SPONSORING:

Proceedings

17th International Conference on the
Computation of Electromagnetic Fields

November 22-26, 2009

Florianópolis, Brazil

CHAIRMAN FOREWORD

It is a great pleasure and honour for us to welcome you all to COMPUMAG 2009, the 17th International Conference on the Computation of Electromagnetic Fields in our town, Florianópolis, state of Santa Catarina, Brazil.

It is the second time that COMPUMAG is held in Brazil. The first one was in 1997, in Rio de Janeiro. That event accomplished an important goal: it encouraged the Brazilian Community to maintain and expand their activities in the area of Electromagnetic Modelling. If today Brazil has a significant standing in this field of research, COMPUMAG 1997 contributed to this achievement. We believe that Compumag 2009 will assume a similar motivating role. In the same spirit, it is our sincere hope that this event will inspire our worldwide community.

At this point, we would like to provide you with some figures and facts about COMPUMAG 2009. The conference has attracted 622 valid submissions from 36 countries. About 220 reviewers of the Editorial Board, led by Nathan Ida, have worked diligently to select the accepted papers. The list of reviewers was enhanced with several new members mostly recommended by the ICS Board. COMPUMAG 2009 has 8 Oral Sessions and 25 Poster Sessions, with 548 accepted contributions, including 8 invited papers. The main criterion for the selection of invited papers was the technical and scientific quality of the papers. The first paper in each Oral Session is an invited paper.

The organisation of the conference started in 2005 when Florianópolis was chosen as the conference venue for 2009. Of course, the preparation activity became intense two years ago. The Brazilian community, especially our colleagues from *Universidade de São Paulo* and *Universidade Federal de Minas Gerais* were very active partners in our organization work. The *SBMag – Sociedade Brasileira de Eletromagnetismo* – was also very supporting since its financial participation was necessary in the conference preparation.

The Local Organizing Committee was formed mainly from members of *GRUCAD – Grupo de Concepção e Análise de Dispositivos Eletromagnéticos*, from the *Universidade Federal de Santa Catarina*, an amazing

team that allowed us to organize COMPUMAG 2009 in a consistent and systematic way. They are a very reliable group of people who worked with serenity and professionalism. All were very enthusiastic when taking up duties and fulfilling tasks to shape the most prestigious conference in our scientific area.

We hope that all of you will benefit from the excellent quality of technical presentations at COMPUMAG 2009, have fruitful discussions and pleasant moments through meeting friends and colleagues and establish new scientific relationships. A meeting of this size cannot be brought together without the dedicated efforts of many people and we would like to take this opportunity to thank everyone involved in the conference. Each attendee and each paper are very important to its success.

As organisers of COMPUMAG 2009 we were particularly keen to encourage young researchers to attend the conference and enjoy all available benefits. We trust we achieved this goal by offering a significantly reduced registration fee for full time students (lower than at any previous COMPUMAG). Additionally, it is fully inclusive (all lunches, conference dinner, social programme). We strongly believe that students should have the same networking opportunities as their supervisors and we hope that this will motivate our young colleagues to work vigorously in the fascinating field of computational electromagnetic.

Finally, we hope that the conference will give you a chance to visit and get to know this country of the South Hemisphere. Florianópolis is a small but beautiful place and you certainly should try to capture its charm. We wish you a pleasant stay in our island and a safe return home after the conference. We also hope that the atmosphere at COMPUMAG 2009 will inspire new friendships amongst engineers and scientists for the benefit of the society in the years ahead.

João Pedro Assumpção Bastos
Chairman

ABSTRACTS 1

AUTHOR'S INDEX I

LOCAL ORGANISING COMMITTEE

The organising committee is composed of members of the three main Brazilian research groups in EM Modeling:

- **GRUCAD** (Grupo de Concepção e Análise de Dispositivos Eletromagnéticos), from the Universidade Federal de Santa Catarina (UFSC);
- **LMAG** (Laboratório de Eletromagnetismo Aplicado), from the Universidade de São Paulo (USP);
- **GOPAC** (Grupo de Otimização e Projetos Assistidos por Computador) from the Universidade Federal de Minas Gerais (UFMG).

Chairman

Prof. João Pedro Assumpção Bastos (GRUCAD, UFSC)

Vice-Chairman

Prof. Nelson Sadowski (GRUCAD, UFSC)

Committee Members

from GRUCAD/UFSC: R. Carlson, N. J. Batistela

from LMAG/USP: J. R. Cardoso, L. Lebensztajn, S.I. Nabeta, V. Silva, C.A.F. Sartori

from GOPAC/UFMG: R.C. Mesquita, J.A. Vasconcelos, R.R. Saldanha, J.A. Ramirez, E.J. da Silva

Secretariat (GRUCAD/UFSC)

Mauricio Valencia Ferreira da Luz

Walter P. Carpes Jr.

Celly D. Melo

Treasurer

Patrick Kuo-Peng (GRUCAD/UFSC)

Technical Support

Mauricio Rigoni

VENUE

“Costão do Santinho” Resort and Spa is the venue of the conference.

- it is one of the best resorts in Brazil, recognized by Brazilians and foreign people as an outstanding hotel, offering an international quality level service
- it is the favourite place to hold conferences since it has several facilities to meet various needs
- the resort has a commercial center with stores, tourism agencies, banks, transportation, pharmacy, etc.
- inside the resort, there are several restaurants, cafes and meeting points located in different places
- several pools, gym rooms, sport and spa facilities are available for the guests
- the resort is located on the Santinho beach, one of the most beautiful of the island

The “Costão do Santinho” Resort is located at the north of the island, 40 km from downtown and 50 km from the airport. Typical prices for taxis to downtown are around 35 Euros (one way).

The Costão do Santinho is located at the Santinho beach

Resort, aerial view

Florianópolis

Overview

Florianópolis is the capital of the state of Santa Catarina, located in southern Brazil. It is located some 700 km south (about 1 hour flight) of São Paulo. Its population is around 450,000 inhabitants and is known as a calm city, with excellent quality of life.

The city of Florianópolis is located on an island called “Ilha de Santa Catarina”. Its dimensions are about 52 km (north-south) by 12 km (east-west). Three bridges connect the city to the continent but only two are operational (the third is a historical monument and a symbol of the city). The airport “Hercílio Luz” is located on the island. Florianópolis boasts 42 beaches, which are quite different from each other. The ones located between the mainland and the island, (Canasvieiras, Jurerê, Cachoeira do Bom Jesus, Ponta das Canas, etc) are calm and the water is warm. Those who prefer a little fresher water with waves would choose the beaches on the ocean side (Joaquina, Moçambique, Campeche, Costão do Santinho, Pântano do Sul, Barra da Lagoa, Mole). The latter beaches offer excellent surfing.

In the interior of the island there is a large lagoon connected to the ocean by a narrow channel, called the “Lagoa da Conceição”, an amazing environment, with alternating water and landscapes. Around this lagoon, there are many bars and restaurants offering international food, but the typical fish dishes are, of course, the most appealing.

In downtown there is the concentration of buildings and commerce. That is also the place where the bridges connect the island to the continent. Being an average size town, the downtown is calm and walking on its pedestrian street (Felipe Schmidt) or on the main plaza (Praça 15 de Novembro) is highly recommended. The old public market (1898) is also an interesting point to be visited.

History

The foundation of Florianópolis dates to **1726** by Azorean (Portuguese) colonization. Shortly afterwards, **Santo Antônio de Lisboa** (1751) and **Ribeirão da Ilha** (1803) were established. They are also located on the island and are now neighborhoods in the city. These two villages boast **old Portuguese colonial buildings** as well as very good restaurants and bars and an atmosphere quite different than the rest of the city. Visiting them is a very pleasant choice.

In **1823 Florianópolis became the capital of the state**. At that time, its name was “Nossa Senhora do Desterro”. The name of the town changed to Florianópolis in 1894 in homage to the **Marechal Floriano Peixoto**. Interestingly, this military man was, and still is considered, a nasty personage by the people of the town. He was instructed by the national government in Rio de Janeiro (at that time) to quell a rebellion after the republican revolution (Brazil was a monarchy until 1889). Many influential people of the town were executed in **this violent repression** by the federal government. As a result, the name **Florianópolis, imposed by Rio de Janeiro**, was never well accepted by the local people. Today, these sad memories have been slowly erased by the time, but, nevertheless, some people still reject this name and prefer to use expressions such as “capital of Santa Catarina” or “Desterro” and even avoid pronouncing the word “Florianópolis”.

Florianópolis was an **important and strategic place** for the Portuguese colonizers, since this land was constantly disputed by Spain. Indeed, the city of Laguna (100 km south of Florianópolis) was on the me-

ridian that **divided the lands of Portugal and Spain** (treatise of Tordesilhas, agreed upon in 1494 by the two countries). Therefore fortresses were built on the island and on the main land, to protect the land from the Spaniards. The most important is the “**Fortaleza da Ilha de Anhatomirim**” which was restored and is a nice place to visit. There are also two fortresses on two small islands called “Ilha de Ratonés Grande” and “Ilha de Ratonés Pequeno”, both easily reached by boat. For a long period, Florianópolis was mainly the administrative capital and, in terms of economy, the **town was far below the industrially developed Blumenau and Joinville** to its north. These two cities were established by **Germans and Italians in the XIX century**.

