This paper describes a technique for the multi-scale numerical modelling of conducted emissions for the inverter lighting fixture placed in a large space of a shielded room. The analysis employs the 3-D finite element method. It is experimentally understood that conducted emissions are mainly generated by the common mode current, therefore the displacement current is also taken into consideration in the model. That is, precise FEM model is employed only for the region displacement current influences. The validity of the computation was confirmed by a comparison with measured results of a lighting fixture.

I. INTRODUCTION

Electromagnetic waves caused by electric and electronic equipment are a serious problem because of interference to other equipment. Conducted emission, superimposed onto the power line, flow into other equipment and cause malfunctions. For this reason, electric and electronic devices are required to reduce conducted emissions. It is experimentally understood that conducted emissions are mainly generated by the common mode current.

On lighting fixtures, a driving method for the inverters commonly used in such fixtures comparatively generates more noise than conventional lighting methods. Therefore the establishment of simulation technology to predict the noise is required during the design of such lighting fixtures. The authors have been studying an analysis technique [1], however, the common mode current has not been considered precisely because of the CPU time.

In this paper, some parts, those thought to be influenced by the common mode current, are modeled in detail and other parts are modeled roughly to get highly accurate analyzed results within reasonable CPU time. The 3-D finite element method is employed for the numerical modelling of conducted emissions from the inverter in the frequency range from 10 to 30 MHz. The validity of this numerical model is confirmed by comparing with the measured results.

II. ANALYSIS METHOD

In this analysis, 3-D finite element method [2] is employed. By considering displacement current, the fundamental

equations of the electromagnetic field in frequency domain can be expressed as follows.

$$\text{rot}(\nu \text{rot} \mathbf{A}) = \mathbf{J}_0 + \mathbf{J}_e + j\omega \mathbf{D} \quad (1)$$

$$\mathbf{J}_e = -\sigma(j\omega \mathbf{A} + \text{grad} \phi) \quad (2)$$

where, ν is reluctivity, \mathbf{A} is vector potential, \mathbf{J}_0 is forced current density, \mathbf{J}_e is eddy current density, \mathbf{D} is dielectric flux density, σ is conductivity, ν , \mathbf{A} , \mathbf{J}_0 , \mathbf{J}_e and \mathbf{D} are complex numbers. In this analysis, the displacement current $j\omega \mathbf{D}$ in equation (1) is taken into consideration, whereas eddy current density \mathbf{J}_e is not calculated since the displacement current is more dominant than the eddy current around this frequency. ω is the angular frequency.

III. BASIC ANALYZED MODEL

The calculation model of analyzed region is shown in Fig. 1. The LISN (Line Impedance Stabilization Network) is placed on the Ground reference plane and all the 6 faces of the shielded room are supposed to be perfect conductor as ground. The number of elements of this model is 690,609 and that of unknown variables is 645,577.

Fig. 1 Position of the implement model in the whole analyzed region

IV. EXPERIMENTAL VERIFICATION METHOD

A method of verifying analyzed results is to compare with the measured conducted emission from the lighting implement. The measurements are conducted in the shielded room. The lighting implement is set on a mounting table whose height is 0.4 m and the power line of 0.8m is wired straight towards the

LISN as shown in Fig.2. The LISN ESH2-Z5 manufactured by Rohde & Schwarz, whose operating frequency is from 9kHz to 30MHz, is set on the ground reference plane and conducted emission, common mode voltage, are measured with a spectrum analyzer 8542E produced by Hewlett-Packard, whose operating frequency is from 9 kHz to 29 GHz.

Fig. 2 Conducted emission measurement in the shielded room

V. IMPROVEMENT OF FEM MODEL

Powerline, that is thought to be influenced by the common mode current, is modeled in detail to calculate displacement current. Basic model of the power line is shown in Fig. 3. Precise model is shown in Fig. 4.

Fig. 3 Basic model of the power line

Fig. 4 Precise model of the power line

VI. ANALYZED RESULTS AND DISCUSSION

Fig. 5 shows the comparison of analyzed and measured conducted emission noise. Analyzed results of precise model of the power line better agree with the measured results than those of the basic model. Displacement current distribution around the power line is shown in Fig. 6. These figures indicate that the accuracy of the analysis is improved with the detailed mesh of the area thought to be influenced by the common mode current. The calculation error of about 5 to 10dB is observed. One of the reasons is considered that the mesh size between lamp line inside the lighting implement and the implement itself is not adequate to calculate the displacement current. The number of elements of these

models, unknown variables and CPU time are shown in Table. I.

Fig. 5 Comparison of analyzed and measured results when the power line modeling is improved

Fig. 6 Displacement current distribution around the power line

TABLE I DISCRETIZATION DATA AND CPU TIME

	Basic Model	Precise Model
Number of elements	229,795	2,807,128
Unknown variable	288,338	3,147,214
CPU Time	43min	10h14min

VII. CONCLUSION

This paper described the technique of multi-scale numerical modelling of conducted emission for the inverter lighting implement placed in a large space of a shielded room employing the 3-D finite element method. The validity of the analysis was clarified through the measurement. The following conclusions were obtained.

- 1) The common mode current flows mainly on power line.
- 2) The power line should be modeled with the proper element size to be able to calculate displacement current.

Consequently, the calculated results using this model were in better agreement with the measurement than those of the previous model in the frequency range from 10 to 30 MHz, thereby showing the validity of the model.

Abstract—This paper presents a method to get a reduced thermal model simplifying the calculation of different temperatures in an electrical machine winding. The equivalent thermal conductivity is deduced from a homogenization of the winding, and a discretization is achieved using the Finite Integration Technique. The model is then reduced, and the corresponding results are compared with finite element simulations.

I. INTRODUCTION

A current tendency in electrical engineering is the use of electrical actuators in rough conditions, particularly in high temperature. For such applications, precise thermal models integrating thermal material (electric insulates and magnetic materials) properties are necessary to describe the system behavior. Thus, one of the main points in the thermal study of electrical machines concerns their winding, where the temperature rises to the maximum. However, the use of numerical tools like finite element methods to estimate the hot spot in the slot can lead to excessive simulation time, due to the heterogeneous structure and the presence of electrical conductors with small geometric dimensions compared to the machine ones. In this paper, a reduced thermal model is proposed to determine different temperatures (maximal, average...) in the slot. The first step corresponds to an thermal homogenisation of a simple geometry slot. Next, the Finite Integration Technique (FIT) is used to establish the reduced thermal model.

II. EQUIVALENT THERMAL CONDUCTIVITY OF THE SLOT

In this study, we consider a slot, made up of only two materials. The first one corresponds to the copper conductors (thermal conductivity λ_1), randomly distributed, and placed in a second material, that can be air or resin (thermal conductivity λ_2). Considering an isotropic distribution of 2D cylindrical conductors, [1] have shown that an estimation of the effective conductivity can be obtained with the estimation of Hashin and Shtrikman. The equivalent thermal conductivity λ_{eq} is expressed:

$$\lambda_{eq} = \lambda_2 \cdot \frac{(1 + \tau)\lambda_1 + (1 - \tau)\lambda_2}{(1 - \tau)\lambda_1 + (1 + \tau)\lambda_2} \quad (1)$$

with τ the occupancy rate of the conductors in the slot. Fig. 1 presents the corresponding results, considering either resin or air in the slot.

The increase of the equivalent thermal conductivity with the occupancy rate is important with the resin, because of its high thermal conductivity comparing to the air one. In the next parts, an occupancy rate of 55% is considered, with resin around the copper ($\lambda_{eq} = 0.87$).

Fig. 1. Equivalent thermal conductivity as a function of the occupancy rate

III. REDUCED THERMAL MODEL OF THE SLOT

A usual solution to get simple thermal models of electrical machines is the nodal approach, considering the elementary volume as isotherm at the temperature of the associated node. The thermal models often consider only one node in the slot, giving one temperature of the winding [2]. The main difficulty of this problem is the determination of the conductance between the two nodes, which depends on geometrical dimensions and thermal material properties, with the choice of the length and surface that have to be considered to get a correct representation of the thermal flux distribution. Fig. 2 shows a static finite element simulation corresponding to the thermal problem (2, with φ the thermal flux, P the heat losses), where Dirichlet boundary condition ($T = 0$) is imposed on the upper side of the structure, and Neumann boundary condition on the other sides.

$$\begin{cases} \text{div}(\vec{\varphi}) = P \\ \vec{\varphi} = -\lambda \cdot \overrightarrow{\text{grad}}T \end{cases} \quad (2)$$

Due to the high iron conductivity, the corresponding part of the machine is quite isotherm, and can therefore be right represented with only one node. On the other hand, the temperature gradient is important in the slot, where the maximum temperature is reached. Thus, the model has to be more detailed in this area.

To treat this problem, we use the FIT method, which is well adapted to highlight the concept of thermal resistances of the different parts of the slot. The FIT method transforms the thermal equations in their integral form into a set of matrix equations on dual grids pair [3]:

Fig. 2. Temperature distribution, FE method

$$C\Phi = P \text{ and } H = C^T T \quad (3)$$

where C is the discrete divergence matrix and $-C^T$ the gradient one. Φ is the thermal flux vector through the facets of the dual mesh, H the thermal grid voltage and T the temperature at the nodes of the primary mesh. To complete the system, we add a behavior law ($H = M\Phi$). In the case of orthogonal grids, the M matrix is diagonal and m_{ii} is equal to:

$$m_{ii} = \frac{1}{S_L} \int_{L_i} \frac{1}{\lambda} \vec{\tau} \cdot d\vec{\gamma} \quad (4)$$

where λ is the local thermal conductivity, S_i the surface of facet i , L_i the length of edge i , $\vec{\tau}$ the unit tangent vector along the edge i . From (3) and the behavior law, the system becomes:

$$[C][M]^{-1}[C^T][T] = [G][T] = [P] \quad (5)$$

If the domain relative to the thermal fluxes is the slot, the unknown temperatures near the boundary are linked to those in the iron, supposed to be at the same temperature T_f .

If we suppose that Joule losses P_0 are uniform in the slot, P can be expressed as $[P] = P_0[D]$ with $D_i = S_i/S$, S being the total surface of the slot.

Equation 5 can be written

$$[T_s] = -T_f[G_s]^{-1}[G_f] + P_0[G_s]^{-1}[D] \quad (6)$$

Due to the property of matrix $[G]$, $[G_s]^{-1}[G_f]$ is a vector $[I]$ with all elements equal to 1, and the system becomes:

$$[T_s] = -[I]T_f + P_0[R] \quad (7)$$

R is the column vector giving the equivalent thermal resistance between the considered point in the slot and the one in the iron. The different equivalent thermal models of the devices using two nodes are represented Fig. 3.

The resistance R_f includes the effect of conduction in the core and the convection exchange with the exterior, supposed to be at temperature T_e . Considering a 9-nodes model for a half slot, the resulting nodal locations are shown Fig. 4.

Depending on the choice for the node i , the temperature T_i can have different meanings:

Fig. 3. Reduced thermal model

Fig. 4. Nodal discretization of a half slot

- maximum temperature in the slot (node 7)
- mean temperature of the slot (obtained by the mean of all the equivalent thermal conductances)

The corresponding results are presented in table I, with a comparison with FE ones. The relative error is lower than 5 %.

TABLE I
COMPARISON OF ANALYTICAL AND FEM RESULTS

	ΔT_{max} ($^{\circ}\text{C}$)	ΔT_{mean} ($^{\circ}\text{C}$)
Reduced model	18.02	10.96
FE Method	18.24	11.43
Relative error (%)	1.2	4.3

IV. CONCLUSION

The results obtained in the static case with the reduced model presents a good accuracy, with low computation needs. In the full paper, an extension of the model for transient analyses will be established in order to get the temperature variations versus time. Ongoing works will concern the adaptation of this reduced model to structures more similar to usual electrical machines.

 nancy@ieav.cta.br

Abstract — This work presents new features of the system named ROME, developed at the Virtual Engineering Laboratory of the Institute for Advanced Studies of Brazilian Air Force, and the analysis of its application on optimization problems. ROME was developed based on Java and RMI technology and aims to manage distributed processing in non-dedicated heterogeneous clusters. The system provides robust mechanisms for self-adjusting load balancing and fault tolerance during the execution of parallel processing.

I. INTRODUCTION

Load balancing, fault-tolerance and scalability are the problems commonly encountered when performing parallel and/or distributed computing. A different approach to the parallelization of systems was developed at the Virtual Engineering Laboratory (LEV) of the Institute for Advanced Studies [1]. The system, named ROME, was developed in Java and uses the remote method invocation (RMI), a mechanism that provides the ability to remotely invoke a method of an object in another Java Virtual Machine (JVM)[2]. The major focus of the project was to develop a system which provides native load balancing and run-time failure recovery. Due to the characteristics of Java, the system is inherently multiplatform allowing its use in clusters composed by computers with different hardware and operating system configurations. It is more appropriate for coarse-grain parallel processing.

The system was developed based on the object oriented programming (OOP) paradigm and designed to be used as a class library, allowing its use with low level of additional programming. The description of classes, their functionalities and an evaluation of the system behavior when managing a optimization problem were presented in [1].

II. BASIC DESCRIPTION OF THE SYSTEM AND NEW FEATURES

Table I presents the main features of system ROME, compared with two of the most popular packages widely used to perform calculations and simulations in the area of parallel scientific computing: the Message Passing Interface (MPI) [3] and Parallel Virtual Machine (PVM) [4].

ROME follows a master/slave model, in the sense that there is an application (master) responsible for dividing the global problem in small tasks, sending the tasks to be solved by the slave applications and gathering back the results. It is composed basically by two main programs: a master machine and a slave machine. However, unlike the traditional master/slave model, the master machine is set to a passive mode, behaving most like a “server application”: the master waits for a “request for a task” of a slave application before

sending a task to it.

The operation using the "request for a task" mode allows implicit load balancing, since the slave application executed in an environment that presents higher performance will call for more tasks than other in a lower performance environment. A slave requests for a task only when the percentage of use of its processor is below a certain value defined by the user.

The system allows configuring the total number of slave machines connected per master machine as well as the number of slave machines for each user's parallel application managed by the master machine.

Two methods for identifying slave application faults are available: the direct detection method and the time estimation method. In the time estimation method, a estimative of the response time of a slave machine is calculated during run-time. If the response time of the slave machine exceeds the estimative (expires), the tasks attributed to it is sent to another slave.

TABLE I
MPI, PVM and ROME CHARACTERISTICS

Characteristics	MPI	PVM	ROME v.1	ROME v.1.1
Heterogeneous architectures	•	•	•	•
Multiplatform	• ⁱ	• ⁱ	•	•
Slaves intercommunication	•	•	•	•
Fault tolerant		• ⁱⁱ	•	•
Native load balancing			•	•
Dynamic identification of slaves			•	•
Native slave redundancy			•	•
Object transmission			•	•
Dynamic identification of multiple core processors				•
Native master redundancy				•
Additional user's programming	High	High	Low	Lower
Programming languages	C, C++, Fortran	C, C++, Fortran	Java ⁱⁱⁱ (C, C++, Fortran, etc)	Java ⁱⁱⁱ (C, C++, Fortran, etc)

ⁱ requires compilation for each operating system, ⁱⁱ requires implementation to recover lost data ⁱⁱⁱ the system is implemented in Java language but the applications can be implemented in any language because they can be executed as processes.

The usage of the system requires the implementation, in Java, of two methods of an abstract class, responsible for the master process, and of two other methods of the slave process class. These methods should be implemented in derived classes. The user's application can be developed either in Java, or be executed as processes. In the last case, the user's application can be developed in any desired language.

9. NUMERICAL TECHNIQUES

In the new version (v1.1), changes were made to further enhance the reliability (fault-tolerance) of the system with the identification of failures in the master machine, allowing a second machine to take control of the parallel processing without losing data of the tasks already computed. Other feature included is the possibility of communication among slaves, i.e., tasks running on different machines or processors can exchange information among themselves. Communication between nodes was made only between master and slaves in the previous version.

The new version also allows using computers that have multiple processors cores, automatically identifying the number of processors available. The system allows to add all or part of them in the processing cluster.

III. RESULTS

In a previous work, ROME was submitted to tests using codes for the optimization of electrooptic modulator devices by using a genetic algorithm (GA) [5]. Figures of merit of each individual generated by the GA are computed by a code based on the Finite Element Method. In this case, each task submitted to a given slave presents almost the same execution time. Fig. 1 shows the relative performance of the slaves used in the parallel processing and the automatic load balancing achieved. The cluster was composed by computers with very different hardware configurations and operating systems. Slave 1 and 10 run in a dual core processor. Slave 10 joined the computation later, by manual interference of the operator.

Fig. 2 illustrates the behavior of the response time estimative of one slave. After five tasks were completed, the system began to compute the estimative using the historical data. For the referred slave the value changed to 400s and remained almost constant for all the computed tasks.

Fig. 1. The dots indicate the relative performance of each processor (left axis) and the histogram represents the number of the processes distributed to each processor (right axis)

In a recent test, ROME was used in a study of doped multi-quantum well (MQW) semiconductor structures [6], involving an optimization process. A MQW can be composed by several wells with different doping concentrations. In this problem, when the doping concentration in the wells is low (less than $5.0 \times 10^{16} \text{cm}^{-3}$), the convergence of the self-consistent computation is fast. However, for high values of doping concentration the convergence process can be much more costly. A homogeneous cluster composed by four multi-core computers was used to carry out the optimization. Fig. 3 shows the adaptation of one processing core of the system to tasks of different response time. In this case, the method for estimating the response time was able to adapt the system to the response

time of the slave. The master machine invalidates a task that do not answer in the predicted time and includes it back in the list of tasks waiting for a free processor. However, the system accepts results of a task whose response time has expired, provided that the task has not been sent to other slave yet. It should be pointed out that, in some cases, the submission of tasks of very different execution time to a processing core can result in a dead-lock. Because the process is invalidated, the estimative of response time is not updated. This procedure continues, occupying all processors.

Fig. 2. Estimative response time of a slave.

Fig. 3. Estimative response time for tasks with a very different response time

IV. FINAL COMMENTS

This work presents new features of system ROME, a robust management system for distributed processing, developed using Java language and the RMI resource.

The system is in testing with the execution of applications developed at LEV. New methods for adapting the system to applications in which the execution time of the tasks executed in the slaves are too different are about to be defined and implemented. In principle, the system allows the identification of slaves connected in LAN or WAN and is a powerful tool for parallel processing in a distributed and heterogeneous environment.

Abstract — In common, the accuracy of FEA result is a strong relation to the mesh characteristics, such as the number of elements, the element shape, the mesh density and so on. However, it is difficult to clarify whether the mesh is suitably generated, and whether the accuracy is sufficient enough. We have proposed the method to simply evaluate the characteristics of mesh and FEA result by using the magnetic flux lines, which are analytically calculated from the FEA result.

I. INTRODUCTION

Often, in order to increase the accuracy of FEA and to shorten the computation time, the graded mesh is employed. However, it may contain the poor-shaped elements causing long computation time and inaccuracy. Sometimes, in order to increase the accuracy, the excessively small elements are generated, therefore the computation time is wasted. The result accuracy and the speed of FEA are a strong relation to the mesh characteristics, such as the number of elements, the element shape and the mesh density. However, we cannot easily judge which mesh characteristics is the most important factor to increase the accuracy of FEA results. Also, we cannot know whether the obtained FEA result has enough accuracy. Usually, the error estimation method [1] is used. However, to estimate the error all over the domain is a labor task, and it is difficult to estimate the error since the true value is unknown. Consequently, another result with more fine mesh is necessary to estimate the error.

In this paper, we have proposed the way to simply and roughly evaluate the mesh characteristics and the result accuracy from the magnetic flux lines calculated from only one FEA result. The actual magnetic flux line in a closed domain is closed. The magnetic flux line analytically calculated from the FEA result [2], [3] is also closed in the domain, but the locus is unrealistically long and complex when the result accuracy is poor. Therefore, the characteristics of the result and the mesh are easily evaluated by drawing a few magnetic flux lines.

II. EVALUATION FROM MAGNETIC FLUX LINE

The methods to analytically calculate magnetic flux lines from tetrahedral and hexahedral edge FEA results were proposed [2], [3]. Surely, the calculated magnetic flux lines in a closed domain are closed and do not go outside the domain, since the result of FEA satisfies $\text{div } \mathbf{B} = 0$. However, when the accuracy is poor, some calculated magnetic flux lines are not simply closed, as shown in Fig. 1(b). The unrealistic magnetic flux lines are generated from the FEA result with poor mesh quality, i.e. bad-shaped elements exist, number of elements is

insufficient, and so on. On the other hand, the magnetic flux line in Fig. 1(a) is actual and it is obtained from the FEA result with good mesh quality. Consequently, by drawing the magnetic flux lines of FEA result, it is possible to judge whether the mesh is suitable for the FEA and whether the accuracy is sufficient enough. It is, however, impossible to obtain the exact value of the accuracy in this method. Of course, the true value of the magnetic field is also unknown.

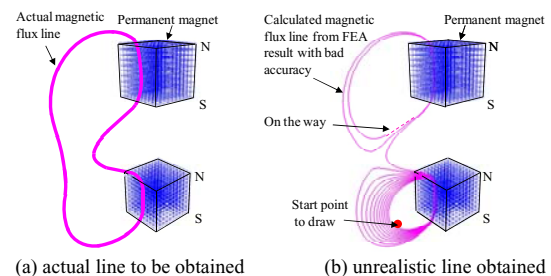

Fig. 1. Actual and unrealistic magnetic flux lines

We have investigated the relation between the calculated magnetic flux lines and the mesh quality. The gap distance generated by drawing round the magnetic flux line obtained from the FEA result is defined as an error indicator, as shown in Fig. 2. The simple test model, as shown in Fig. 3, consists of a permanent magnet in a closed domain, and six different meshes generated by the mesh generator in [2] are prepared. The properties of six meshes are shown in Table I.

Fig. 2. The definition of the gap distance occurring from inaccurate result.

III. RESULTS OF EVALUATION

The gap distances of 6 magnetic flux lines on each mesh are plotted in Fig. 4, and the loci of the magnetic flux lines on Mesh I, III, V and VI are visualized in Fig. 5. In Figs. 4 and 5, the solutions in the cases of Mesh II and III have the high accuracy, since the magnetic flux lines are almost single loop. On the other hands, the Mesh I is too rough though the computation time and the ICCG convergence reveal good

TABLE I
PROPERTIES OF MESHES

Mesh No.	I	II	III
No. of Elements	29,791	226,9981	531,441

Fig. 3. Simple test model consisting of a permanent magnet.

performance. The Meshes IV, V and VI contain some bad-shaped elements, even though Mesh VI has the largest number of elements. The magnetic flux line 1 in Fig. 5(d) shifts to y -direction, therefore the gap distance is large.

The graded mesh is, often, used to shorten the computation time while keeping the high accuracy. However, the graded hexahedral mesh contains some distorted elements, as the result, the accuracy becomes poor. On the Fig. 5 (c), the loci of the magnetic flux line 1, the most outer line, are multiple-looped, since the line 1 passes through the distorted elements with poor quality on changing mesh density. The magnetic fields B_z and B_y on the $+x$ -direction line from the center of the permanent magnet are plotted in Fig. 6. The magnetic fields about B_z agree well, but the magnetic field B_y of the Mesh VI is obviously wrong since $B_y = 0$. The large gap distance results from such small error.

When the property of the magnetic flux lines is good, the ICCG convergence and the accuracy are good enough. Therefore, by drawing the magnetic flux lines using the method [2] from only one FEA result, it is possible to judge whether the properties of the mesh is good or poor, without computing the exact value of the error.

IV. CONCLUSION

In this paper, the method to roughly judge the accuracy of the edge FEA result has been proposed. In the method, it is checked whether the magnetic flux line calculated from the FEA result with good property is closed or not.

Abstract—Inductive coil gun's performance analysis is very important for experimental research and its electromagnetic optimization design. Circuit simulation is carried out based on current filament model (CFM), the governing equations of CFM may boil down to initial value problem of non-linear variable coefficient ordinary differential equations, which can be solved by numerical method and is easy to program. From circuit simulation, the dependence of system performance on variable parameter can be found. Field model is built based on composite grid method (CGM). CGM uses two sets of mutual independent grids to discrete solution region, the coarse grids discrete the global region and the fine grids discrete the moving part, so the trouble of remeshing in normal finite element technique based on one set of grid is overcome. In this paper performance analysis of three stages coaxial inductive coil gun is carried out based on field-circuit method. Three dimensional moving conductor eddy current (MCEC) field simulation of coil gun is realized, field variables distribution in the launching process is obtained. By comparing the results of circuit model and field model validity of the two models is proved.

I. INTRODUCTION

Coil launcher commonly constitutes by five parts: pulse power, high-speed switch, exciting coil, armature and projectile [1]. The pulse power loads electromagnetic energy on exciting coil after pulsed on. Transient magnetic field produced by the exciting coils induces circumferential eddy current in the armature. The circumferential eddy current interacts with radial component of the magnetic field which produces Lorentz force to drive the armature and projectile in the direction of muzzle. When armature arrives at an appropriate position, the next stage is fired, this process continues until the projectile is out of bore.

Coil gun's launching is a complex electromagnetic transient process; to obtain main performance parameters is not easy. Compared with expensive prototype experiments, numerical simulation can save design cost and improve work efficiency greatly in the optimized design of coil gun. Numerical simulation model for coil gun can be divided into two types: circuit model and multi-physical field model [2]. The circuit model has the virtue of simple and easy realization. According to the circuit model, dependence of variable parameters on result can be found easily. The multi-physical field model solves the problem from partial differential equation or integral equation, and can obtain various field quantities accurately, such as magnetic flux density and eddy current density [3].

In the analysis of coil gun only use circuit model can't get the field distribution, so precise analysis is impossible [4];

only use field model can't complete the whole analysis procedure, since the current of exciting coils which is material property in field model doesn't know in advance. So it is absolutely essential to analyze coil gun based on field and circuit combined model.

II. BASIC PRINCIPLES OF CIRCUIT MODEL AND FIELD MODEL

A. Current Filament Model

There are two types of circuit model: current sheet model (CSM) [5] and current filament model (CFM) [6]. CSM replaces the currents in an actual barrel and in a cylindrical tubular projectile (sleeve) with two equivalent current sheets located at their equivalent radius; by computing the magnetic field produced by the two current sheets the Lorentz force applied on projectile can be obtained. CFM divides massive conductive parts of the system into elementary volume elements, in which uniform distribution of current is assumed, a current filament is associated with every volume element, and its electrical parameters are calculated, the electrical and mechanical equations governing the behaviors of the system are formulated on the basis of the adopted equivalent network (schematic diagram of CFM is shown in Fig. 1.). Considering the definite physical meaning and simple solving process of CFM, this paper uses it to establish circuit model.