In the 1970s, with the establishment of the Federal University of Santa Catarina and Eletrosul (utility company for the South Region of Brazil) Florianópolis **became a more important town and a cultural center of the state**. Recently many other private universities were also established in the capital and its economy is flourishing. Because of its privileged nature and the quality of life, many people moved to Florianópolis in the 90s and the **city is constantly growing in population**. Residential and commercial buildings as well as hotels have been constructed regularly in these last years. Since it is the most touristy and demanded town in the South Region, its **population swells by about 50% each summer** only to revert to its normal size by the end February.

GENERAL INFORMATION

Conference Desk

The Conference Desk is located near the entrance of the Conference Area of the Hotel Costão do Santinho Resort. It will be open all day long, throughout the conference. Staff members will be available there to assist you in all matters related to the conference itself.

Açoriana Tourism Agency Desk

This tourism agency has a desk close to the Conference Desk. They will provide you information about tourist activities in Florianópolis, the post-conference tour, flight information, etc.

Welcome Reception

The Welcome Reception takes place on Sunday, November 22nd, between 19:30 and 21:30 in the hotel chalet by the Santinho beach. Finger food and refreshments will be served, in a convivial atmosphere, to celebrate the reunion of the COMPUMAG community and the beginning of the conference.

Lunches

All lunches are served in the Lunch room, between 12:10 and 13:30. Please, make sure to have with you, when presenting yourself at the restaurant's door, the appropriate lunch ticket for that day.

Conference Dinner

The Conference Dinner takes place on Wednesday, November 25th, from 20:00 to 23:30, in the Alameda Casa Rosa. A typical Brazilian music performance will be presented to the guests. The coaches will be ready at 19:00 at the Venue entrance. Make sure you have the appropriate ticket and, please, be on time for the buses departure.

AUTHOR INFORMATION

Guidelines for Oral Presentations

Timing

Oral presentations are allocated **15 minutes** for the talk and an additional **5 minutes** for questions and discussion. Session timings are listed in the technical program booklet. Session chairs will strictly enforce these time limits. A useful estimate is to allot approximately one minute for each transparency or slide prepared for the talk.

As for **invited papers**, the allocated times are **25 minutes** for presentation and **5 minutes** for questions and discussion.

Format

All oral presentations should be prepared in Microsoft Powerpoint format. There will be a number of computers available at the Conference Computer Room with the same version of Powerpoint installed as in the plenary room, in order to allow all speakers checking their presentation in advance (fonts, resolution, etc.). After this check, the presentation can be uploaded into the Conference media system. You are asked to hand in the file of your presentation, on a CD-rom or a USB Memory stick, **the day before** the session where it will be presented. An assistant will be present in Media Center, every day between 8:00-10:30 and 14:00-17:10 to receive your file and upload it on the system.

Presentation

The day of their oral presentation, all speakers should “check in” with the session chairman at least 10 minutes before the scheduled start of the session in order to confirm the name of the author (or co-author) who will present the talk. Talks will be called at the time scheduled in the technical program booklet. Session chairs have the responsibility of reporting “no-shows” to the Editorial Committee. No-show papers will not be considered for publication in the IEEE Transactions on Magnetics journal. All speakers are urged to prepare visuals in advance of the conference and to

practice their talk. The success of the conference depends on the quality of the technical work as well as their presentations.

Guidelines for Poster Presentations

Attendance

Please arrive at least 10 minutes ahead of the scheduled poster session to arrange your poster and check that all necessary supplies are present. One or more of the authors including a prime presenter should be present at the poster for most of session and be capable of explaining it. Session chairs have the responsibility of determining whether papers have actually been presented. Failure to attend or adequately explain your poster will result in your poster being deemed a “no show”. No-show papers will not be considered for publication in the IEEE Transactions on Magnetics journal.

Dimensions

Poster boards will be available for the presentation of poster papers. Before the session begins, the conference organizer will place the paper number on the top left of the board, as shown on the opposite picture. Prepare your poster in the format 90cm (width) x 130cm (height). Your paper title and author names, affiliations should be displayed prominently across the top of your poster. Push pins or stickers will be provided by the conference organization. Please, keep in mind that your poster will be seen by everyone at the conference. Pay very close attention to the visual appearance of your presentation, be clear and concise, and keep text to a minimum.

Removal

All poster materials must be removed promptly at the end of the session. Poster materials not collected immediately by an author will be removed and discarded by the organizers to allow preparation for the next poster session.

Software Companies Exhibits

During the conference, next to the Poster Session Room I, you have the opportunity to visit the stands of our software and industrial exhibitors,

presenting the latest innovations offered by state-of-the-art computational electromagnetic products available on the market.

Emerald Compel Award

This prize will be awarded to a young researcher, who is a participant of Compumag 2009 registered as a STUDENT. The paper may be co-authored, but the recipient must have contributed significantly, the evidence of this being demonstrated for example by the fact that he/she is listed as the first author. Finally, the paper must be presented by the young researcher in either an oral or a poster session. A special Awards Committee, working together with session chairs and the Board of the International Compumag Society, will select about 6 papers which will be commended and the authors will receive certificates on behalf of the ICS Board. One of these authors (in exceptional circumstances two for a joint award) will be identified as the recipient of the Emerald COMPEL award.

More information about the COMPEL journal can be found at:

<http://www.emeraldinsight.com/info/journals/compel/compel.jsp>.

Final submission

Papers presented at the conference will be considered for publication in 2010 special issue of the “IEEE Transactions on Magnetics” journal after a second peer-review process. The length of all extended papers is limited to **4 pages for regular** papers and **7 pages (minimum) for the invited** papers. Templates and general information on this topic can be found in the conference web site www.compumag2009.com.

Marechal, Yves, G2ELAB, Grenoble, France **(PB1)**
Matsuo, Tetsuji, Kyoto University, Japan **(PC5)**
Mazauric, Vincent, Schneider Electric, France **(PD1)**
Mesquita, Renato Cardoso, Universidade Federal de Minas Gerais, Brazil **(OD2)**
Muramatsu, Kazuhiro, Saga University, Japan **(PB4)**
Nabeta, Silvio, Escola Politécnica, USP, Brazil **(PA6)**
Nicolet, André, Université Paul Cézanne, France **(PC8)**
Perrussel, Ronan, CNRS, Université de Lyon, France **(PA5)**
Piriou, Francis, L2EP-University of Lille, France **(OA2)**
Preis, Kurt, IGTE, Technical University Graz, Austria **(PB6)**
Raizer, Adroaldo, GEMCO, Univ. Federal da Santa Catarina, Brazil **(PB3)**
Ramirez, Jaime, Universidade Federal de Minas Gerais, Brazil **(PB2)**
Razek, Adel, LGEP, France **(PC6)**
Ren, DaQi, The University of Tokyo, Japan **(PC7)**
Ren, Zhuoxiang, Mentor Graphics Corporation, USA **(PD3)**
Sabariego, Ruth V., University of Liège, Belgium **(PC1)**
Saldanha, Rodney R., Universidade Federal de Minas Gerais, Brazil **(PB5)**
Sartori, Carlos, Escola Politécnica, USP, Brazil **(PB4)**
Scorretti, Riccardo, CNRS, France **(PC8)**
Silva, Elson J., Universidade Federal de Minas Gerais, Brazil **(PB6)**
Silva, Viviane Cristine, Escola Politécnica, USP, Brazil **(PA3)**
Sykulski, Jan, University of Southampton, United Kingdom **(OA2)**
Takahashi, Norio, Okayama University, Japan **(OC1)**
Tounzi, Abdelmounaim, L2EP-University of Lille, France **(PA2)**
Trowbridge, Bill, Honorary President of the ICS, United Kingdom **(OA1)**
Xie, Dexin, Shenyang University of Technology, China **(OC2)**
Yamazaki, Katsumi, Chiba Institute of Technology, Japan **(PA6)**
Zhu, Jianguo, University of Technology, Sydney, Australia **(OC1)**

SCHEDULE

	Monday, 23/Nov	Tuesday, 24/Nov	Wednesday, 25/Nov	Thursday, 26/Nov
08:30 10:20	Opening Session* and OA1	OB1	OC1	OD1
<i>Coffee Break</i>				
10:40 12:10	PA1 (PSR I) PA2 (PSR I) PA3 (PSR II)	PB1 (PSR I) PB2 (PSR I) PB3 (PSR II) PB4 (PSR II)	PC1 (PSR I) PC2 (PSR I) PC3 (PSR II) PC4 (PSR II)	PD1 (PSR I) PD2 (PSR I) PD3 (PSR II) PD4 (PSR II)
<i>Lunch</i>				
13:30 15:00	PA4 (PSR I) PA5 (PSR I) PA6 (PSR II)	PB5 (PSR I) PB6 (PSR I) PB7 (PSR II)	PC5 (PSR I) PC6 (PSR I) PC7 (PSR II) PC8 (PSR II)	OD2 (13:30-15:20)
<i>Coffee Break</i>				
15:20 17:10	OA2	OB2	OC2	Closing Session
20:00			Conference Dinner	

Oral sessions take place in the **Plenary Session Room**.