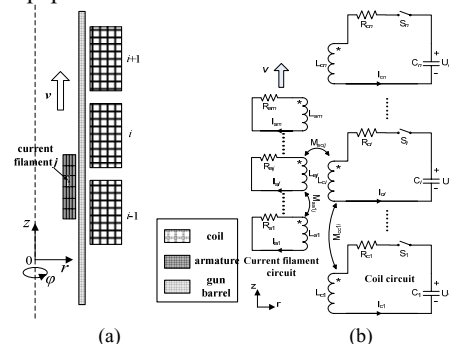

Fig. 1. Schematic diagram of CFM (a. CFM of coil gun; b. equivalent circuit)

B. Composite Grid Method

Launching process of coil gun is a complex moving conductor eddy current (MCEC) problem. In order to solve the problem, this paper applies a novel method — composite grid method (CGM). CGM developed from the conventional multi-grid method uses two grid sets: one coarse grid for the global region and one fine grid for the local region [7], as shown in Fig. 2. The results of the coarse mesh are interpolated onto the boundary of the fine mesh as its Dirichlet condition. Then fine mesh region is solved and reaction force

on its boundary is obtained, the reaction force reacts on the coarse mesh and global region is re-solved. The iteration continues until result convergence. The calculation procedure of CGM is shown in Fig. 3. Since the two grid sets are created independently, CGM overcomes the trouble caused by only one set of grid and it is very convenient to handle with MCEC problems [8].

Fig. 2. Solution region and discrete grids of CGM

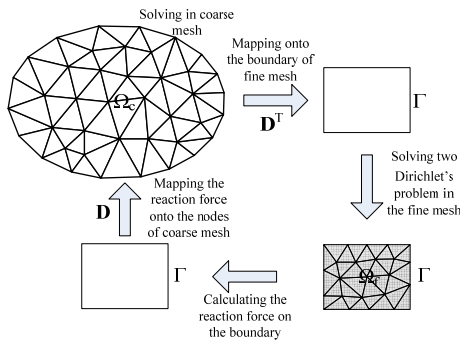

Fig. 3. Calculation procedure of CGM

III. COUPLE THE TWO METHOD IN ANALYSIS OF COIL GUN

A three-stage coaxial inductive coil gun simulation model according to field-circuit technique is built in this paper. First, we use circuit model to simulate launching process. The structure diagram of coil gun and division of current filament is shown in Fig. 4. Current waveform of exciting coils and current filaments obtained from circuit simulation are shown in Fig. 5.

Fig. 4. Structure diagram of coil gun and division of current filament

Fig. 5. Current waveform of circuit model (a. Current of exciting coil; b. Current of the first four current filaments)

Then the 3D field model based on CGM is built as shown in Fig. 6. The currents got by circuit model are loaded in field model as material properties of exciting coils and the field model is solved. Field quantities such as eddy current field,

magnetic flux density are displayed in Fig. 7. Results of the two models are compared (as shown in Fig. 8.) and the agreement of the two methods is proved.

Abstract— Model refinements of magnetic circuits are performed via a subdomain finite element method based on a perturbation technique. A complete problem is split into subproblems, some of lower dimensions, to allow a progression from 1-D to 3-D models. Its solution is then expressed as the sum of the subproblem solutions supported by different meshes. The procedure simplifies both meshing and solving processes, and quantifies the gain given by each model refinement on both local fields and global quantities.

I. INTRODUCTION

The perturbation of finite element (FE) solutions provides clear advantages in repetitive analyses and helps improving the solution accuracy [1]-[4]. It allows to benefit from previous computations instead of starting a new complete FE solution for any variation of geometrical or physical data. It also allows different problem-adapted meshes and computational efficiency due to the reduced size of each subproblem.

A subproblem FE method is herein developed for coupling solutions of various dimensions, starting from simplified models, based on ideal flux tubes defining 1-D models, that evolve towards 2-D and 3-D accurate models. It is an extension of the method proposed in [2]-[4], applied to refinements up to 3-D models. From the so calculated field corrections, the associate corrections of global quantities inherent to magnetic models, i.e. fluxes, magnetomotive forces (MMFs), currents and voltages, are also evaluated. The developments are performed for the magnetic vector potential FE magnetostatic and magnetodynamic formulations, paying special attention to the proper discretization of the constraints involved in each subproblem. The method is illustrated and validated on test problems.

II. COUPLING OF MAGNETIC MODELS OF VARIOUS DIMENSIONS

A. Series of coupled subproblems

Instead of solving a complete problem, generally with a 3-D model, it is proposed to split it into a sequence of subproblems, some of lower dimensions, i.e. 1-D and 2-D models. Its solution is then to be expressed as the sum of the subproblem solutions.

Each subproblem is defined in its own domain, generally distinct from the complete one. At the discrete level, this aims to decrease the problem complexity and allow distinct meshes with suitable refinements. Each subproblem approximates at best its contribution to the complete solution. The domains of

the subproblems can overlap [2], [3] or not [1], [4]. Herein, non-overlapping subdomains are considered. They are separated by interfaces $\Gamma_{f,p}$, through which a sequence of boundary conditions (BCs) or interface conditions (ICs) is to be defined.

B. Canonical magnetostatic or magnetodynamic problems

Each subproblem p is defined in a domain Ω_p , with boundary $\partial\Omega_p = \Gamma_p = \Gamma_{h,p} \cup \Gamma_{b,p}$. It is governed by magnetostatic or magnetodynamic equations with volume and surface sources or constraints. Classical volume sources fix remnant inductions in magnetic materials and current densities in stranded inductors. Similar volume sources can also express changes of permeability and conductivity from one problem to another [3]. Also, the usually homogeneous surface sources, i.e. BCs or ICs on the traces of the magnetic field \mathbf{h}_p and flux density \mathbf{b}_p , respectively $\mathbf{n} \times \mathbf{h}_p|_{\Gamma_{f,p}}$ and of $\mathbf{n} \cdot \mathbf{b}_p|_{\Gamma_{f,p}}$, with \mathbf{n} the unit exterior normal, can be extended to non-zero constraints calculated from previous problems. ICs have the general forms

$$[\mathbf{n} \times \mathbf{h}_p]_{\gamma_p} = \mathbf{j}_{f,p}, \quad [\mathbf{n} \cdot \mathbf{b}_p]_{\gamma_p} = \mathbf{b}_{f,p}, \quad (1a-b)$$

where the notation $[\cdot]_{\gamma} = \cdot|_{\gamma^+} - \cdot|_{\gamma^-}$ expresses the discontinuity of a quantity through an interface γ (with sides γ^+ and γ^-) in Ω_p . The associated surface fields $\mathbf{j}_{f,p}$ and $\mathbf{b}_{f,p}$ are generally zero, defining classical ICs for the physical fields, i.e. the continuities of the tangential component of \mathbf{h}_p and of the normal component of \mathbf{b}_p . If nonzero, they define possible surface sources that account for particular phenomena occurring in the idealized thin region between γ^+ and γ^- .

C. Sources at subproblem interfaces

Portions of a 3-D structure satisfying a translational or rotational symmetry can be first studied via 2-D models. This consists in neglecting some end effects, zeroing either $\mathbf{n} \times \mathbf{h}_p|_{\Gamma_{f,p}}$ or $\mathbf{n} \cdot \mathbf{b}_p|_{\Gamma_{f,p}}$. Besides, if the field is chosen to be zero out of Ω_p , a discontinuity of one of its traces is then voluntarily defined through $\Gamma_{f,p}$.

With such assumptions, two subproblems 1 and 2 with adjacent non-overlapping subdomains Ω_1 and Ω_2 share a common interface $\Gamma_{f,1} = \Gamma_{f,2}$ through which a field discontinuity occurs. A third subproblem, 3-D, serves then to correct the field distribution in a certain neighborhood Ω_3 on both sides of the interface, then denoted $\Gamma_{f,3}$. This is done via ICs

$$[\mathbf{n} \times \mathbf{h}_3]_{\Gamma_{f,3}} = \mathbf{j}_{f,3}, \quad [\mathbf{n} \cdot \mathbf{b}_3]_{\Gamma_{f,3}} = \mathbf{b}_{f,3}. \quad (2a-b)$$

with the surface sources

$$\mathbf{j}_{f,3} = -(\mathbf{n} \times \mathbf{h}_1|_{\Gamma_{f,1}} - \mathbf{n} \times \mathbf{h}_2|_{\Gamma_{f,2}}), \quad \mathbf{b}_{f,3} = -(\mathbf{n} \cdot \mathbf{b}_1|_{\Gamma_{f,1}} - \mathbf{n} \cdot \mathbf{b}_2|_{\Gamma_{f,2}}). \quad (3a-b)$$

This work was supported by the F.R.S.-FNRS (Belgium), the CNPq (Brazil), the Belgian Science Policy (IAP P6/21) and the Walloon Region.

These sources compensate the traces 1 and 2 to recover the continuity of the total solution. Note that $\Gamma_{f,1}$, $\Gamma_{f,2}$ and $\Gamma_{f,3}$ are similar and only differ at the discrete level due to their different supporting meshes.

The ICs (2a) and (2b) in a magnetic vector potential (\mathbf{a}) FE formulation are considered via natural and essential constraints respectively [3]. The essential constraint strongly fixes the discontinuity of the trace of \mathbf{a} through $\Gamma_{f,3}$ (continuity if $\mathbf{b}_{f,3}=0$), whereas the natural constraint weakly acts via a surface integral term in the FE formulation. This surface term, with (2a) and (3a), involves the traces of previous solutions, each one being actually involved in similar surface terms in the associated previous FE formulations, thus linked with their other volume integrals. At the discrete level, these surface integrals must be substituted with those volume integrals, limited to one single layer of FEs touching the interface [1]-[4]. Because each solution is calculated in a different mesh, mesh-to-mesh projections of solutions are necessary. They can be profitably limited to the single layers of FEs. This procedure is of key importance for ensuring consistency between all the formulations and their coupling. It will be detailed in the extended paper and it will be shown to allow the accurate calculation of the global quantities (flux, MMF, current, voltage) at each step of the series, in particular the correction due to the end effects.

III. APPLICATION EXAMPLES

As a primary illustration, two flux tubes are first separately considered before being connected in series (Fig. 1). The solutions in each separate tube are simply calculated via 1-D models. When the tubes are connected, their junction surface acts as an interface $\Gamma_{f,3}$, with continuity of the normal magnetic flux density ($[\mathbf{n} \cdot \mathbf{b}_3]_{\Gamma_{f,3}} = 0$) and discontinuity of the tangential magnetic field ($[\mathbf{n} \times \mathbf{h}_3]_{\Gamma_{f,3}} \neq 0$). This gives the requested source for a 2-D model, calculating the field correction limited to a certain neighborhood Ω_3 on both sides of the interface, with a locally refined mesh.

Fig. 1. Field lines (top) and magnetic flux density (bottom) of the initial problem with two ideal flux tubes in series (\mathbf{b}_1 and \mathbf{b}_2 in both tubes *left*), its local correction at the junction (\mathbf{b}_3 , *middle*) and the complete solution (\mathbf{b} , *right*).

A stranded inductor is then studied via the coupling of a 2-D plane model for its portion with a translational symmetry, a 2-D axisymmetrical model for its end winding and a 3-D model for the 3-D correction on both sides of the interface separating the portions (Figs. 2 and 3). Because the correction is local to the interface, the associated 3-D mesh only needs to be refined in its vicinity.

Various results and discussions will be given in the extended paper, in particular regarding the correction of both local and global quantities, the way to consider additional regions (e.g. the magnetic or conducting plate below the inductor in Fig. 2; based on [1] and [3] for magnetostatic and magnetodynamic models), the way the fields decrease at infinity

with the different models and the adaptation of the domain of each subproblem with its effect on the convergence of the complete solution. Parameterized analysis modifying some subproblems (e.g. end windings) while keeping the others constant will be shown to benefit from the developed method.

Fig. 2. Field lines generated by a stranded inductor (half geometry): solution of a 2-D plane model in the XY plane ($z=0$) (\mathbf{b}_1 , portion on the *left*) and of a 2-D axisymmetrical model in the YZ plane ($x=0$) (\mathbf{b}_2 , portion on the *right*); the interface between the two portions is shown.

Fig. 3. Magnetic flux density along the coil axis in the 3-D system: \mathbf{b}_1 for the 2-D plane model (implicitly extended as a constant up to $z=100$ mm), \mathbf{b}_2 for the 2-D axisymmetrical model, \mathbf{b}_3 for the 3-D correction and \mathbf{b} for the complete 3-D model. The solution $\mathbf{b}_1+\mathbf{b}_2+\mathbf{b}_3$ is generally obtained with a higher accuracy than \mathbf{b} for a lower computational cost thanks to the coupling of meshes, some of lower dimensions.

IV. CONCLUSIONS

The developed subdomain FE method allows to split magnetic models into subproblems of lower complexity with regard to meshing operations and computational aspects. A natural progression from simple to more elaborate models, from 1-D to 3-D geometries, is thus possible, while quantifying the gain given by each model refinement on both local and global quantities.

Abstract— During the course of evolution living organisms have developed sophisticated behavior, intricate communication capabilities, decentralized colony control, group foraging strategies and a high degree of cooperation when tackling tasks. Bio-inspired optimization techniques, which operate in analogy to the swarming and social behavior found in nature, have been adopted to solve a variety of engineering problems. In this paper an optimization strategy based on an improved bacterial foraging strategy based on Gaussian distribution is proposed. The validity of the given algorithm is tested on the TEAM workshop benchmark problem 22.

Index Terms— TEAM workshop benchmark problem 22, optimization, swarm intelligence, electromagnetic optimization, bacterial foraging algorithm.

I. INTRODUCTION

Recently, great efforts have been devoted to the application of optimization metaheuristics inspired by swarm intelligence approaches, and in this context the development of bio-inspired swarm intelligence methodologies based on bacteria colony behavior is an emergent research area [1],[2].

A particularly interesting group behavior has been demonstrated for several motile species of bacterial colonies, where intricate stable spatio-temporal patterns based on stimuli of cell-cell signaling and foraging are formed in semi-solid nutrient media. Defining chemotaxis as a bias of movement according to the gradient of a chemical agent, chemotactic signaling is a response to an agent emitted by the bacteria [3]. Basically, chemotaxis is a foraging behavior that implements a type of optimization where bacteria try to climb up the nutrient concentration and avoid noxious substances. Relying on these biological concepts, an optimization method based on the foraging of *Escherichia coli* can be defined [4].