PSR I: Poster Session Room I

PSR II: Poster Session Room II

* The Opening Session takes place between 08:30 and 09:00 at the Plenary Session Room

Sessions

- OA1: Static and Quasi-static Fields
- OA2: Coupled Problems
- OB1: Wave Propagation and Nanomagnetism
- OB2: Optimization
- OC1: Material Modelling and Numerical Techniques
- OC2: Devices and Applications and Electromagnetic Compatibility
- OD1: Electric Machines and Drives
- OD2: Numerical Techniques and Software Methodology
- PA1: Static and Quasi-Static Fields I
- PA2: Static and Quasi-Static Fields II
- PA3: Coupled Problems I
- PA4: Static and Quasi-Static Fields III
- PA5: Coupled Problems II
- PA6: Electrical Machines and Drives I
- PB1: Optimization I
- PB2: Optimization II
- PB3: Waves Propagation I
- PB4: Numerical Techniques I
- PB5: Optimization III
- PB6: Waves Propagation II, Nanomagnetism, Photonics and Optoelectronics
- PB7: EMC – Electromagnetic Compatibility
- PC1: Material Modelling I
- PC2: Electrical Machines and Drives II
- PC3: Devices and Applications I
- PC4: Numerical Techniques II
- PC5: Material Modelling II
- PC6: Electrical Machines and Drives III
- PC7: Numerical Techniques III
- PC8: TEAM, Education and Software Methodology
- PD1: Electrical Machines and Drives IV
- PD2: Electrical machines and Drives V
- PD3: Devices and Applications II
- PD4: Numerical Techniques IV

TECHNICAL PROGRAM

Monday, November 23rd

Session OA1: Static and Quasi-static Fields

09:00-10:30 – Room: Plenary Session Room

OA1.1	1
(Invited) Surface-Impedance Boundary Conditions in Dual Time-Domain Finite-Element Formulations	
<i>Ruth V. Sabariego, Patrick Dular, Christophe Geuzaine, Johan Gyselinck</i>	
OA1.2	3
Kriging for eddy-current testing problems	
<i>Sandor Bilicz, Emmanuel Vazquez, Szabolcs Gyimothy, Jozsef Pavo, Marc Lambert</i>	
OA1.3	5
Adaptive Parabolic-Elliptic Time Integration Method for Electroquasistatic Problems	
<i>Zsolt Badiacs</i>	
OA1.4	7
Numerical experimentations on the coupling between PEEC and volume integral method	
<i>Le Duc Tung, Chadebec Olivier, Meunier Gerard, Lembeye Yves, Guichon Jean- Michel, Delinchant Benoit</i>	

Session PA1: Static and Quasi-static Fields I

10:40-12:10 – Room: Poster Session Room I

PA1.1	9
Electromagnetic Device Analysis using a Meshless Approach coupled to a Kohonen Network	
<i>Rajeev Das, David Lowther</i>	

PA1.2	11
Hysteresis Phenomenon Implementation in FIT: Validation with Measurements	
<i>Julien Korecki, Abdelkader Benabou, Yvonnick Le Menach, Jean Pierre Ducreux, Francis Piriou</i>	
PA1.3	13
Influence of a rough thin layer on the potential	
<i>Clair Poignard, Ronan Perrussel, Ionel Ciuperca</i>	
PA1.4	15
Shell's magnetization identification from very close magnetic measurements	
<i>Yannick Vuillermet, Olivier Chadebec, Jean-Louis Coulomb, Laurent Demillier, Laure-Line Rouve, Gilles Cauffet</i>	
PA1.5	17
Interaction Body Force Field and Total Force on Permanent Magnet by Virtual Air-gap Approach	
<i>Se-Hee Lee, Young-Sun Kim, Ho-Young Lee, Heung-Geun Kim, Hong-Soon Choi</i>	
PA1.6	19
Block-preconditioning for hybrid discretisations in combination with Lagrange-multiplier coupling	
<i>Stephan Koch, Herbert De Gersem, Thomas Weiland</i>	
PA1.7	21
MHD Convection of a Electrically Conductive Fluid with Variable Thermal Conductivity	
<i>Mohsen Pirmohammadi, Majid Ghassemi, Asghar Keshtkar</i>	
PA1.8	23
Introduction of a Direct Solver at Subdomains in Non-linear Magnetostatic Analysis with HDDM	
<i>Shin-Ichiro Sugimoto, Jian Zhao, Masao Ogino, Hiroshi Kanayama, Shinobu Yoshimura</i>	
PA1.9	25
A Discrete Geometric Approach to solving 2D non-linear magnetostatic problems	
<i>Paolo Bettini, Ruben Specogna, Francesco Trevisan</i>	

PA1.10	27
Optimal Selection of the Integration Surface in the Hybrid FEM-DBCI Method	
<i>Nunzio Salerno, Giovanni Aiello, Salvatore Alfonzetti</i>	
PA1.11	29
Periodic and Anti-periodic boundary conditions with the Lagrange multipliers in the FEM	
<i>Mathieu Aubertin, Thomas Henneron, Francis Piriou, Pierre Guerin, Jean Claude Mipo</i>	
PA1.12	31
Analysis of the Ionized Field under HVDC Transmission Lines Including Wind's Effect Based on Finite Element Method	
<i>Tiebing Lu, Han Feng, Xiang Cui, Zhibin Zhao, Lin Li</i>	
PA1.13	33
A new self-consistent 3D unbounded magnetic field FE computation for electron guns	
<i>Antonino Laudani, Salvatore Coco, Giuseppe Pollicino, Paola Tirrò</i>	
PA1.14	35
Using a direct field calculation method to solve magnetostatic design inverse problem	
<i>Raphael Vilamot, Carole Henaux, Bertrand Nogarede</i>	
PA1.15	37
Calculation of the Flux Linkage of a 12/8 Dual-Channel SRM Including Mutual Coupling and Saturation: From Magnetic Circuit Model to FEM Analysis	
<i>Wen Ding, Deliang Liang</i>	
PA1.16	39
Effects of Core Materials on Magnetic Bearing Parameters	
<i>Bronislaw Zbigniew Tomczuk, Jan Zimon, Andrzej Waindok</i>	
PA1.17	41
Optimization of Electrostatic Micromotor by a Non-linear Interior Point Method	
<i>Adriano Chaves Lisboa, Rodney Rezende Saldanha, Douglas Alexandre Gomes Vieira</i>	

PA1.18	43
A Modified FEM-DBCI Method for Static and Quasi-Static Electromagnetic Field Problems	
<i>Nunzio Salerno, Giovanni Aiello, Salvatore Alfonzetti, Giuseppe Borzi', Emanuele Dilettoso</i>	
PA1.19	45
Dynamic Simulation of Surge Corona with Time-dependent Upwind Difference Method	
<i>Wei Li, Bo Zhang, Jinliang He, Rong Zeng</i>	
PA1.20	47
Using Neumann Series for Reduction of Computational Effort of Quasistatic EM-Simulations	
<i>Carsten Potratz, Daniel Kluess, Robert Souffrant, Hartmut Ewald, Ursula van Rienen</i>	
PA1.21	49
Exposure of working population to pulsed magnetic fields	
<i>Aldo Canova, Fabio Freschi, Luca Giaccone, Maurizio Repetto</i>	

Session PA2: Static and Quasi-static Fields II

10:40-12:10 – Room: Poster Session Room I

PA2.1	51
Comparative Study Applying Constant Current Source and Constant Voltage Source to Treat Cancer Using Electrochemical Therapy	
<i>Marcos Telló, Luciana Oliveira Oliveira, Rosemari Teresinha Oliveira, Orlando Parise Jr., Antonio Carlos Buzaid, Rodrigo Zanella, Helio Radke Bittencourt, Augusto Cardona</i>	
PA2.2	53
Calculation of Poynting Vector and Analysis on the Energy Transfer of Transmission Line	
<i>Fan Yang, Wei He, Yuxin Yun, Dongping Xiao</i>	
PA2.3	55
A Particle Trajectory Code using the FEM approach: preliminary results	
<i>César Candido Xavier, Cláudio Costa Motta</i>	