In this work, an improved approach based on a bacterial foraging strategy using a variable speed with Gaussian probability distribution function is proposed and tested on the TEAM workshop problem 22 in comparison with the classical foraging strategy proposed in [1].

II. FUNDAMENTALS OF BACTERIAL FORAGING OPTIMIZATION

Natural selection tends to eliminate animals with poor foraging strategies and to favor gene propagation of those with

good foraging strategies, since these have higher chances of succeeding in reproduction.

Bacterial colonies have developed sophisticated modes of cooperative behavior which enable them to respond to adverse growth conditions and it has been shown that this behavior manifests itself in the formation of complex colonial patterns. This phenomenon can be modeled by four simple and distinct behaviors (steps): chemotaxis, swarming, reproduction, and elimination and dispersal.

The presence of a flagellum allows the bacteria to move in two different forms: they might run (swim for a period of time), movement achieved by the flagellum rotation counter clockwise, or they can tumble, achieved by the flagellum rotation clockwise. Bacteria switch between these two modes of operation during their entire lifetime (rarely the flagellum stops rotating).

After a run period, a bacterium tumbles, and the tumble interval is about 0.14 ± 0.19 s, according to Passino [2]. After the tumble, the bacterium is pointed in a random direction. When the flagellum are rotated counter clockwise, the bacterium will move towards the direction it's turned, at an average speed of 10–20 $\mu\text{m/s}$, meaning, about 10 times its length by second, for a mean interval of 0.86 ± 1.18 s.

The local environment where bacteria live might change, either gradually or suddenly. Therefore, bacteria can suffer a process of elimination, through the appearance of a noxious substance, or a process of dispersion, through the action of other substances.

A bacterium position after a tumble can be determined through equation (1), where the position in that instant is calculated in terms of the position in the previous instant and the step size $C(i)$ applied in a random direction $\phi(j)$, generated by the bacterium tumble,

$$\theta'(j+1, k, l) = \theta'(j, k, l) + C(i) * \phi(j, k, l). \quad (1)$$

where i indicates the bacterium, j the chemotactic step, k the reproductive step and l the elimination and dispersal step.

To adapt such strategy to optimization problems, an equation to determinate the cost of each position is needed, to generate the comparison between the position and the

environment. In standard BFS notation, the cost is determined by the equation,

$$J(i, j, k, l) = J(i, j, k, l) + J_{cc}(\theta'(j, k, l), P(j, k, l)). \quad (2)$$

In which the cost (fitness) of a position $J(i, j, k, l)$ is also affected by the attractive and repulsive forces existing among the bacteria of the population, $J_{cc}(\theta'(j, k, l), P(j, k, l))$.

After a determined number of chemotactic steps (steps including the movement and the cost determination of each bacterium position), a reproductive step occurs. In this reproductive step bacteria are sorted in decreasing order by their cumulative cost. The lower half of the list dies, these are the bacteria that couldn't gather enough nutrients during the chemotactic steps, and the upper half divide themselves into two new bacteria, located in the same position.

Summarizing, the locomotory response of a cell to its environment is such that the cell responds by changing both the direction and the duration of the next movement step. This response requires some directional information from the environment that bacteria obtain by comparing an environmental property at two different time steps.

A. Improved bacterial foraging strategy

The parameter $C(i)$, $i=1,2,\dots,S$ regulates the speed of the movement taken in one step of bacteria colony, where S is population size (total number of bacteria). In this work, new approaches for the setup of parameter $C(i)$ are proposed.

In this paper, the an improved bacterial foraging strategy (IBFS) is proposed based on the studies of mutation operators in fast evolutionary programming [5], [6] and fast particle swarm optimization [7]-[8] for the setup of speed parameter $C(i)$ of bacteria.

The aim is to modify the constant $C(i)$ in conventional bacterial foraging strategy proposed by Passino [2] by a Gaussian distribution which can improve local searches. The IBFS approach tested is based on the following configuration: $C(i)=0.01 \cdot |\text{Gauss}| \cdot (ub-lb)$, $i=1,2,\dots,S$, where $\text{Gauss}(\cdot)$ are random numbers generated according to a Gaussian probability distribution with zero mean, and ub and lb are upper and lower bound of search space.

The simulation results of the IBFS method are compared with the classical bacterial foraging strategy (CBFS) approach with constant velocity, where $C(i)=0.01 \cdot (ub-lb)$, $i=1,2,\dots,S$.

III. OPTIMIZATION RESULTS

The TEAM workshop problem 22 concerns the optimal design of a superconducting magnetic energy storage (SMES) device in order to store a significant amount of energy in the magnetic field with a fairly simple and economical coil arrangement which can be rather easily scaled up in size. The benchmark consists in a continuous, constrained, eight-parameter problem and all details are given in [9].

In the TEAM 22 problem study, the following control parameters have been adopted for both the IBFS and CBFS approaches: population size $S=20$, number of chemotactic steps $N_c = 10$, maximum number of steps for bacterium

movement in a turn $N_s = 5$, number of reproductions $N_{re} = 5$, number of elimination-dispersals events $N_{ed} = 5$, and elimination-dispersal probability $p_{ed} = 0.3$. The stopping criterion was 10,000 evaluations of objective function.

The experiments were conducted for 30 independent runs.

Table I reveals that IBFS is clearly superior to CBFS for this benchmark problem.

TABLE I
ANALYSIS OF RESULTS (30 RUNS) FOR TEAM WORKSHOP PROBLEM 22

Optimization Approaches	Objective Function OF in 30 Runs			
	Maximum (Worst)	Mean	Minimum (Best)	Std. Dev.
CBFS	8.7454	3.4360	0.8333	3.5638
IBFS	2.7362	1.3107	0.0917	0.9529

IV. CONCLUSION AND FUTURE RESEARCH

In this paper, the CBFS and IBFS approaches are compared on the basis of the TEAM 22 benchmark problem. In the extended version of the papers both techniques will be compared with other families of stochastic optimizers and more details regarding the implementation and the tuning of the control parameters of both CBFS and IBFS approaches will be given.

Ongoing research is aimed at designing an IBFS for multiobjective problems.

A Population Based Incremental Learning Method for Robust Optimal Solutions

S. L. Ho¹, and Shiyou Yang^{1,2}

¹Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong

²College of Electrical Engineering, Zhejiang University, Hangzhou, 310027, China

Abstract—A Population Based Incremental Learning (PBIL) method is proposed to search the robust optimal solution of an inverse problem in which some tolerances or small perturbations on the decision variables are inevitable. The numerical results serve to demonstrate the advantages and disadvantages of the proposed algorithm and the necessity to devote efforts in the development of robust oriented optimal algorithms.

I. A PBIL METHOD FOR ROBUST OPTIMAL SOLUTIONS

Traditionally, the main goal of most optimization studies is to find the global optimal solutions of a single or multiple objective function(s). In real engineering applications, uncertainties and tolerances are inevitable, hence if the global solution being found is very sensitive to design variables, small variation or perturbation on the optimized decision variables will give rise to significant performance degradation of the ‘global optimal design’. Therefore, the preferred design solution is probably not the global optimal solution, but the ‘optimal’ one that has a high tolerance or robustness against small variation of the decision parameters [1]. Consequently, it is necessary to develop techniques which identify the robust optimal solutions of a design problem.

To evaluate the robust performance of a solution, an expected fitness function as defined below is commonly used.

$$f_{\text{exp}}(x) = \int_{-\infty}^{\infty} f(x + \delta) p(\delta) d\delta \quad (1)$$

where, δ is the disturbance on the design variable x distributed based on a probability function $p(\delta)$, $f(x)$ is the original objective function of the design problem.

The expected fitness function defined in (1), rather than the original one, is proposed to be used in the iterative process of a robust algorithm to assess the solutions. Since there is no close form for the probability function $p(\delta)$, the expected fitness value of a solution x is generally determined from

$$f_{\text{exp}}(x) = \frac{1}{n} \sum_{i=1}^n f(x_i) \quad (2)$$

where n is the number of sampling points generated in a small neighborhood of the specific point x .

Obviously, a set of additional function evaluations are required to determine the expected fitness of a specific solution. However, the function evaluations in inverse problems are nontrivial and hence are computationally heavy.

A. The PBIL Method

The proposed PBIL method is developed by combining genetic algorithm (GA) and competitive learning so as to reduce the difficulties of crossover and mutation operations in GA, whilst retaining the stochastic search nature of a GA

[2],[3]. The PBIL method therefore is similar to GA in using a binary encoded representation of an optimal problem. The salient feature of this algorithm is the introduction of a real valued probability vector. The length of this real valued probability vector is identical to that of the encoded chromosome of a feasible solution in optimal problems. The value of each element of the vector is the probability of having a ‘1’ in that particular bit position of the encoded chromosome. In every generation, this probability vector is used to generate a new population in such a way that the probability for the i^{th} bit of a chromosome to become ‘1’ is proportional to the value of the i^{th} element of this probability vector. After evaluating the objective functions of the new population, this probability vector is updated using only the best individual of the current population and shifts it towards the chromosome of the best individual.

B. Mechanism for Expected Fitness Assignment

Generally speaking, the robust optimal solutions of a multimodal objective function are either those of the local (global) optima or those distributed on the boundaries of the parameter space. For an idea robust oriented optimizer, the expected fitness assignment procedure of the aforementioned solutions instead of all the intermediate ones are activated in order to reduce unnecessary computational burdens without scarifying the solution quality. Based on this argument, only the best two elites and boundary solutions in the current population are proposed to be designated with the expected fitness values. Obviously, the implementation of such a mechanism will save a huge amount of computation costs, which are otherwise required by available robust optimal methods, in which the expected fitness values for all the solutions are uniformly assigned.

C. Generation of Additional Sample Points

As formulated in (2), to evaluate the expected fitness of a potential robust solution, some additional sampling points and their objective function evaluations are generally required. Since the function evaluation is computationally heavy due to the involvement of numerical simulation such as finite element analysis, it would be desirable if the individuals in the current population could be used for determining the expected fitness value of a potential solution. However, the precondition for the current individuals to be designated a fitness value of a specified solution is that the distances between these individuals and the solution in question will not exceed a small threshold. In this regard, the intrinsic mechanism for generating a new population of the PBIL method is such that the whole population is generated by

using a single probability vector and satisfies this precondition absolutely (this is also the reason why PBIL method is being proposed in this study for robust optimizations). Consequently, the application of the mechanism for generating new populations of the proposed PBIL method eliminates the additional computation burden for generating additional samples and function evaluations.

D. Formulation to Compute Expected Fitness

To consider the effect of the distribution of neighborhood points on the expected fitness value, a distance-weighted formula for fitness computations of a solution x_i is proposed as

$$f_{\text{exp}}(x) = \frac{\sum_{i=1}^n w_i f(x_i)}{\sum_{i=1}^n w_i} \quad (3)$$

where, $w_i = 1/\|x - x_i\|^\alpha$ is the distance-weighted factor of the i^{th} sampling point of x , α is a positive constant, n is the number of the total sampling points.

II. APPLICATIONS

A. Application One

This is a high frequency inverse problem. The problem is to exploit the minimal number of elements to optimize a completely non-uniform antenna array to produce a satisfactory or acceptable field pattern. The desired field pattern is a shaped beam with a cosecant variation and the details about this problem are referred to [4].

To produce a field pattern which is close enough to the desired one using the proposed method, a 19 element non-uniform antenna array is selected and used to optimize the complex excitations and locations of each element so as to find the robust solution of this inverse problem. Also, for performance comparison purpose, a general purpose PBIL algorithm is employed to find the global optimal of the same problem. After 43655 iterations, the proposed algorithm finds a robust solution with an objective function value of 0.09044. These are compared to 40102 iterations of the general purpose PBIL for the global solution with an objective function value of 0.079049. The array factors of the final solutions of the proposed and the general purpose PBIL methods are compared in Fig. 1, and the robustness of these two optimal solutions against some small tolerances are shown in Fig. 2. From these numerical results it can be seen that although the final solution of the general purpose PBIL algorithm is better than that of the proposed robust optimal method, the robustness of the optimal solution of the latter is considerable stronger than that of the former, as the maximum sidelobe level of the final design of the general purpose PBIL, when subject to a small perturbation, exceeds the predefined limit of -25 decibel. Moreover, the higher iteration numbers with the proposed algorithm compared with those of other available robust optimizers is not an issue as almost all of the intermediate solutions of available optimizers are required to be assigned a fitness value, whereas the proposed one assigns the fitness values intelligently.

B. Application Two

The geometry optimization of the multi-sectional arcs of

the pole shoe of a large salient pole hydro-generator [5] is then solved. For performance comparison purpose, a general purpose PBIL algorithm is also used in this case study. The final numerical results are given in Table I. Similar conclusions as those for application example one are also observed.

Moreover, the numerical results as reported serve to demonstrate that it is essential to conduct robust optimal designs for an inverse problem in which uncertainties are inevitable.

Abstract—This work tackles the evaluation of a multigrid cycling strategy using inner flexible Krylov subspace iterations. It provides a valuable improvement to the Reitzinger and Schöberl algebraic multigrid method for systems coming from edge-element discretizations.

I. INTRODUCTION

In finite element method libraries, the linear system solvers play a key role in terms of performances in the computing time and in the memory consumption. Multigrid methods are among the most efficient iterative linear system solvers for elliptic problems [1]. In this work, we focus on the discretization with the lowest order edge element of a curl-curl equation

$$\operatorname{curl} \delta \operatorname{curl} \mathbf{U} + \gamma \mathbf{U} = \mathbf{f} \text{ on } \Omega \subset \mathbb{R}^d \ (d = 2 \text{ or } 3), \quad (1)$$

which gives rise to a linear system $Ax = f$. Several Algebraic MultiGrid (AMG) algorithms have been proposed for “efficiently” solving this system [2]–[7]. We use the main ideas of the algorithm proposed by Reitzinger and Schöberl (RS), who were the first to propose an edge prolongation matrix satisfying a *commutativity property* [3]. Our motivation comes from the fact that this algorithm has the fastest setup time and gives the sparsest prolongation and coarse grid matrices among the available methods. However, it also gives the poorest rate of convergence, leading, in the literature, to a non-optimal multigrid solver. We combine the RS algorithm ideas with a Krylov-based multigrid cycle in order to recover classical multigrid performance. Numerical experiments are performed on 2D problems.