PA2.4	57
Hierarchical Block Wavelet Compression for BEM Problems of Arbitrary Dimension	
<i>Christian Scheiblich, Remus Banucu, Jan Albert, Veronika Reinauer, Wolfgang M. Rucker</i>	
PA2.5	59
A quick and efficient method to compute radial flux density distribution in the airgap of a superconducting inductor	
<i>Gaël Malé, Smail Mezani, Renaud Moulin, Jean Lévêque, Abderrezak Rezzoug</i>	
PA2.6	61
Solution of Dual Stochastic Static Formulations Using Double Orthogonal Polynomials	
<i>Stephane Clenet, Nathan Ida, Roman Gaignaire, Olivier Moreau</i>	
PA2.7	63
Nonlinear Eddy Current Analysis by BEM Minimum Order Formulation	
<i>Kazuhisa Ishibashi, Zoran Andjelic, David Pusch</i>	
PA2.8	65
A perturbation method for the $T-\Omega$ eddy-current formulation	
<i>Ruben Specogna, Lorenzo Codecasa, Patrick Dular, Francesco Trevisan</i>	
PA2.9	67
Electromagnetic Inspection of Outer Side Defect on Steel Tube with Steel Support using 3D Nonlinear FEM Considering of Non-Uniform Permeability and Conductivity	
<i>Yuji Gotoh, Atsushi Kiya, Norio Takahashi</i>	
PA2.10	69
Discontinuous Galerkin method with T,Phi-Phi Formulation for 3D eddy current problems	
<i>Stefan Außerhofer, Oszkár Bíró</i>	
PA2.11	71
A Mesh-Free Model of Eddy-Current Losses for 2D Analysis of Ferromagnetic Laminations	
<i>Paavo Rasilo, Antero Arkkio</i>	
PA2.12	73
Boundary Element Modelling of Earth Effects on Railway Track Transmission Line Impedances	
<i>Luca Di Rienzo, Zichi Zhang</i>	

PA2.13	75
Integral Formulation and Genetic Algorithms for Defects Geometry Reconstruction using Pulse Eddy Currents	
<i>Gabriel Preda, Mihai Rebican, Florea I. Hantila</i>	

Session PA3: Coupled Problems I

10:40-12:10 – Room: Poster Session Room II

PA3.1	77
A Coupling Procedure for Plasma, Iron and 3D Eddy Currents in the JET Tokamak	
<i>Raffaele Fresa, Raffaele Albanese, Giovanni Artaserse, Guglielmo Rubinacci, Fabio Villone, Bruno Viola</i>	
PA3.2	79
Magnetic Saturation Modeling within Finite Volume Method	
<i>Loïc Rondot, Vincent Mazauric, Gerard Meunier</i>	
PA3.3	81
Weak Coupling between Electromagnetic and Structural Models for Electrical Machines	
<i>Siegfried Rainer, Oszkár Bíró, Bernhard Weilharter</i>	
PA3.4	83
Comparing Weak and Strong PEEC-MoM Coupling	
<i>MOKHTARI Lounes, DELINCHANT Benoit, CHEVALIER Thierry, COULOMB Jean Louis</i>	
PA3.5	85
Dynamic Electro-Flow-Thermal 2D Model of a Transformer Using the CBS algorithm	
<i>Marco Arjona, R.B.B Ovando-Martínez, C Hernandez</i>	
PA3.6	87
FEM for directly coupled magneto-mechanical phenomena in electrical machines	
<i>Katarzyna Anna Fonteyn, Anouar Belahcen, Reijo Kouhia, Antero Arkkio</i>	
PA3.7	89
3D Numerical Modeling of the Thermo-Inductive Technique Using Shell Elements	
<i>Brahim Ramdane, Didier Trichet, Mohamed Belkadi, Javad Fouladgar</i>	

PA3.8	91
Coupled Mechanical-Electrical-Thermal Modeling of Electric Contacts based on the Cell Method	
<i>Federico Moro, Carmelo Majorana, Massimo Guarnieri, Mazzucco Gianluca</i>	
PA3.9	93
Improvements to convergence of coupled nonlinear circuit modelling	
<i>Simon Taylor, Nick Robertson, John Simkin</i>	
PA3.10	95
Particular Electromagnetic Field Computation for Permanent Magnet Generator Wind Turbine Analysis	
<i>Charalampos Patsios, Antonios Chaniotis, Evagelos Tsambouris, Antonios Kladas</i>	
PA3.11	97
A Fully Coupled Three-dimensional Dynamic Model of Polymeric Membranes for Fuel Cells	
<i>Massimo Guarnieri, Piergiorgio Alotto, Federico Moro</i>	
PA3.12	99
Coupled 3D Fluid Flow-Thermal FEM Model for Power Transformer Temperature Analysis	
<i>Marina Antonios Tsili, Eleftherios Ioannis Amoiralis, Antonios Kladas, Athanassios Souflaris</i>	
PA3.13	101
Inductively Heated Incompressible Flow of Electrically Conductive Liquid in Pipe	
<i>Ivo Dolezel, Lenka Dubcova, Pavel Karban, Jakub Cerveny, Pavel Solin</i>	
PA3.14	103
Equivalent stress criteria for the effect of stress on magnetic behavior	
<i>Laurent DANIEL, Olivier HUBERT</i>	
PA3.15	105
Shape Formation of Ferrofluid Droplet in Magnetic Field and Gravity by FEA coupled with LSM	
<i>Young Sun Kim, Il Han Park</i>	

Session PA4: Static and Quasi-Static Fields III

13:30-15:00 – Room: Poster Session Room I

PA4.1	107
FEM/BEM Hybrid Method for Magnetic Field Evaluation Due to Underground Power Cables	
<i>Vitor Malo Machado</i>	
PA4.2	109
Voltage and current sources for massive conductors suitable with the $A-\chi$ Geometric Formulation	
<i>Ruben Specogna, Pawel Dlotko, Francesco Trevisan</i>	
PA4.3	111
Efficient Computation of Eddy Current losses in SMC PM machines with 3D Time-Harmonic FEA	
<i>Ahmed Chebak, Philippe Viarouge, Jérôme Cros</i>	
PA4.4	113
Decoupling of Nonequidistant Time Steps by Fixed Point Method for Nonlinear Eddy Currents	
<i>Gergely Koczka, Oszkár Bíró</i>	
PA4.5	115
Homogenization for periodical electromagnetic structure: which formulation?	
<i>Gerard Meunier, Vincent Charmoille, Christophe Guerin, Patrice Labie</i>	
PA4.6	117
Geometric interpretation of frequency-domain surface-impedance boundary conditions	
<i>Herbert De Gersem</i>	
PA4.7	119
Field Analysis for Thin Shields in the Presence of Ferromagnetic Bodies	
<i>Ioan R. Ciric, Florea I. Hantila, Mihai Maricaru</i>	
PA4.8	121
Evaluating the Guidance Force Capabilities of Flat Passive Maglev Guideway Topologies Using the A-phi Formulation	
<i>Jonathan Bird</i>	

PA4.9	123
Improved Accuracy of Electro-Quasistatic Simulations of Large-Scale 3D High Voltage Equipment Including Nonlinear Field-Grading	
<i>Daniel Weida, Thorsten Steinmetz, Markus Clemens</i>	
PA4.10	125
3-D Calculation of Surface Electric Field around Conductor of UHVAC Transmission Lines	
<i>Dongping XIAO, Wei HE, Mingyou CHEN, Fan YANG</i>	
PA4.11	127
Analytical Prediction of Eddy-Current Loss in Armature Windings of Permanent Magnet Brushless AC Machines	
<i>Yacine Amara, Pascal Reghem, Georges Barakat</i>	
PA4.12	129
Complementarity of Dual Eddy Current Formulations on Dual Meshes	
<i>Zhuoxiang Ren, Hui Qu</i>	
PA4.13	131
Numerical Model of Transient Electromagnetic Field around the Grounding System by FEM	
<i>Anton Habjanic, Marko Jesenik, Mladen Trlep</i>	
PA4.14	133
A New Formulation Using Differential Permeability Based on the Source-Field Method	
<i>Nelson Sadowski, João Pedro Assumpção Bastos, Jean Viane Leite</i>	
PA4.15	135
Homogenization of Form-Wound Windings in Finite Element Modelling of Electrical Machines	
<i>Johan Gyselinck, Ruth V. Sabariego, Patrick Dular, Nelson Sadowski, Patrick Kuo-Peng</i>	
PA4.16	137
Electrokinetic Model Refinement via a Perturbation Finite Element Method – From 2-D to 3-D	
<i>Mauricio Valencia Ferreira da Luz, Patrick Dular, Ruth V. Sabariego, Patrick Kuo-Peng, Nelson Jhoe Batistela</i>	
PA4.17	139
Magneto-convection in an Enclosure with Partially Active Vertical Walls	
<i>Mohsen Pirmohammadi, Majid Ghassemi</i>	

PA4.18	141
Comparison between BEM + ACA and classical FEM for 3D low-frequency eddy-current analysis	

David Pusch, Jasmin Smajic, Zoran Andjelic

PA4.19	143
An Energy-Based Error Criterion for Eddy Current Transient Analysis	

Loïc Rondot, Dimitrios Ladas, Vincent Mazauric

PA4.20	145
Magneto-Mechanical effects under low fields and high stresses - Application to a ferromagnetic cylinder under pressure	

Antoine Viana, Laure-Line Rouve, Gilles Cauffet, Jean-Louis Coulomb

Session PA5: Coupled Problems II

13:30-15:00 – Room: Poster Session Room I

PA5.1	147
Large-Scale Analysis of Magnetic Beads Behavior in Magnetic Field with Fast Multipole Method	

Takuya Tatsuishi, Yasuhito Takahashi, Masahiko Miwa, Shinji Wakao

PA5.2	149
Dynamic Analysis Method of Linear Resonant Actuator with Multi-Movers Employing 3-D Finite Element Method	

Yasuyoshi Asai, Katsuhiko Hirata, Tomohiro Ota

PA5.3	151
New FEM Approach for Multi Physics Problems Modeling in EPM Applications	

Yves Du Terrail Couvat, Annie Gagnoud

PA5.4	153
Analysis of Transient Eddy Current and Conductor Motion in an Electromagnetic Repulsion Mechanism with Meshless Collocation Method	

Guangyuan Yang, K.R. Shao, Youguang Guo, Jianguo Zhu

PA5.5	155
Coupled Magneto-Thermal FEM Model of Direct Heating of Ferromagnetic Bended Tubes	

Michele Forzan, Alexandr Aliferov

PA5.6	157
Streamer Simulation based on Discontinuous Galerkin Method and Hierarchical Reconstruction	
<i>Chijie Zhuang, Rong Zeng, Bo Zhang, Shuiming Chen, Jinliang He</i>	
PA5.7	159
Buoyancy Force Evaluation on Nonmagnetic Solid Object Submerged in Magnetic Liquid Subjected to Non-uniform Magneto-static Field	
<i>Hong Soon Choi, Young Sun Kim, Il Han Park</i>	
PA5.8	161
Field-circuit Co-simulation of Controllable Reactor using Integral Equation Method	
<i>Yang Xiaobo, Zoran Andjelic, Cherry Yuen</i>	
PA5.9	163
Steady and Transient Electromagnetic-thermal Fields Analysis for Induction Machines Using FEM and FVM	
<i>Shuhong Wang, Qiuwang Wang, Zhe Ren, Wei Sun, Dan Liao, Jie Qiu, Limin Zhou, Youming Jiang, Jian Guo Zhu, Youguang Guo, Yi Wang, Wei Xu</i>	
PA5.10	165
Electromagnetic-Structure-Acoustic Coupled Analysis Method of GMM Transducer Speaker	
<i>Katsuhiro Hirata, Byungjin Yoo, Atsurou Oonishi</i>	
PA5.11	167
3D Transient Field-Circuit Modeling of Inductive Fault Current Limiters	
<i>Dalibor Cvoric, Domenico Lahaye, Sjoerd W.H. de Haan, J. Abraham Ferreira</i>	
PA5.12	169
Hybrid Analytical-FEM Method for Microwave Heating Analysis in a Single Mode Cavity	
<i>Diogo Batista Oliveira, Elson Jose Silva</i>	
PA5.13	171
Distributed Models for Air-Core Ethernet Transformers	
<i>Isaak Mayergoyz, David Bowen, Charles Krafft</i>	
PA5.14	173
Dynamic simulation of an electromechanical energy scavenging device	
<i>Aldo Canova, Elvio Bonisoli, Fabio Freschi, Sandro Moos, Maurizio Repetto, Stefano Tornincasa</i>	

PA5.15	175
Accurate Control of Position by Induction Heating-Produced Thermoelasticity	
<i>Ivo Dolezel, Pavel Karban, Petr Kropik, David Panek</i>	
PA5.16	177
Physics Based High Frequency Transformer Modeling by Finite Elements	
<i>Osama A Mohammed, Nagy Y Abed</i>	
PA5.17	179
Permanent Magnet Motor Damping Analysis by using a particular 2D FEM technique	
<i>Minos E. Beniakar, Themistoklis D. Kefalas, Antonios G. Kladas</i>	
PA5.18	181
Performance Investigation of Canned Induction Motor for Coolant Pump in Nuclear Reactor	
<i>Jian Li, Jungtae Song, Yunhyun Cho</i>	
PA5.19	183
Field-Circuit Method for the Non-Steady State Analysis in the Active Magnetic Bearings	
<i>Bronislaw Zbigniew Tomczuk, Jan Zimon, Andrzej Waindok</i>	
PA5.20	185
Study of a double-star synchronous machine fed by a dual Voltage Source Inverter	
<i>André de Andrade, Meynard, Thierry:Nelson Sadowski, Patrick Kuo-Peng</i>	
PA5.21	187
Magneto-elastic finite element modeling based on a multiscale approach	
<i>Xavier Mininger, Laurent Daniel, Laurent Santandrea, Laurent Bernard, Frédéric Bouillault</i>	

Session PA6: Electrical Machines and Drives I

13:30-15:00 – Room: Poster Session Room II

PA6.1	189
Novel Design Method of a Single-phase Induction Motor considering Magnetic Balance	
<i>Myoung-Hyun Choi, Byung-Taek Kim</i>	

PA6.2	191
Finite-Element Analysis for a Rolling-Rotor Electrical Machine	
<i>Antero Arkkio, Grzegorz Kaminski, Asko Niemenmaa, Pawel Staszewski</i>	
PA6.3	193
Numerical Modelling of Transformer Inrush Current	
<i>Ermanno Cardelli, Vincenzo Esposito, Antonio Faba</i>	
PA6.4	195
Gaussian Modulated Pulse Excitation for SM Parameter Estimation Using a 2D-FE Model	
<i>Marco Arjona, Concepcion Hernandez, Merit Cisneros-Gonzalez</i>	
PA6.5	197
Efficient FEA Identification of Equivalent Circuit Inductances for DFIM Design	
<i>Davide Aguglia, René Wamkeue, Philippe Viarouge, Jérôme Cros</i>	
PA6.6	199
Comparison of Analytical and Finite Element Calculation of Eddy-Current Losses in the Solid Back-Iron of PM Machines with Concentrated Fractional Pitch Windings	
<i>Anoop Jassal, Henk Polinder, Domenico Lahaye</i>	
PA6.7	201
Numerical Analysis of the Induced Current in an XY-Actuator with Soft Magnetic Composite	
<i>Nolvi Francisco Baggio Filho, Ály Ferreira Flores Filho</i>	
PA6.8	203
Least Square Support Vector Machine Network-Based Modeling for Switched Reluctance Starter/Generator	
<i>Wen Ding, Deliang Liang</i>	
PA6.9	205
An Accurate Magnetic Field analysis for Estimating Motor Characteristics Taking Account of Elasto-Plastic Deformation in the Magnetic Core	
<i>Shinichi Yamaguchi, Akihiro Daikoku, Yoshihiro Tani, Toshinori Tanaka, Chiyo Fujino</i>	
PA6.10	207
Calculation of Radial Forces in Cage Induction Motors at Start – the Effect of Rotor Differential	
<i>David George Dorrell</i>	

PA6.11	209
Eddy-current Losses and Temperature Rise in the Form-wound Stator Winding of an Inverter-fed Cage Induction Motor	
<i>Mohammad Jahirul Islam, Huynh Van Khang, Anna-Kaisa Repo, Antero Arkkio</i>	
PA6.12	211
Semi-Analytical Solution of Cogging Torque in SMPMM	
<i>Frédéric Dubas, Christophe Espanet</i>	
PA6.13	213
Interactive Postprocessing Formulations in 3D	
<i>Martin Hafner, Marc Schöning, Marcin Antczak, Andrzej Demenko, Kay Hameyer</i>	
PA6.14	215
Comprehensive Magnetic Model of Surface Mounted PM Machines Incorporating Saturation Saliency	
<i>Yi Wang, Jianguo Zhu, Youguang Guo, Shuhong Wang, Wei Xu</i>	
PA6.15	217
Magnetic Field in an Axial-Flux Permanent-Magnet Synchronous Generator	
<i>Tze-Fun Chan, Weimin Wang, Loi Lei Lai</i>	
PA6.16	219
Unified Scheme for Implementing the Fixed-Point and Newton-Raphson Methods in Finite-Element Programs of Electromagnetic Field Problems	
<i>Emad Dlala, Antero Arkkio</i>	
PA6.17	221
Parametric Design Coupled with Dynamic Equation of the BLDC Motor for Electric Vehicle	
<i>YoungKyoung Kim, Se-Hyun Rhyu, Jung-Pyo Hong</i>	

Session OA2: Coupled Problems

15:20-17:10 – Room: Plenary Session Room

OA2.1	223
(Invited) Discrete Magneto-Elasticity: A geometrical approach	
<i>Alain Bossavit</i>	
OA2.2	225
Nonlinear coupled FE-circuit model for th optimization of hybrid motors	
<i>Nouredine Takorabet, Eric D. Kenmoe-Fankem, Farid Meibody-Tabar, Francois. M. Sargos</i>	

OA2.3	227
Co-Simulation as Multirate Time Integration of Field/Circuit Coupled Problems	
<i>Sebastian Schoeps, Andreas Bartel, Herbert De Gersem</i>	
OA2.4	229
Efficient Numerical Modelling of Field Diffusion in High-Temperature Superconducting Wires	
<i>Igor O. Golosnoy, Jan K. Sykulski</i>	
OA2.5	231
Unipolar and Bipolar Charge Injection and Transport in Dielectric Liquid by Finite Element Method	
<i>Se-Hee Lee, Il-Han Park, Francis O’Sullivan, Markus Zahn</i>	