II. COMPONENTS OF THE ALGORITHM

A. Recursive Krylov-based multigrid cycle

The multigrid preconditioning algorithm on grid k (denoted by MGp) is given by *Algorithm 1* where matrix A_k represents the discrete problem on grid k (grid 0 is the coarsest) and P_k is the prolongation matrix from grid $k - 1$ to grid k .

Algorithm 1: INPUT r_k , OUTPUT $z_k = \text{MGp}(r_k)$

- 1) Relax using smoother M_k : $z_k \leftarrow M_k^{-1} r_k$.
- 2) Restrict residual: $r_{k-1} \leftarrow P_k^T (r_k - A_k z_k)$.
- 3) Compute an approximate solution $\tilde{\theta}_{k-1}$ to:

$$A_{k-1} \tilde{\theta}_{k-1} = r_{k-1}. \quad (2)$$

- 4) Prolongate coarse-grid correction: $z_k \leftarrow z_k + P_k \tilde{\theta}_{k-1}$.
- 5) Relax using smoother M_k : $z_k \leftarrow z_k + M_k^{-1} (r_k - A_k z_k)$.

If $k - 1$ is zero, the solution of (2) is exact. If not, a common strategy is to perform once $\text{MGp}(r_{k-1})$ (V-cycle) or twice (W-cycle) to approximately solve (2). Following [8], we propose to consider a K_2 -cycle which is a W-cycle completed by the two first iterations of a flexible Krylov subspace method. An example with the flexible conjugate gradient is given by *Algorithm 2*.

Algorithm 2: INPUT r_{k-1} , OUTPUT $\tilde{\theta}_{k-1} = \text{CS}(r_{k-1})$

- 1) First iteration:

$$d_{k-1} \leftarrow \text{MGp}(r_{k-1}); \alpha_{k-1} \leftarrow \frac{r_{k-1}^T d_{k-1}}{d_{k-1}^T A_{k-1} d_{k-1}};$$

$$\tilde{\theta}_{k-1} \leftarrow \alpha_{k-1} d_{k-1}; r_{k-1} \leftarrow r_{k-1} - \alpha_{k-1} A_{k-1} d_{k-1}.$$

- 2) Second iteration:

$$c_{k-1} \leftarrow \text{MGp}(r_{k-1});$$

$$d_{k-1} \leftarrow d_{k-1} - \frac{c_{k-1}^T A_{k-1} d_{k-1}}{d_{k-1}^T A_{k-1} d_{k-1}} c_{k-1};$$

$$\tilde{\theta}_{k-1} \leftarrow \tilde{\theta}_{k-1} + \frac{r_{k-1}^T d_{k-1}}{d_{k-1}^T A_{k-1} d_{k-1}} d_{k-1}.$$

The iteration cost in time and memory of both K_2 - and W-cycle is roughly equivalent. Moreover, their convergence rate are *theoretically similar* [8]. Nevertheless, in practice the K_2 -cycle has a better convergence rate than the W-cycle [8].

B. Prolongation matrix and smoother

Reitzinger and Schöberl proposed to construct an edge prolongation matrix P^{edg} satisfying a commutativity property:

$$P^{\text{edg}} G^H = G^h P^{\text{nod}}. \quad (3)$$

In this equality, P^{nod} is a nodal prolongation matrix obtained from a nodal auxiliary matrix and G^h and G^H are respectively fine and coarse edge-node incidence matrix.

At the finest level, G^h is given by the relation between vertices and edges on the finite element mesh. At the same level, the nodal auxiliary matrix B , following the proposition in [9], contains information about the edge-node incidence, the lengths of the edges and coefficient δ from (1). The construction of P^{nod} is then performed by the double pairwise-aggregation algorithm proposed in [10]. Once P^{nod} is known, the definition of the coarse edge incidence matrix G^H and the edge prolongator P^{edg} are straightforward. To apply the construction recursively, coarse grid matrices are obtained by Galerkin product:

$$A^H = (P^{\text{edg}})^T A P^{\text{edg}}, \quad B^H = (P^{\text{nod}})^T B P^{\text{nod}}. \quad (4)$$

The smoother is a symmetric version of the smoother proposed in [11] in a geometric multigrid context. It uses on each grid the corresponding edge-node incidence matrix.

III. NUMERICAL RESULTS

The behavior of the method with an increasing size of the problem and several kinds of parameters δ and γ is studied.

A. Structured mesh

The examples are taken from [12]. The domain is a unit square and Dirichlet boundary conditions are enforced. The mesh with triangles is structured but this fact is not used by the solver. For the parameters, three situations are considered:

- 1) Homogeneous parameters: $\delta = \gamma = 1$.
- 2) Oscillating with discontinuities for $\delta = f(x, y)$ and $\gamma = 1$. Function f have the following definition:

$$f = C(2 + \sin(40\pi x))^2(2 + \cos(40\pi y))^2$$

$$\text{with } C = \begin{cases} 10 \text{ in }]0, 0.5[\times]0, 0.5[, \\ 10^4 \text{ in }]0.5, 1[\times]0, 0.5[, \\ 10^{-1} \text{ in }]0, 0.5[\times]0.5, 1[, \\ 10^2 \text{ in }]0.5, 1[\times]0.5, 1[. \end{cases}$$

- 3) Oscillating with discontinuities for $\delta = f(x, y)$ and for $\gamma = f(y, x)$.

The behavior of the iterative method is evaluated by computing the average convergence rate σ_{est} in energy norm:

$$\sigma_{\text{est}} = \left(\frac{\text{er}_k^t \text{Aer}_k}{\text{er}_0^t \text{Aer}_0} \right)^{1/(2k_f)}$$

with er_k the error at the k -th iteration and k_f the iteration where the stopping criterion is reached.

An examination of the convergence rate of the two-grid algorithm provides information to predict the behavior of the multigrid cycle. In Table I, the two-grid convergence rate is quasi-independent of the size of the problem and is bounded away from 1. Case 3 is the worst situation probably because the aggregation does not take into account variation of γ ; it may explain the bad convergence rate for one particular mesh in this case (in bold). The number of unknowns is divided roughly by 4 between fine and coarse grids which is the best trade-off between coarsening and the overall arithmetic complexity.

With such convergence rates for the two-grid solver, it is illustrated in Table II that the convergence rates of the W-cycle (and of course of the V-cycle) deteriorates as the number of grids increases. On the contrary, the convergence rate of the K_2 -cycle has a remarkable stability.

TABLE I
RESULTS OBTAINED WITH A TWO-GRID SOLVER.

	d.o.f. fine grid	736	3008	12160	48896
Case 1	d.o.f. coarse grid	184	751	3040	12224
	σ_{est}	0.62	0.68	0.70	0.71
Case 2	d.o.f. coarse grid	187	788	3087	12404
	σ_{est}	0.64	0.72	0.69	0.69
Case 3	d.o.f. coarse grid	187	788	3087	12404
	σ_{est}	0.61	0.72	0.87	0.68

TABLE II

COMPARISON BETWEEN A W-CYCLE AND A K_2 -CYCLE SOLVER. CASE 3 ON THE MESH WITH 48896 D.O.F.

# grids	3	4	5	6	7
d.o.f. coarsest grid	3279	844	216	55	11
K_2 -cycle, σ_{est}	0.68	0.68	0.68	0.68	0.68
W-cycle, σ_{est}	0.83	0.89	0.93	0.95	0.97

B. Unstructured mesh

Coefficients δ and γ are those defined in Case 3. The domain is still a unit square but an unstructured mesh, refined at the center of the square, is considered. Table III confirms the results obtained for the structured meshes.

TABLE III

COMPARISON BETWEEN A TWO-GRID, A W-CYCLE AND A K_2 -CYCLE SOLVER.

d.o.f. finest grid	2043	8988	36717
two-grid, σ_{est}	0.64	0.61	0.61
# grids	5	6	5
d.o.f. coarsest grid	6	9	216
K_2 -cycle, σ_{est}	0.64	0.62	0.61
W-cycle, σ_{est}	0.90	0.80	0.95

The change of cycling proposed for the RS algorithm seems to make this algorithm robust and optimal in 2D. The proposed algorithm can be straightforwardly extended to 3D problems but our actual Matlab implementation does not enable us to propose results on challenging problems and also to discuss computational time and memory requirements. We are working on an implementation in Fortran90 in order to propose valuable comparisons on realistic problems.

A p -adaptive scheme for scalar fields, using high-order, singular finite elements

J. P. Webb

McGill University, Department of Electrical and Computer Engineering
3480 University Street, Montreal, H3A 2A7, Canada
jon.webb@mcgill.ca

Abstract — For problems with sharp edges, where the electric or magnetic field is singular, p -adaptive finite-element analysis loses some of its effectiveness. This can be remedied by including singular elements which are better able to model the potentials near such edges. The singular elements are hierarchical and the p -adaption takes places over the combined set of singular and regular elements. Results show that a greatly improved adaptive convergence is obtained.

I. INTRODUCTION

The adaptive finite element (FE) method is generally accepted as being an effective technique for computing electromagnetic fields [1]. In p -adaption, the elements of the starting mesh are not changed in shape or size, but instead more basis functions are added to elements in which the unknown field is thought to need improvement. Since most finite elements use polynomial basis functions, this is usually done by increasing the polynomial order of the elements. For this to work, a range of element orders must be available, and they must be hierarchical, so that two neighboring elements can be of different orders without causing a discontinuity in the field.

P -adaption has the advantage over h -adaption that it does not require mesh refinement, which can be costly and unreliable. In smooth regions, away from material interfaces, p -adaption is known to provide exceptional accuracy. However, near sharp corners and edges, where the electric or magnetic field is mathematically singular, p -adaption loses some of its effectiveness. It can be improved by combining it with mesh refinement in hp methods, e.g. [2]. An alternative, which avoids mesh refinement entirely, is proposed here. In the elements connected to the singular corners and edges, the usual polynomial basis functions of the hierarchal elements are replaced by singular basis functions that are better able to represent the field behavior in those regions. The singular elements are also hierarchical and can support p -adaption, which then proceeds on the entire mesh of regular and singular elements.

II. REGULAR AND SINGULAR HIERARCHICAL ELEMENTS

The proposed method computes a scalar potential in 3D, e.g., the magnetic or electric scalar potential. The regular elements are the scalar, hierarchical tetrahedra described in [3]. The p^{th} -order element can represent all polynomials of degree p in 3D.

The singular elements are built from these by a process of transformation. This is explained more fully in [4], but the

main steps are as follows. First, two kinds of singular element are identified: those with just one vertex on a sharp edge (“Point” elements) and those with just two vertices on a sharp edge (“Line” elements). All other elements are assumed to have no vertices on a sharp edge and are regular. New local coordinates are introduced in the Point and Line elements and in both cases, one of the coordinates, ρ , represents the normalized distance from the sharp edge. Next, the polynomial basis functions are re-expressed in the new coordinates. Each then takes the form of a polynomial in ρ .

This polynomial is transformed by replacing each term ρ^k by ρ^{ν_k} , where ν_k are singularity indices. These are non-integer in general and are obtained from the analytic expression for the scalar potential near a sharp edge. They depend on the geometry and materials at the edge. For example, if two zero-potential plates meet at an interior angle $\alpha > \pi$, forming a sharp edge, the indices are $\nu_k = k\pi/\alpha$.

The transformation produces a set of new basis functions that are much better at modeling the potential near the singularity. Moreover, the p^{th} -order singular element has the same number of basis functions as the p^{th} -order regular element, and the Line, Point and regular elements may all be set to any orders without introducing discontinuities in the potential.

III. ERROR INDICATOR AND THE ADAPTION SCHEME

At each adaptive step, the order of element e is increased or not depending on the value of an error indicator. The indicator used in this work exploits the hierarchical nature of the elements and is based on the approach taken in [5], though that work described an indicator specifically for the scattering parameters of a microwave device.

Suppose the discrete, weighted-residual problem solved at any stage of the adaption is to find the unknown potential u belong to a discrete space V :

$$a(u, w) = b(w) \quad \forall w \in V \quad (1)$$

where a and b are bilinear and linear forms, respectively, and w is a weight function. Let V_e be the slightly larger function space in which the order of element e has been increased by 1, and let u_e be the discrete solution in this larger space. The error indicator is an estimate of the square of the energy norm of the difference between u and u_e :

$$a(u_e - u, u_e - u) \quad (2)$$

It can be shown that expression (2) is exactly equal to

$$b(u_e - u) - a(u_e - u, u) \quad (3)$$

but that (3) is more accurate than (2) when u_e is approximated, which it must be because it would be too expensive to obtain u_e exactly. It is approximated by $u + \Delta u_e$, where u is the solution to (1), as before, and Δu_e is a linear combination of just the *new* basis functions added to element e when its order is increased. Let ΔV_e be the space spanned by these new basis functions. To determine Δu_e , we solve:

$$a(u + \Delta u_e, \Delta w_e) = b(\Delta w_e) \quad \forall \Delta w_e \in \Delta V_e \quad (4)$$

This results in a local matrix problem, equal in dimension to the number of extra basis functions added to element e . It is solved for each element in the problem. From (3), the indicator is:

$$I_e = |b(\Delta u_e) - a(\Delta u_e, u)| \quad (5)$$

At each adaptive step, the elements are ranked according to (5) and a specified fraction of them with the highest errors have their orders increased by 1. This fraction is set to 25% for the results below.