Tuesday, November 24th

Session OB1: Wave Propagation and Nanomagnetism

08:30-10:20 – Room: Plenary Session Room

- OB1.1** 233
(Invited) Masking with Generalized Cloaking
Andre Nicolet, Frederic Zolla, Christophe Geuzaine
- OB1.2**235
Micromagnetic Analysis of a Shielded Write Head Using Symmetric
Multiprocessing System
*Yasushi Kanai, Kazuya Koyama, Manabu Ueki, Toshio Tsukamoto, Kazuetsu
Yoshida, Simon Greaves, Hiroaki Muraoka*
- OB1.3**237
Efficient implementation of UPML in the finite integration technique using
hexahedral and prismatic elements
Ruben Torrado, Laurent Bernard, Lionel Pichon
- OB1.4** 239
An Electromagnetic Field Computation Using Space-Time Grid and FIT
Tetsuji Matsuo
- OB1.5**241
Solution of the frequency domain Maxwell equations by a high order non-
conforming discontinuous Galerkin method
Stéphane Lanteri, Mohamed El Bouajaji, Victorita Dolean, Ronan Perrussel

Session PB1: Optimization I

10:40-12:10 – Room: Poster Session Room I

- PB1.1** 243
Identification of Hidden Ferrous 3D Objects Using a GMR Sensor Array
*Alice Köstinger, Michael Jandl, Markus Kienesberger, Christian Magele, Werner
Renhart, Gunter Winkler*
- PB1.2** 245
Multiobjective Particle Swarm Approach for the Design of a Brushless DC
Wheel Motor
Leandro dos Santos Coelho, Leandro Zavarez Barbosa, Luiz Lebensztajn

PB1.3	247
Coupling Particles Swarm Optimization for Multimodal Function Optimization	
<i>Minh-Trien Pham, Baatar Nyambayar, Chang Seop Koh</i>	
PB1.4	249
Automatic Differentiation Applied for Optimization of Dynamical Systems	
<i>Petre Enciu, Laurent Gerbaud, Frederic Wurtz</i>	
PB1.5	251
Influence of Sensor Variations on the Condition of the Magnetostatic Linear Inverse Problem	
<i>Roland Eichardt, Jens Haueisen</i>	
PB1.6	253
The application of topological gradients to defect identification in magnetic flux leakage-type NDT	
<i>Min Li, David Lowther</i>	
PB1.7	255
Grid-enabled Tabu Search for Electromagnetic Optimization Problems	
<i>Sara Carcangiu, Alessandra Fanni, Anna Mereu, Augusto Montisci</i>	
PB1.8	257
An Exact Optimization Code Combined with a Hybrid Model for Magnetic Couplings Design	
<i>Julien Fontchastagner, Frederic Messine, Yvan Lefevre</i>	
PB1.9	259
Electromagnetic Device Design Based on New Sequential Optimization Strategies	
<i>Gang Lei, Keran Shao, Youguang Guo, Jianguo Zhu, J. D. Lavers</i>	
PB1.10	261
A Metaheuristic Algorithm for Multiobjective Designs of Inverse Problems	
<i>S.L. Ho, Shiyong Yang</i>	
PB1.11	263
The Use of Feature Selection to Create a Compact Prototype for Electromagnetic Device Optimization	
<i>Jun Ouyang, David Lowther</i>	

PB1.12	265
Optimization of Electromagnetic and Magnetic Shielding using ON/OFF Method	
<i>Norio Takahashi, Shunsuke Nakazaki, Daisuke Miyagi</i>	
PB1.13	267
Reducing the Design Space of Standard Electromagnetic Devices using Bayesian Response Surfaces	
<i>Linda Wang, David A. Lowther</i>	
PB1.14	269
Nonlinear Filtering on Mesh Discretization Errors by Neural Networks	
<i>Douglas Alexandre Gomes Vieira, Adriano Chaves Lisboa, Vasile Palade, Rodney R. Saldanha</i>	
PB1.15	271
Particle Swarm Optimization of Coupled Electromagnetic-Electromechanical Systems	
<i>Nizar F. Al-Aawar, Toufic M. Hijazi, Abdul Rahman A. Arkadan</i>	
PB1.16	273
Self-Adjoint Material Sensitivity Analysis for Solving Inverse Problems in RF Domain	
<i>Dong-Hun Kim, Jin-Kyu Byun, Hyang-Beom Lee, Hyeong-Seok Kim</i>	
PB1.17	275
Spatio-temporal reconstruction of magnetic nanoparticle distributions	
<i>Daniel Baumgarten, Jens Haueisen</i>	
PB1.18	277
Non-Iterative Methods for Locating Inclusions in Electrical Impedance Tomography	
<i>Flavio Calvano, Guglielmo Rubinacci, Antonello Tamburrino</i>	
PB1.19	279
A Research of PTP MRAM about Shape Optimization for High Gb/Chip	
<i>Hyuk Won, Gwan Soo Park, Dong Sok Kim, Jae Min Kim</i>	
PB1.20	281
Brain source localization: a MILP approach	
<i>Fabio Freschi</i>	

PB1.21	283
A Hybrid Design of Distribution Transformers Using 2D-FE and a Conventional Method	
<i>Marco Arjona, Concepcion Hernandez</i>	
PB1.22	285
Inverse Magnetic Field Calculation For Underground Grid Condition Monitoring	
<i>Sheppard Salon, MVK Chari, J. Braunstein, J. Selvaggi</i>	
PB1.23	287
A Practical Approach to Robust Design of an RFID Triple-Band PIFA Structure	
<i>Jae-Hyeong Ko, Dong-Hun Kim, Hyang-Beom Lee, Hyeong-Seok Kim</i>	
PB1.24	289
Parameter Extraction and Optimal Design of Spiral Inductor Using Evolution Strategy and Sensitivity	
<i>Jae-Hyeong Ko, Jin-Kyu Byun, Hyeong-Seok Kim</i>	

Session PB2: Optimization II

10:40-12:10 – Room: Poster Session Room I

PB2.1	291
Optimization of perfectly matched layer parameters for finite element modeling of grounding systems	
<i>Luiz Lebensztajn, Viviane Cristine Silva, Lucas Blattner Martinho</i>	
PB2.2	293
Corrosion diagnosis of a ship mock-up from near electric field measurements	
<i>Arnaud Guibert, Jean-Louis Coulomb, Olivier Chadebec, Corinne Rannou</i>	
PB2.3	295
Dynamic Multiobjective Clonal Selection Algorithm for Engineering Design	
<i>Lucas de Souza Batista, Diogo Oliveira, Frederico Gadelha Guimaraes, Elson Jose Silva, Jaime Arturo Ramirez</i>	
PB2.4	297
Stochastic uncertainty quantification of the conductivity in EEG source analysis by using polynomial chaos decomposition	
<i>Roman Gaignaire, Guillaume Crevecoeur, Luc Dupré, Christophe Geuzaine, Patrick Dular</i>	

PB2.5	299
The EMC Method Applied to the Design of Local and Asymmetric Gradient Coils for MRI	
<i>Hector Sanchez Lopez, Michael Poole, Feng Liu, Stuart Crozier</i>	
PB2.6	301
Two complementary methods to face with convexity issues in topology optimization problems	
<i>Thibaut Labbé, François Glineur, Bruno Dehez</i>	
PB2.7	303
A Multiobjective Gaussian Particle Swarm Approach Applied to Electromagnetic Optimization	
<i>Piergiorgio Alotto, Leandro dos Santos Coelho, Helon Vicente Hultmann Ayala</i>	
PB2.8	305
Magnetic Field Synthesis in the Design of Inductors for Magnetic Fluid Hyperthermia	
<i>Fabrizio Dughiero, Paolo Di Barba, Elisabetta Sieni</i>	
PB2.9	308
Stochastic Finite Element Analysis for Parasitic Extraction of Interconnects with Material Parameter Variations	
<i>Xiaoyu Xu, Hui Qu, Li Kong, Zhuoxiang Ren</i>	
PB2.10	310
Kriging assisted design of a synchronous superconducting generator with YBCO windings	
<i>Bartosz Lukasik, Kevin Goddard, Mihai Rotaru, Jan K. Sykulski</i>	
PB2.11	312
Multiobjective Efficient Global Optimization – A Win-win Approach to Optimal Design and Model Development	
<i>Alexandru Claudiu Berbecea, Sangkla Kreuawan, Frédéric Gillon, Pascal Brochet</i>	
PB2.12	314
Parallel hybrid algorithms based on Artificial Life for Multimodal Optimization	
<i>Francesco Riganti Fulginei, Alessandro Salvini, Antonino Laudani, Salvatore Coco</i>	
PB2.13	316
Two-level refined direct method for electromagnetic optimization and inverse problems	
<i>Guillaume Crevecoeur, Ahmed Abou-Elyazied Abdallah, Luc Dupré</i>	