IV. TEST CASE

The adaptive algorithm is applied to the geometry shown in Fig. 1, which shows a gap between two stripline transmission lines. Half the geometry is shown: there is a plane of symmetry at $x=0$. The gap capacitance is found by setting the electric potential on the narrower strip to 1V, and on the wider strip to 0V. The box walls at $y=0$, $y=b$ and $x=0$ are left unconstrained, and the other three box walls are constrained to 0V. Solving this electrostatic problem by the FE method gives the potential throughout the box, from which the stored energy and capacitance can be found.

Fig. 1. A gap between two stripline transmission lines. $b=11a/5$, $h=a/5$. The strips are of equal length and the gap between them is $a/5$. The wider strip has a half-width (shown) of $2a/5$ and the narrower strip has a half-width of $a/5$.

The volume is subdivided into a coarse, unstructured mesh of 160 tetrahedra. For the case “**Singular adaption**” in Fig. 2, the tetrahedra touching the sharp edges (shown with thick red lines in Fig. 1) are made into singular Line or Point elements. In the “**Regular adaption**” case, all the elements use polynomial basis functions. Each point shows the result of one FE solution in the adaptive iteration, starting with all element orders equal to 1. The highest element order allowed is 4. The sharp edges have an interior angle $\alpha = 2\pi$, so $\nu_k = k/2$. Nothing special is done about the two sharp *corners* that are present, where the behavior of the potential is different.

A reference value of the stored energy is obtained by using independent FE software [6] with an h -adapted mesh of 116,803 third-order tetrahedra. The reference value is estimated to be within 0.1% of the true energy.

Fig. 2 clearly shows the limitation of traditional p -adaption. Using only regular elements, the error cannot be made smaller than about 5%. On the other hand, by including singular elements, not only does the error fall more swiftly as the adaption proceeds, but the final accuracy is about 0.6%.

Fig. 2. Error in computed energy versus the number of degrees of freedom for the stripline example, during an adaptive solution using either regular elements alone, or a combination of regular and singular elements.

A Discrete (2+1)-D Formulation for 3-D Field Problems with Continuous Symmetry

Bernhard Auchmann*, Bernd Flemisch†, and Stefan Kurz‡

*CERN/TE, Geneva, Switzerland, Email: bernhard.auchmann@cern.ch,

†Universität Stuttgart, IWS, Stuttgart, Germany, ‡ETAS GmbH, Stuttgart, Germany

Abstract—We describe a general formalism that allows to reduce the spatial dimension of a field problem from 3-D to (2+1)-D. Subsequently we identify conditions under which the third dimension can be eliminated. Eventually we see that the resulting 2-D field problems only decouple if an orthogonality criterion is fulfilled. The approach is based solely on differential-form calculus and can therefore be easily transferred into a discrete setting. As a numerical example we compute the fields of twisted wires.

Index Terms—Continuous Symmetries, Dimensional Reduction, Discrete Electromagnetism

I. DIMENSIONAL REDUCTION

DIMENSIONAL reduction occurs in different contexts: Relativistic 4-D field problems are reduced, mostly implicitly, to 3-D problems with time as a parameter. 3-D problems with symmetries (axi-symmetry, symmetry along a Cartesian axis) are reduced to 2-D problems. This paper constitutes a step in the endeavor to unite all different aspects in a single, differential-form based framework.

We denote by \mathcal{X}^p the space of p -vector fields of tangent vectors on a 3-dimensional Riemannian manifold M , and by \mathcal{F}^p the space of differential p -forms on M . We use the *generalized contraction operator* $i : \mathcal{X}^q \times \mathcal{F}^p \rightarrow \mathcal{F}^{p-q} : (\mathbf{v}, \omega) \mapsto i_{\mathbf{v}}\omega$, $p \geq q$, which is induced from the standard contraction with a 1-vector according to the rule $i_{\mathbf{w}\wedge\mathbf{u}} = i_{\mathbf{u}}i_{\mathbf{w}}$ for $\mathbf{u} \in \mathcal{X}^1$, $\mathbf{w} \in \mathcal{X}^{q-1}$. Moreover we define the *multiplication operator* as $j : \mathcal{F}^1 \times \mathcal{F}^p \rightarrow \mathcal{F}^{p+1} : (\boldsymbol{\mu}, \omega) \mapsto j_{\boldsymbol{\mu}}\omega = \boldsymbol{\mu} \wedge \omega$. The operators i and j are defined in the obvious way on the respective dual spaces, [2]. The duality product is denoted by $\cdot | \cdot$.

Let $\boldsymbol{\mu} \in \mathcal{F}^1$ be an exact 1-form $\boldsymbol{\mu} = d\lambda$ that defines a (codimension one) foliation of the 3-dimensional manifold M . $\varphi : U \rightarrow M$ denotes the embedding of the 2-dimensional manifold U in M at $\lambda = \text{const}$. We define the horizontal (w.r.t. the foliation) component of a differential form by the introduction of a directional vector field $\mathbf{u} \in \mathcal{X}^1$ that is transversal to the foliation so that $i_{\mathbf{u}}\boldsymbol{\mu} = 1$. We denote $\mathcal{F}_{\mathbf{u}}^p := \{\omega \in \mathcal{F}^p | i_{\mathbf{u}}\omega = 0\}$ the space of horizontal differential forms and $\mathcal{X}_{\boldsymbol{\mu}}^p = \{\mathbf{v} \in \mathcal{X}^p | i_{\boldsymbol{\mu}}\mathbf{v} = 0\}$ the space of horizontal vector fields. The horizontal component $\omega_{\parallel} \in \mathcal{F}_{\mathbf{u}}^p$ of a form ω is defined by the relation $\omega_{\parallel} | \varphi_*\mathbf{v} = \varphi_*\omega | \mathbf{v}$, $\mathbf{v} \in \mathcal{X}^p(U)$. It can be shown that $\omega_{\parallel} = i_{\mathbf{u}}j_{\boldsymbol{\mu}}\omega$. Moreover, each $\omega \in \mathcal{F}^p$ can be uniquely represented by a pair of horizontal forms $(\omega_{\parallel}, \omega_{\perp}) = (i_{\mathbf{u}}j_{\boldsymbol{\mu}}, i_{\mathbf{u}})\omega \in \mathcal{F}_{\mathbf{u}}^p \times \mathcal{F}_{\mathbf{u}}^{p-1}$. Conversely, $\omega = \omega_{\parallel} + j_{\boldsymbol{\mu}}\omega_{\perp}$.

For all relevant operators of exterior calculus on M we introduce counterparts (denoted by a hat) that are defined on

the horizontal subspaces. On the other hand, these operators are defined on U as well (subscripted by U), either intrinsically or induced by the embedding. For example, for the *horizontal exterior derivative* $\hat{d} := i_{\mathbf{u}}j_{\boldsymbol{\mu}}d : \mathcal{F}_{\mathbf{u}}^p \rightarrow \mathcal{F}_{\mathbf{u}}^{p+1}$ it can be shown that $\varphi^* \circ \hat{d} = d_U \circ \varphi^*$.

Let $g : \mathcal{X}^p \rightarrow \mathcal{F}^p$ denote the Riesz isomorphism of the metric on M . We define $\hat{g} : \mathcal{X}_{\boldsymbol{\mu}}^p \rightarrow \mathcal{F}_{\mathbf{u}}^p$ such that $\hat{g}\mathbf{v} | \mathbf{w} = g\mathbf{v} | \mathbf{w} \forall \mathbf{v}, \mathbf{w} \in \mathcal{X}_{\boldsymbol{\mu}}^p$. If g_U denotes the Riesz isomorphism of the induced metric on U , then $g_U = \varphi^* \circ \hat{g} \circ \varphi_*$.

Let $\Omega \in \mathcal{F}^3$ denote the normalized and $\hat{\Omega} := i_{\mathbf{u}}\Omega \in \mathcal{F}_{\mathbf{u}}^2$ the *horizontal volume form* on M , $\hat{\Omega} | \hat{g}^{-1}\hat{\Omega} = 1$. Then $\Omega_U = \pm \varphi^*\hat{\Omega}$, depending on the orientation of U . We assume that U is oriented such that the positive sign holds.

The explicit definition of the Hodge operator on M reads $* : \mathcal{F}^p \rightarrow \mathcal{F}^{3-p} : \alpha \mapsto i_{\hat{g}^{-1}\alpha}\hat{\Omega}$. The *horizontal Hodge operator* is defined analogously, $\hat{*} : \mathcal{F}_{\mathbf{u}}^p \rightarrow \mathcal{F}_{\mathbf{u}}^{2-p} : \alpha \mapsto i_{\hat{g}^{-1}\alpha}\hat{\Omega}$, and again $\varphi^* \circ \hat{*} = *_U \circ \varphi^*$.

II. CONTINUOUS SYMMETRY

We use the above definitions to decompose the magnetic vector potential A , the electric current density J , and eventually the curl-curl equation of magnetostatics, $d \frac{1}{\mu} * dA = J^1$:

$$\begin{pmatrix} \hat{d} & 0 \\ \mathcal{L}_{\mathbf{u}} & -\hat{d} \end{pmatrix} \frac{1}{\mu} \hat{*} \begin{pmatrix} -\eta i_{\mathbf{v}} & \eta \\ \frac{1}{\eta}(1 + \eta^2 j_{\boldsymbol{\nu}} i_{\mathbf{v}}) & -\eta j_{\boldsymbol{\nu}} \end{pmatrix} \begin{pmatrix} \hat{d} & 0 \\ \mathcal{L}_{\mathbf{u}} & -\hat{d} \end{pmatrix} \begin{pmatrix} A_{\parallel} \\ A_{\perp} \end{pmatrix} = \begin{pmatrix} J_{\parallel} \\ J_{\perp} \end{pmatrix}, \quad (1)$$

where $\eta = \|\boldsymbol{\mu}\|$, $\boldsymbol{\nu} = (g\mathbf{u})_{\parallel}$, and $\mathbf{v} = \hat{g}^{-1}\boldsymbol{\nu}$. The 2x2 block representation of the exterior derivative and the Hodge operator in terms of the horizontal operators has been derived in [1], eq. (19) and (46)², respectively.

Continuous symmetry means that \mathbf{u} denotes a direction in which the Lie derivatives $\mathcal{L}_{\mathbf{u}}$ vanish, i.e. no variation of fields, material parameters and metric (\mathbf{u} is a Killing field) along \mathbf{u} .

For the system (1) to be decoupled, we need the symmetry direction \mathbf{u} to be orthogonal to the foliation, thus $\boldsymbol{\mu} \wedge g\mathbf{u} = 0$, or, equivalently $\boldsymbol{\nu} = \mathbf{v} = 0$. Since $g\mathbf{u}$ is not an integrable form in general, a foliation that ensures decoupling does not generally exist.

¹ μ denotes the linear magnetic permeability, not to be confused with the 1-form $\boldsymbol{\mu}$.

²Note that the parameters \mathbf{v} and $\boldsymbol{\nu}$ are defined slightly differently in [1]. \mathbf{v} in [1] has to be replaced by $-\xi\eta^2\mathbf{v}$, and $\boldsymbol{\nu}$ by $-\frac{1}{\xi}\boldsymbol{\nu}$.

III. DISCRETIZATION

A mimetic discretization of the pulled-back version of (1) requires discrete counterparts of each of the operators. For this paper we restrict ourselves to 2-D triangular meshes and first-order approximation of p -forms by p -cochains. The derivative operators are well-known to be discretized by incidence matrices. For a discrete Hodge operator we refer to [3], among several possibilities.

The vector-field \mathbf{v} can be discretized by a 1-chain v , see [4]. The 1-form ν and the right-hand side forms are discretized by the de Rham map. The multiplication operator can be derived from the discrete cap product [5] that approximates the continuous wedge product.

A discrete contraction operator has been proposed in [4]. We give a brief outline of the basic concept. The continuous contraction fulfills $i_v \beta | s = \lim_{t \rightarrow 0} t^{-1} \beta | \text{extr}(s, \mathbf{v}, t)$ for a 2-form β , a 1-vector-field \mathbf{v} , and a 1-chain s ³. The extrusion of s in the 2-manifold U is done by transporting the points of s by the flow of the vector-field \mathbf{v} , parameterized by t .

On the discrete level we wish to contract a 2-cochain β by a 1-chain v which stems from the discretization of \mathbf{v} . To this end we extrude all edges e_i in the complex by edges e_j , $j \neq i$. If the edges i and j coincide in a node, the result of the extrusion is a triangle spanned by the two edges which can be approximated by a 2-chain. The extrusion is the empty point-set otherwise. Next the extrusion 2-chain is mapped to the reals by the 2-cochain β . Eventually the above limit process yields

$$i_v \beta | e_i = \sum_j \sum_k \frac{|\mathbf{e}_i \wedge \mathbf{e}_j|}{|\mathbf{f}_k|} v^j \lambda_{ij}^k \beta_k \quad (2)$$

which defines the i -th coefficient of the 1-cochain $i_v \beta$. The factor λ_{ij}^k equals the orientation $\text{or}(\mathbf{e}_i \wedge \mathbf{e}_j)$ if the triangle formed by e_i and e_j has a nonzero intersection with the positively oriented face f_k , and 0 otherwise. Bold-font letters denote the 1- and 2-vectors for edges and faces, and v^j and β_k are the chain and cochain coefficients of v and β , respectively.

This result has been validated by numerical experiments, it differs however from the formulae given in [4], [6].

IV. HELICOIDAL SYMMETRY - NUMERICAL EXAMPLE

In the axi-symmetric case we use cylindrical coordinates (r, φ, z) and set $\boldsymbol{\mu} = d\varphi$, $\mathbf{u} = \partial_\varphi$, and hence $\eta = \frac{1}{r}$. For $\mathcal{L}_{\partial_\varphi} = 0$ we find with $\boldsymbol{\nu} = 0$ and $\mathbf{v} = 0$

$$-\hat{d} \frac{1}{r} \frac{1}{\boldsymbol{\mu}} \hat{*} \hat{d} A_\perp = J_\parallel, \quad -\hat{d} r \frac{1}{\boldsymbol{\mu}} \hat{*} \hat{d} A_\parallel = J_\perp, \quad (3)$$

as the dimensionally reduced representation of the curl-curl equation.

As an example of a non-orthogonal splitting, we use helicoidal coordinates (R, ϕ, Z) , $R = r$, $Z = z$ and $\phi = \varphi - \alpha z$, to represent thin wires along $\mathbf{u} = \partial_Z$. The foliation is given by $\boldsymbol{\mu} = dZ$. We compute $\eta = 1$, $\boldsymbol{\nu} = \alpha R^2 d\phi$, and $\mathbf{v} = \alpha \partial_\phi$.

With this information at hand we proceed to a mimetic discretization of (1). The kernel of the system matrix is

³This is essentially the same as requiring $i_v \beta | \mathbf{w} = \beta | j_v \mathbf{w}$.

composed from the space of constant 0-cochains (A_\perp part) and the image of the discrete gradient (A_\parallel part). A regularization scheme $S' = S + KK^T$ is employed, where S is the system matrix, K is a basis of the kernel of S , and S' is the regularized matrix. This approach is feasible despite the asymmetry of S since $\text{kern} S = \text{kern} S^T$.

As an example we calculate the fields of three twisted wires for vanishing sum of the three currents through the 2-D cross-section U , see Fig. 1.

Fig. 1. Left: Currents flowing along helicoidal paths through a 2-D cross-section U . Right: Vector proxies of the parallel magnetic induction in U .

V. CONCLUSION

We have given a (2+1)-D formulation of 3-D magneto-static field problems. Continuous symmetry along a transversal direction eliminates the third dimension. In case there exists a foliation that is orthogonal to the symmetry direction, the equations can be decoupled, resulting in two independent 2-D field problems.

We have applied the theory to a field problem with helicoidal symmetry and successfully produced first results. A thorough validation will follow in the full paper. During the process we have had to reopen the question how to properly discretize the contraction operator. Additional work is required to provide an answer in more general cases, including an analysis of the mimetic properties of the discrete contraction. We will get back to this matter in the full paper as well.

Abstract—A discrete 1D Green's function for accurately computing the 2D electromagnetic field in complicated domains is introduced. The key advantages of the proposed method is laid on the accuracy as well as the availability on complex domains. The 2D Green's function for solving electromagnetic field computations in a 2D domain is strongly depend on the geometry of the domain. The boundary element method uses only the fundamental solution instead of the Green's function itself since it is even easier to find the fundamental solution than to do the Green's function. In this case, however, attentions must be paid, due to the singularity of the fundamental solution, to the singular integrals on the boundary of the domain. It is another merit of our method to circumvent such a singular integral.

I. INTRODUCTION

Green's function methods for solving electromagnetic field computations in 2D strongly depend on problem domains. The boundary element method [1], [2] is well known technique using only the fundamental solution instead of the Green's function since it is even easier to find the fundamental solution than to do the Green's function itself. However, attentions must be paid in this case to the singular integrals over the boundary since the fundamental solution has the blow-up singularity at a singular point. To avoid the singular integral and accurately compute the 2D electromagnetic field in complicated domains, we introduce a discrete 1D Green's function for a 1D differential operator separated from the 2D differential one to govern the electromagnetic field in a 2D domain.

The first attempt has been made to solve the higher dimensional elliptic boundary value problems using the axial Green's function method (AGM) [3]. As a matter of fact, although the AGM is an accurate approach in a complicated domain, it needs the numerical integration on parallel lines to each axis in 2D to solve the elliptic type of boundary value problems since the axial Green's function is found in an integral form due to variable coefficient. In case of the static electromagnetic field, the governing equation has the type of Poisson problem which is elliptic with constant coefficient, so that we can find the discrete 1D Green's function simpler than the axial Green's function of AGM. It has nothing to do with numerical integrations. Since the numerical integrations is in general a time consuming work, it becomes more efficient way to use the discrete 1D Green's function proposed in this paper instead using the axial Green's function in [3]. Through the static

electromagnetic field computation, we show the efficiency and accuracy of the method using the discrete 1D Green's function.

II. DISCRETE 1D GREEN'S FUNCTION METHOD

Let us first consider the following Dirichlet problem in 1D which can describe the 1D electrostatic potential:

$$L_t(u) \equiv u''(t) = f(t) \quad \text{in } \Omega = [a, b] \quad (1)$$

$$u(a) = u_a, u(b) = u_b. \quad (2)$$

Assume $P_n = \{a = t_0 < t_1 < \dots < t_n = b\}$ is an arbitrary partition of the interval $[a, b]$. If $\bar{u}_h(t)$ is a piecewise linear interpolation for a given function $u(t)$ on P_n , then it is readily obtained that

$$\bar{u}_h(t) = \sum_{k=1}^{n-1} \frac{1}{2} \left(\frac{u(t_{k+1}) - u(t_k)}{\Delta t_{k+1}} - \frac{u(t_k) - u(t_{k-1})}{\Delta t_k} \right) |t - t_k| + At + B \quad (3)$$

for some constants A and B where $\Delta t_k = t_k - t_{k-1}$ is the length of k -th subinterval on $[a, b]$. Applying the boundary conditions (2) and then rearranging terms, the interpolation in (3) can be translated into

$$\bar{u}_h(t) = \sum_{k=1}^{n-1} \frac{1}{2} \beta_k(u) G(t, t_k; a, b) + u^B(t; a, b, u_a, u_b) \quad (4)$$

provided we define

$$\beta_k(u) \equiv \frac{u(t_{k+1}) - u(t_k)}{\Delta t_{k+1}} - \frac{u(t_k) - u(t_{k-1})}{\Delta t_k}, \quad (5)$$

$$G(t, \tau; a, b) \equiv |t - \tau| - \left[\frac{b-t}{b-a} |a - \tau| + \frac{t-a}{b-a} |b - \tau| \right], \quad (6)$$

$$u^B(t; a, b, u_a, u_b) \equiv u_a \frac{b-t}{b-a} + u_b \frac{t-a}{b-a}. \quad (7)$$

As a matter of fact, the coefficient $\beta_k(u)$ can be written as follows for $k = 1, 2, \dots, n-1$,

$$\beta_k(u) = u''(t_k) \frac{\Delta t_k + \Delta t_{k+1}}{2} + \frac{1}{6} (u'''(t_k^+) \Delta t_{k+1}^2 - u'''(t_k^-) \Delta t_k^2) \quad (8)$$

for some t_k^\pm with $t_{k-1} < t_k^- < t_k < t_k^+ < t_{k+1}$.

Based on the interpolation (3) and the approximation (8), the inverse differential operator approximated with second order accuracy for the 1D problem in (1) and (2) is obtained as the form

$$u_h(t) = \sum_{k=1}^{n-1} \frac{1}{2} h_k f(t_k) G(t, t_k; a, b) + u^B(t; a, b, u_a, u_b) \equiv \langle f, G_t \rangle + u_t^B = L_t^{-1}(f) \quad (9)$$

where $h_k = \frac{1}{2}(\Delta t_k + \Delta t_{k+1})$ implies the average length of adjacent subintervals at t_k for $k = 1, 2, \dots, n-1$.

It can be proved that the approximate solution in (9) has $O(h^2)$ -convergence for arbitrary subintervals due to (8). We call $\frac{1}{2}G$ in (9) the discrete 1D Green's function since it acts as a Green's function in a discrete sense.

III. OPERATOR DECOMPOSITION FOR 2D ELECTROSTATIC POTENTIAL PROBLEM

The electrostatic potential problem in 2D is expressed in the Poisson problem. Assume Ω is an open bounded domain in \mathbb{R}^2 and $\mathbf{x} = (x, y)$ a point in Ω . Using the 1D inverse operator in (9), our aim is to solve the 2D Poisson problem defined by

$$L_x(u) + L_y(u) = u_{xx} + u_{yy} = f \quad \text{in } \Omega, \quad (10)$$

$$u = u^{\partial\Omega} \quad \text{on } \partial\Omega. \quad (11)$$

Introducing a new variable ϕ enables us to decompose the Poisson equation into two equations

$$L_x(u) = \phi \quad \text{in } \Omega, \quad (12)$$

$$L_y(u) = f - \phi \quad \text{in } \Omega, \quad (13)$$

$$u = u^{\partial\Omega} \quad \text{on } \partial\Omega. \quad (14)$$

As a result of elimination of u (see [3]) from (12), (13), and (14) at the cross point $(x_i, y_j) \in \Omega$ of x -axial line(X_{y_j}) and y -axial line(Y_{x_i}) illustrated in fig 1(left), we can write

$$L_x^{-1}(\phi) = L_y^{-1}(f - \phi) \quad \text{at } (x_i, y_j) \in \Omega, \quad (15)$$

provided (x_i, y_j) is a cross point of x -axial line X_{y_j} and y -axial line Y_{x_i} . Equivalently, from the definitions of the bracket $\langle \cdot, \cdot \rangle$ and the boundary value operator u^B in (9), the formulation for ϕ becomes

$$\langle \phi, G_x \rangle + u_x^B = \langle f - \phi, G_y \rangle + u_y^B \quad \text{at } (x_i, y_j) \in \Omega. \quad (16)$$

After discretizing and solving the resultant linear system in (16) by the BiCGM, we obtain ϕ and then by inserting it into (9) instead of f the numerical solution u_h can be calculated. Moreover, directly differentiating it, the first order derivatives are estimated on any cross point.

IV. NUMERICAL RESULTS AND CONCLUSION

Fig 1, the error decay of u_h is of order $O(h^2)$ and its first derivatives have the convergence rate faster than $O(h)$. The uniform axial lines are used in this case and it is also checked that the same convergence order can be achieved even in non-uniformly distributed axial lines. Fig 2 shows the numerical solution for the electrostatic potential problem on L -shaped

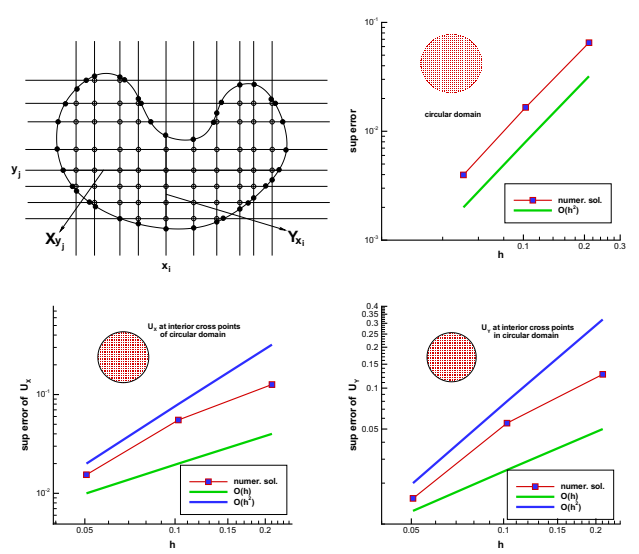

Fig. 1. Schematic diagram for axial lines X_{y_j} and Y_{x_i} which meet at (x_i, y_j) (top left), $O(h^2)$ convergence rates of the numerical solution $U = u_h$ (top right) and its first derivatives U_x (bottom left) and U_y (bottom right): Exact solution $u(x, y) = \cos(xy)$ in $(x-3)^2 + (y-3)^2 < 1.5^2$.

Fig. 2. 2D electrostatic potential problem: Domain configuration(left) and the numerical solution u_h (right)

domain. Although the exact solution u is known to have a derivative singularity at the corner, the discrete 1D Green's function method for the 2D electrostatic problem yields an accurate numerical solution. As we anticipated from the fact that there is no numerical integrations at all, this method is far faster than the original AGM in [3] particularly for the Poisson problem. Our method is not a difference scheme but rather close to the integral one, so that it helps the method stable and accurate.

Abstract— we introduce a parallel programming method to solve massive matrix multiplications on multi-core and multi-GPU platform with CUDA. Based on the different power features of each power-related processing element (PE) including CPUs and GPUs, we provide a load scheduling approach to adjust the workload distribution among each PE in order to optimize the overall power efficiency of the system during the matrix computation. On GPU kernel programming, some memory management methods have been implemented for enhancing the utilities of GPU shared memories therefore accelerating computation speed. The timing and power consumptions have been measured when the above methods have been implemented. Comparing with non load scheduling program, it can save up to 25% of energy; also the multi GPU timing performance has enhanced 40% than single GPU.

Index Terms—Software Methodology: (g) programming techniques, (h) massively parallel algorithms.

I. INTRODUCTION

An optimal way of multiplying matrices is a fundamental operation in solving electromagnetic problems requiring large numbers of elements for high-accuracy solutions. Faster matrix multiplication would give more efficient algorithms for many standard linear algebra problems, such as solving systems of linear equations and finding determinants. The performance of matrix multiplication is highly dependent on the underlying computational algorithm as well as the system architecture. The Graphics Processing Units (GPU) are now considered as serious challengers for high-performance computing solutions because of its suitability for massively parallel processing and vector computations. However they have power consumptions up to 300W. Power efficiency investigation is also required by program design because a large scale computation may need hundreds hours of continuous execution, the program design strategies will significantly affect the overall energy expense. [1]

We introduce in this paper (1) Parallel matrix multiplication by Parallel CUDA kernel on multi-GPUs.to reach a very high GFLOPS. (2) A load balancing approach to adjust the workload distribution therefore minimizing the power consumption. (3) The performance results. [2], [3]

II. LARGE MATRIX MULTIPLICATION ON CPU-GPU MULTIPROCESSING PLATFORM

For given matrices $A \in R^{m \times n}$ and $B \in R^{n \times m}$, there are various algorithms to implement $C = AB$ in parallel. Here we partition the matrix A, let $A = (A_1^T, A_2^T \dots A_n^T)^T$, where $A_i \in R^{1 \times n}$ ($i = 1, 2, \dots, n$) is each row in matrix A. We calculate $C = AB$ follow the procedure, as shown in Fig 1.