PB2.14	318
Application of Response Surface Methodology to Electric Machine Design with Multivariate Adaptive Regression Splines	
<i>Kenta Takayasu, Asuka Otake, Masahiko Miwa, Shinji Wakao, Tamio Okutani, Yasuhito Takahashi, Masahiro Tanai, Kazuhiko Onda</i>	
PB2.15	320
A Research on the Optimm Design of Magnet Structure for Improving Measurement Accuracy in the Dual Magnetic Float Type Level Gauge	
<i>Dong Sok Kim, Jae Min Kim, Gwan Soo Park</i>	
PB2.16	322
Examination of Optimal Design of IPM Motor using ON/OFF Method	
<i>Norio Takahashi, Takaya Yamada, Daisuke Miyagi</i>	
PB2.17	324
Optimization of Inductors Using Evolutionary Algorithms and Its Experimental Validation	
<i>Kota Watanabe, Felipe Campelo, Yosuke Iijima, Kenji Kawano, Tetsuji Matsuo, Takeshi Mifune, Hajime Igarashi</i>	
PB2.18	326
Multiobjective Optimization of Electrooptic Modulators with Floating Electrodes	
<i>Ademar Muraro Jr, André Cortes, Angelo Passaro, Nancy Mieko Abe, Airam J. Preto, Stephan Stephany</i>	
PB2.19	328
A Multi-frequency Strategy for Reconstruction of Deep Stress Corrosion Cracks from ECT Signals of Multiple Liftoffs	
<i>Li Wang, Zhenmao Chen</i>	
PB2.20	330
Accelerating Evolution Algorithm Using Kriging Metamodel	
<i>Dong-kung Woo, Jang-Ho Seo, Chany Lee, Hyun-Kyo Jung</i>	
PB2.21	332
Topology Optimization of Electrostatic Actuator Using Level Set Method and Shape Design Sensitivity	
<i>Young Sun Kim, Il Han Park</i>	

PB2.22	334
Electromagnetic Characterization of Biological Tissues with Particle Swarm Optimization	
<i>Nicolas Siauue, Corine Lormel, Romain Marion, Julien Dardenne, Fabien Sixdenier</i>	

Session PB3: Waves Propagation I

10:40-12:10 – Room: Poster Session Room II

PB3.1	336
Analysing the Relevant Features of GPR Scattered Waves in Time- and Frequency-Domain	
<i>Lucas Travassos, D. A. G. Vieira, V. Palade, N. Ida</i>	
PB3.2	338
Recent developments on a DGTD method for time domain electromagnetics	
<i>Stéphane Lanteri, Hassan Fahs, Loula Fezoui, Victorita Dolean, Francesca Rapetti</i>	
PB3.3	340
Detection of Defects in Wiring Networks using Time Domain Reflectometry	
<i>Smail Mostafa Kamel, Pichon Lionel, Olivas Marc, Auzanneau Fabrice, Lambert Marc</i>	
PB3.4	342
Finite Element Multiharmonic Modelling for Nonlinear Optics	
<i>Pierre Godard, Frederic Zolla, Andre Nicolet</i>	
PB3.5	344
An Amplitude Finite Element Formulation for Multiple-Scattering by a Collection of Convex Obstacles	
<i>Christophe Geuzaine, Patrick Dular, Roman Gaignaire, Ruth Sabariego</i>	
PB3.6	346
Finnite element analysis of electromagnetic scattering using p-adaption and an Iterative absorbing boundary condition	
<i>Prakash Paul, Jon Webb</i>	
PB3.7	348
Investigation on the shading effect of reinforced concrete construction to lightning radiation field based on TDIE method	
<i>Zhibin Zhao, Mingxia Zhang, Xiang Cui, Lin Li, Tiebing Lu</i>	

PB3.8	350
2D Scattering Integral Field Equation Solution through a IMLS Meshless-Based Approach	
<i>Williams Lara Nicomedes, Renato Cardoso Mesquita, Fernando José da Silva Moreira</i>	
PB3.9	352
Numerical Techniques for Multi-Objective Synthesis of an Inverted-S Antenna	
<i>Lei Liu, Junwei Lu, Shiyong Yang, Guangzheng Ni</i>	
PB3.10	354
Blending PSO and ANN for Optimal Design of FSS Filters with Koch Island Patch Elements	
<i>Rossana M. S. Cruz, Paulo H. da F. Silva, Adaildo Gomes d'Assunção</i>	
PB3.11	356
Coefficients of Finite Difference Operator for Rectangular Cell NS-FDTD Method	
<i>Tadao Ohtani, Kenji Taguchi, Tatsuya Kashiwa, Yasushi Kanai</i>	
PB3.12	358
Investigation of UHF Circular Loop Antennas for RFID	
<i>Kurt Preis, Thomas Bauernfeind, Oszkar Biro, Igor Ticar</i>	
PB3.13	360
Full Wave Analyses of Electromagnetic Fields with an Iterative Domain Decomposition Method	
<i>Amane Takei, Shin-ichiro Sugimoto, Masao Ogino, Shinobu Yoshimura, Hiroshi Kanayama</i>	
PB3.14	362
A New Waveguide Design Based in Thin Films of Niobium and Tantalum	
<i>Marcílio Nunes Freire, José Patrocínio da Silva</i>	
PB3.15	364
Analysis of Simple FSS Cascading With Dual Band Response	
<i>Antonio Luiz Pereira de Siqueira Campos, Robson Hebraico Cipriano Maniçoba, Lincoln Machado de Araújo, Adaildo Gomes d'Assunção</i>	
PB3.16	366
A broadband symmetric surface integral equation based on Calderón projector	
<i>Annalisa Buffa, Guglielmo Rubinacci, Antonello Tamburrino</i>	

PB3.17..... 368
Local Timestepping Techniques Using Taylor Expansion for Modeling
Electromagnetic Wave Propagation with Discontinuous Galerkin - FEM
Steffen Schomann

PB3.18 370
Safety Assessment of UWB Radio Systems for Body Area Network by the
FDTD Method
Valerio De Santis, Mauro Feliziani, Francescaromana Maradei

Session PB4: Numerical Techniques I

10:40-12:10 – Room: Poster Session Room II

PB4.1.....372
Computation Method for Transients in Underground Cables with Lossy Earth
Return Path
Xose M. Lopez-Fernandez, Casimiro Alvarez-Mariño, Vitor Malo Machado

PB4.2374
FDTD Analysis of a Metamaterial with Particles Having Oh Point Group
Symmetry
Tiago Carvalho Martins, Victor Dmitriev

PB4.3376
Discrete Constitutive Relations for the Discrete Geometric Approach over
Hexahedral Grids
Ruben Specogna, Lorenzo Codecasa, Francesco Trevisan

PB4.4 378
Domain Decomposition Methods with Second Order Transmission Conditions
for Solving Multiscale Electromagnetic Wave Problems
Zhen Peng, Vineet Rawart, Jin-Fa Lee

PB4.5 380
Improving the Mixed Formulation for Meshless Local Petrov–Galerkin
Method
*Alexandre Ramos Fonseca, Bruno Carvalho Corrêa, Elson José da Silva, Renato
Cardoso Mesquita*

PB4.6 382
Effectiveness of Higher Order Time Integration in Time Domain Finite
Element Analysis
Yoshifumi Okamoto, Koji Fujiwara, Yoshiyuki Ishihara

PB4.7	384
Extended Meshfree Point Collocation Method for Electromagnetic Problems with Layered Singularity	
<i>Young-Cheol Yoon, Do Wan Kim</i>	
PB4.8	386
Strategies for accelerating non-linear convergence for T- Ω formulation	
<i>Ping Zhou, Dingsheng Lin, Bo He, Sameer Kher, Zoltan Cendes</i>	
PB4.9	388
Shape Optimization of Rotating Machines Using Time-Stepping Adaptive Finite-Element Method	
<i>Katsumi Yamazaki, Yuji Kanou</i>	
PB4.10	390
Algorithmically Efficient Ray Tracing for the Simulation of Wall Heating in Particle Accelerator Structures	
<i>Eike Michael Scholz, Markus Clemens, Martin Dohlus</i>	
PB4.11	392
Hierarchical Sparsified Models for the Substrate of Integrated Circuits	
<i>Daniel Ioan, Gabriela Ciuprina</i>	
PB4.12	394
SUPG 3D vector potential formulation for electromagnetic braking simulations	
<i>François Henrotte, Enno Lange, Holger Heumann, Kay Hameyer</i>	
PB4.13	396
Robust FEM-BEM Coupling for Magnetostatics on multi-connected Domains	
<i>David Pusch, Joerg Ostrowski</i>	
PB4.14	398
Edge element multigrid solution of time-harmonic 3-D non-linear eddy- current problems	
<i>Chao Chen, Oszkár Bíró</i>	
PB4.15	400
FE Analysis of Magnetic Particle Dynamics on Fixed Mesh with Level Set Function	
<i>Young Sun Kim, Myung Ki Baek, Il Han Park</i>	