- (1) Assign computations $(A_{im/p+1}, \dots, A_{(i+1)m/p})B$ to GPU i ($i = 0, 1, \dots, p-1$);
- (2) Run local computation on each GPU $(C_{im/p+1}, \dots, C_{(i+1)m/p}) = (A_{im/p+1}B, \dots, A_{(i+1)m/p}B)$;
- (3) Write the result in matrix C to CPU memory.

GPU is viewed as a compute device operating as a processor to the main CPU (host). Data-parallel, compute intensive functions should be loaded to the GPU device. Also a different level of parallelism is applied on CPU side with OpenMP to parallelize applications in a coherent and efficient way. A CUDA kernel can be called by any of the CPUs running OpenMP. To well utilize the GPU shared memory in one block, we schedule the workload segment as same size as the shared memory, this can significantly improve GPU efficiency. The usage of Multi-GPU can gain 40% speedup than single GPU. (The programming details will be provided in the long paper).

Fig.1 Parallel Matrix Multiplication on Multi CPU-GPU platform

III. POWER AWARE

In a multiprocessing system, power can be defined at various levels of granularity such as system, cores, and components, represented as P_{system} , P_{core} , $P_{component}$. the overall system power consumption can be defined as (1)

Fig.2. Scheduled workload for Matrix Multiplication on Multi CPU-GPU platform

$$P_{system}(w) = \sum_{i=1}^N P_{CPU}^i(w^i) + \sum_{j=1}^M P_{GPU}^j(w^j) + P_{comm} + P_{heat} \quad (1)$$

Where N is the number of CPU cores, M is the number of GPUs, w is the workload, w^i and w^j represent the workload assigned to the CPU i and GPU j , respectively. If a core i is composed by k components and a GPU is composed by l components, their power consumption can be represent as

$$P_{CPU}^i = \sum_{n=1}^k P_{CPU}^{(i,k)}(w^i) \text{ and } P_{GPU}^j = \sum_{n=1}^l P_{GPU}^{(j,l)}(w^j), \text{ respectively.}$$

A basic principle for power aware load scheduling is to (1) try to move workloads to low-power component; (2) minimize the number of used high-power component; (3) try to reduce the working time, in order to save system power.

In this work, (1) and (3) have been implemented. In detail we schedule the portion of the computations to be run on CPUs by using multi threads, then the CPU utilization is enhanced, and the overall time performance is improved, finally the total energy consumption is reduced. We change

- (1) Assign computations ($A_{im/p+1}, \dots, A_{(i+1)m/p-k}$) B to GPU i ($i = 0, 1, \dots, p-1$);
- (2) Assign computations ($A_{(i+1)m/p-k}, \dots, A_{(i+1)m/p}$) B to CPU i ($i = 0, 1, \dots, p-1$);
- (3) Run local computation on each CPU and GPU, and then write the result in matrix C to CPU memory.

Where k is the number of vectors to be assigned to CPU, also in above algorithm, we assume the number of CPU and GPU are same. (We will provide detailed approach in the long paper).

IV. RESULTS

We provide the results from DELL M1730 with duo cores platform composed by 2 Intel(R) Core(TM) 2 Extreme CPU X9000 @ 2.80GHz, and two Nvidia GeForce graphic cards 8800MGTX. One thing need to be noted that, the double precise in CPU is 64bits; however GPU can only use float which is 32bits. We use Kahan Summation Formula to improve the precision for the multiplication result.

We calculated $m \in [1000, 10000]$ and $n \in [2000, 20000]$ double precise matrix multiplication on above CPU-GPU platforms utilizing the GPU programming method in (I) and power aware load scheduling method in (II). The peak performance for one GPU can reach 654.82 GFLOPS. The timing result is shown in Fig.1. When applying load scheduling, we have 20-30% speedup than without load scheduling. (Detail analysis will be in the long paper)

Fig.3. Timing Performance

Fig.4. Power Performance

We have measured the power consumption of the computation by using power analyzer from AC power input, and without AC power by measure the battery. The power consumption values measured from the program are shown in Fig. 4. The Load balancing approach can improve power performance around 5 -30% depending on the problem size and working environment (in this DELL M1730).

V. CONCLUSION

A CPU-GPU programming method for large- scale matrix multiplication on multi-core platform has been proposed. Power aware load scheduling approach are introduced to the algorithm model for timing and power performance improving.

Abstract— A wide class of finite element electromagnetic applications require computing very large sparse matrix vector multiplications (SMVM). Due to the sparsity pattern and size of the matrices, solvers can run relatively slowly. The rapid evolution of graphic processing units (GPUs) in performance, architecture and programmability make them very attractive platforms for accelerating computationally intensive kernels such as SMVM. This work presents a new algorithm to accelerate the performance of the SMVM kernel on the NVIDIA graphic cards.

I. INTRODUCTION

The performance of finite element (FE) electromagnetic applications can be dominated by the iterative solvers used, such as conjugate gradient (CG) based methods. As problems become larger and more complex, the computation overhead of these kernels dramatically increases the execution time of such solvers on single core CPUs. Thus the development of efficient methods to improve the performance of iterative solvers on parallel processors is almost inevitable.

One of the most important kernels in iterative solvers such as the CG method is the sparse matrix vector multiplication (SMVM). This operation is performed at each iteration and often consumes a majority of the computation time. The main objective of the SMVM kernel is to calculate Ax where A is a sparse matrix and x is a dense vector. Major limitations of SMVM computation involving FE matrices are large memory storage and bandwidth requirements as well as indirect and irregular memory accesses.

Graphic Processing Units (GPUs) have recently evolved into very attractive commodity data-parallel coprocessors. Easy to learn programming interfaces such as CUDA [1] have allowed massive multithreading and increased utilization of large numbers of cores on the GPU, making them cost efficient highly parallel platforms to solve computationally intensive scientific problems [2].

The main objective of this work is to accelerate the performance of finite element SMVM kernels on the NVIDIA GT 8800 graphic cards using a new algorithm, namely PCSR (Prefetch-Compressed Row Storage).

II. GPU ARCHITECTURE

The NVIDIA GT 8800 graphic card (Fig. 1) consists of 12 *streaming multiprocessors* (SMs), each containing eight *scalar processors* (SPs), or processors cores running at 1.5GHz. Each of the SMs access a separate 16KB shared Memory and a total of 8192 registers. The 12 SMs are connected via 512MB of off-chip device memory.

Using the CUDA programming model, the GPU is viewed as a compute device capable of executing a large number of threads in parallel. While the main core of the code is run on the CPU, parts of the applications that exhibit rich data parallelism are implemented as kernel functions on the device

(GPU). Data required by the kernel is transferred to the GPU global memory and the parallel portion of the application is then executed on the device using many different threads. The programmer divides the threads into threads blocks which are distributed amongst the SMs allowing each multiprocessor to run a maximum of 8 blocks. Thread blocks allocated to one SM communicate via fast shared memory, but blocks from different SMs can only communicate through global memory with a memory access latency of up to 600 cycles. Every 32 threads in a block execute the same instruction and are called a warp. When threads in the same warp follow different paths of control flow, we say that these threads *diverge* in their execution. Thread divergence forces the threads in a warp to execute sequentially thus reduces the execution speed of the application and should be avoided [1].

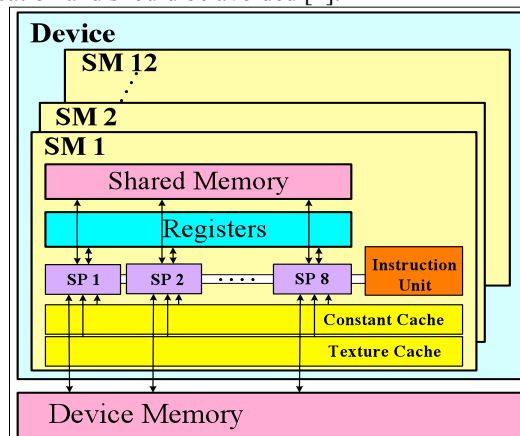

Fig. 1. The GT8800 underlying architecture.

III. SMVM IMPLEMENTATION ON GPUS

The SMVM kernel is one of the most popular operations in finite element simulations. One of the most commonly used data structures for solving such kernels is the Compressed Row Storage (CSR) format. CSR stores the nonzero elements of the sparse matrix into a value vector (VAL) while a corresponding array (INDX) holds the column index of each entry. The format also uses a pointer array (PTR), which points to the first entry of each row in VAL and INDX [3].

Although the computation capabilities of GPUs are very promising (up to 250GFLOPS for GT8800), many challenges exist in optimizing the performance of scientific applications such as the SMVM kernel on such platforms. Some are as follows: global memory access latency, limited shared memory, thread synchronizations, thread divergence, inadequate number of threads and limited global memory bandwidth. The way the programmer addresses these issues differs depending on the application [1].

Since the release of CUDA in 2007, few works have investigated the SMVM kernel optimization on the GPUs.

Buatois *et al.* [4] investigated the performance of Blocked-CSR on the G80 series of NVIDIA graphic cards. Their method does not address thread divergence and is not efficient for sparse matrices with small average non-zeros per row. Sengupta *et al.* [5] proposed the use of segmented scan for calculating SMVM on GPUs. Wiggers *et al.* [6] reorders the matrix rows to increase parallelism in the SMVM kernel. Compared to previous work, our proposed algorithm introduces new methods to hide global memory access latency (data prefetch) and also introduces a new partitioning scheme that enables the programmer to achieve maximum performance by changing the size of the partitions for each block and thread. Detailed description of the methods and its major contributions are described in the next section.

IV. THE PREFETCH-CSR ALGORITHM

The proposed algorithm, PCSR (Prefetch-Compressed Row Storage), is composed of a novel partitioning scheme and a kernel implementation strategy. The partitioning scheme determines the number of threads per block (n) and blocks per kernel (m) during execution. The VAL and INDX vectors in the CSR format are first padded with zeros to be divisible into m equal sections, each sent to a separate block. As shown in Fig. 2, each block then calculates their allocated section of the value vector in n iterations. While some threads are prefetching the required data for iteration $x+1$ from global memory into shared memory, the remaining threads proceed with the addition and multiplications required to calculate the result vector related to rows uploaded in the previous iteration. Major advantages and contributions of the new algorithm in overcoming some of the GPU programming limitations for the SMVM kernel are as follows:

- Pre-fetching the required data for the next iteration in each thread block hides much of the global memory access latencies; thus, while many threads are waiting on global memory accesses, other threads proceed with the necessary calculations for the current data in shared memory.
- Unlike previous techniques, in the new algorithm the threads only need to be synchronized once, minimizing the number of idle threads throughout execution.
- Simultaneous upload of required values of the x vector for each iteration into the shared memory regularizes the accesses to the x vector, enables parallel uploading of the x vector values, and decreases the memory access overhead by loading it into fast shared memory.
- Rows split by iterations in each block can communicate through the very fast on-chip register file avoiding excessive global memory accesses.
- By varying m and n in the proposed partitioning scheme, maximum performance can be determined via changing the number of threads executing per SM while considering the register and shared memory limitations of each multiprocessor.
- Thread divergence is also decreased by allocating the calculations for the result vector to consecutive threads in a warp while threads in other warps upload data into shared memory.

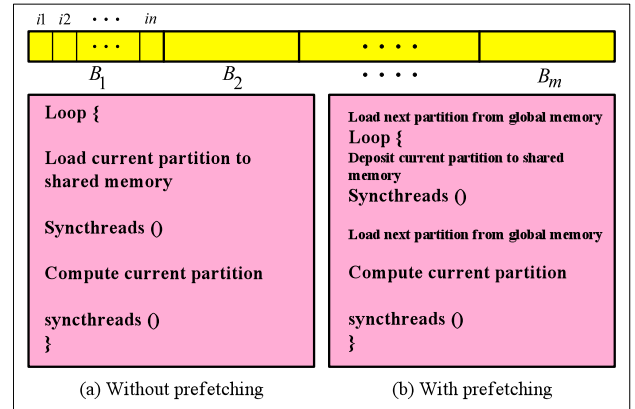

Fig. 2. The Prefetch-CSR Algorithm.

Sample results of PCSR for the *bcsstk* matrix from [6] are shown in Table I. The speedups demonstrated show the performance of the PCSR algorithm vs. the non-prefetch CSR on the GPU (m and n are the same in both methods). As n increases the number of iterations per block increase, allowing the prefetch algorithm to hide more of the memory access latency. Although the performance of PCSR compared to non-prefetch CSR further increases for values of m below 12, the general performance compared to CPUs of both algorithms for $m < 12$ decreases due to having idle SMs (full details in long version paper). Speedups of up to 1.5 with full utilization of all SMs, shows the importance of prefetching data in CSR using GPUs. Since previous non-prefetching CSR algorithms [3] on the GPU have shown up to 10 times speedup compared to the CPU, speedup increases of 1.5 for PCSR compared to previous algorithms can accelerate CSR on the GPUs up to 15 times compared to the CPU (PCSR speedup results compared to the CPU will be presented in the long version paper).

TABLE I
PCSR ALGORITHM SPEEDUP COMPARED TO NON-PREFETCH CSR
ON GT 8800

Partitioning values	$n=1$	$n=12$	$n=15$	$n=30$
	$m=180$	$m=15$	$m=12$	$m=6$
Speedup	1	1.3	1.5	1.9

In the long version of the paper we will propose a technique to minimize thread divergence in the SMVM algorithm and increase the instruction mix, and m and n partitioning values will also be varied to achieve maximum performance.