PB4.16	402
A Step Forward in Wavelet-Based Algebraic Multigrid Method Using the Lifting Technique	
<i>Fabio Henrique Pereira, Silvio Ikuyo Nabeta</i>	
PB4.17	404
Solution of Static Field Problems with Random Domains	
<i>Stephane Clenet, Duy Hung Mac, Jean-Claude Mipo, Olivier Moreau</i>	
PB4.18	406
Quality Evaluation of Automatically Generated Hexahedral Mesh for FEA	
<i>Yuichiro Motooka, So Noguchi, Hajime Igarashi</i>	
PB4.19	408
Parallel Sparse Matrix Solver on the GPU Applied to Simulation of Electrical Machines	
<i>Wendell O. Rodrigues, Frédéric Guyomarc'h, Jean-Luc Dekeyser, Yvonnick Le Menach</i>	

Session PB5: Optimization III

13:30-15:00 – Room: Poster Session Room I

PB5.1	410
Design of Conventional C-core Magnets Using a Multi-Step Optimization Procedure	
<i>Felipe Campelo, Jaime Arturo Ramirez, Hajime Igarashi</i>	
PB5.2	412
Self-consistent Optimization of Multi-Quantum Well Structures by a Genetic Algorithm	
<i>Angelo Passaro, Roberto Yuji Tanaka, Ademar Muraro Jr., Gustavo S. Vieira, Nancy Mieko Abe</i>	
PB5.3	414
Impact of Wave Propagation Effects in Electrical Tomography	
<i>Markus Neumayer, Gerald Steiner</i>	
PB5.4	416
Optimal Design of Electromagnetic Valve Actuator using Generic Algorithm	
<i>Jinho Kim, Junghwan Chang, Kyuyoung Han</i>	

PB5.5	418
Niched Pareto-Archived Evolutionary Programming for Multi-Objective Electromagnetic Optimization	
<i>Nunzio Salerno, Emanuele Dilettoso, Santi Agatino Rizzo</i>	
PB5.6	420
Optimization of Vibratory Behavior of Electromagnetic Devices through Material Properties Evaluation	
<i>Ferkha Nassira, Mekideche Mohamed Rachid, Miraoui Abdellatif, Djerdir Abdesslem</i>	
PB5.7	422
An Improved Continuous Genetic Algorithm for Electromagnetic Optimization	
<i>Paulo H. da F. Silva, Rossana M. S. Cruz, Adaildo Gomes d'Assunção</i>	
PB5.8	424
Differential Evolution-based Technique for Thermal Parameters Identification of a Transformer FEM model	
<i>Adnan Glotic, Joze Pihler, Nermin Sarajlic, Mensur Kasumovic, Majda Tesanovic</i>	
PB5.9	426
Multi-objective Optimization of an Axial Flux Wind Generator	
<i>João Antônio Vasconcelos, Selênio Rocha Silva, Laís Martins Araújo, Claret Laurente Sabioni, Jonas Alves de Almeida Pereira, Moisés Ferber de Vieira Lessa, Bruno Marciano Lopes</i>	
PB5.10	428
GA-based optimized design of the novel compact transversal-type UWB bandpass filter	
<i>Sungtek Kahng, Eunchul Shin, Koon-Tae Kim, Hyeong-Seok Kim</i>	
PB5.11	430
Software Methodology for Optimization of Weakly Coupled Multiphysical Problems using Object Oriented Programming	
<i>Michael Jaendl, Alice Köstinger, Ralph Kutschera, Christian Magele, Werner Renhart</i>	
PB5.12	432
Sensitivity based generation of optimized data set for ECT inversion	
<i>Szabolcs Gyimothy, Imre Kiss, Jozsef Pavo, Sandor Bilicz</i>	

PB5.13	434
Dynamic Multilevel Optimization of Machine Design and Control Parameters for PMSM Drive System Based on Correlation Analysis	
<i>Shuhong Wang, Xiangjun Meng, Jie Qiu, Jian Guo Zhu, Yi Wang, Youguang Guo, Dikai Liu, Wei Xu</i>	
PB5.14	436
Variational Level Set Methods in the Roentgen Images Segmentation	
<i>Tomasz Rymarczyk, Stefan Franciszek Filipowicz, Jan Sikora, Marek Tymburski</i>	
PB5.15	438
Numerical tool for the design of magnetic sensors based on GMI effect	
<i>Lena ABI RACHED, Francisco ALVES, Yann LE BIHAN</i>	
PB5.16	440
Harmony Search with Cauchy Operator Applied to the Hysteresis Modeling of a Transformer	
<i>Leandro dos Santos Coelho, Viviana Cocco Mariani</i>	
PB5.17	442
Automatic Design of Insulation Structure of Power Transformer Based on Sensitivity Analysis	
<i>Liu Yang</i>	
PB5.18	444
The Use of Case-Based Reasoning in Creating a Prototype for Electromagnetic Device Optimization	
<i>Jun Ouyang, David Lowther</i>	
PB5.19	446
Slot Shape Optimization for Permanent Magnet Synchronous Machines by Evolution Strategy and Time-Stepped Finite Element Analysis	
<i>Yang Zhan, Andrew M. Knight</i>	
PB5.20	448
Numerical-analytical coupled optimization of a echatronic system with particular attention to the embedded linear machine	
<i>Alexander Thomas Oswald</i>	
PB5.21	450
3-D Optimal Design of Laminated Yoke of Billet Heater for Rolling Wire Rod using ON/OFF	
<i>Norio Takahashi, Shunsuke Nakazaki, Daisuke Miyagi, Naoki Uchida, Keiji Kawanaka, Hideyuki Namba</i>	

PB5.22	452
Multiobjective Differential Evolution Approach for the TEAM Workshop Problem 25	
<i>Luiz Lebensztajn, Leandro dos Santos Coelho</i>	
PB5.23	454
A Populational Particle Collision Algorithm Applied to Electromagnetic Optimization	
<i>Piergiorgio Alotto, Leandro Dos Santos Coelho</i>	

**Session PB6: Waves Propagation II, Nanomagnetism,
Photonics and Optoelectronics**

13:30-15:00 – Room: Poster Session Room I

PB6.1	456
Microstrip Ring Antennas on Double-Layered Ferrimagnetic Substrates	
<i>Christianne F. L. Vasconcelos, Sandro Gonçalves Silva, Maria Rosa M. L. Albuquerque, José de Ribamar S. Oliveira, Adaildo Gomes d'Assunção</i>	
PB6.2	458
CFL Conditions for Finite Integration Methods Using Parallelogram and Parallelepiped Grids	
<i>Tetsuji Matsuo</i>	
PB6.3	460
A hybrid model for path loss calculation in urban environment	
<i>Leandro Carísio Fernandes, Antonio José Martins Soares</i>	
PB6.4	462
Temperature Dependence of Optical Fiber	
<i>Jose Patrocínio da Silva, Vitaly Felix Rodriguez Esquerre, Diego Souza Bezerra, Hugo Enrique Hernandez Figueroa</i>	
PB6.5	464
Analysis of the Effects of Irregular Terrain on Radio Wave Propagation Based on a Three-dimensional Parabolic Equation	
<i>Marco Aurélio Nunes da Silva, Emanuel Costa, Markus Liniger</i>	
PB6.6	466
Determination of Electromagnetic Sources Through Field Measurements	
<i>Ibrahim Akduman, Hulya Sahinturk, Ali Yapar</i>	
PB6.7	468
Improved FE-mesh truncation by surface operator implementation to speed up antenna design	
<i>Werner Renhart, Christian Magele, Christian Tuerk</i>	
PB6.8	470
Application of Method of Moments for Near Field Optics with Metal Nanoparticles	
<i>Karlo Queiroz Costa, Victor Dmitriev</i>	

PB6.9	472
Eigenvalue analysis of lossy waveguide structures using hybrid H(curl) second order finite elements	
<i>Christian Scheiber, Oszkàr Bíró</i>	
PB6.10	474
Efficient Interface Conditions for Finite Difference Time Domain Methods	
<i>Dirk Schulz</i>	
PB6.11	476
FDTD Analysis of UHF-band RFID for Metallic Objects	
<i>Yuta Watanabe, Kota Watanabe, Hajime Igarashi</i>	
PB6.12	478
The Auxiliary Problem For Transient Lossy Transmission Lines With Non-Matched Loads	
<i>Turhan Karaguler</i>	
PB6.13	480
A low cost parallel and distributed architecture for full micromagnetic numerical codes	
<i>Carlo Ragusa, Bartolomeo Montrucchio, Maurizio Repetto, Vittorio Giovara, Fabio Freschi, Baochang Xie</i>	
PB6.14	482
A Research of Various MRAM Design for High Gb/Chip on Perpendicular Pole System	
<i>Hyuk Won, Gwan Soo Park, Kang Seo, Il hwan Park</i>	
PB6.15	484
Theoretical Analysis of Field Distribution and Attenuation in a Ag/GaN Periodic Plasmon Waveguide	
<i>Anderson Oliveira Silva, Victor Dmitriev</i>	
PB6.16	486
Model for Antenna Positioning in Indoor Environments Using 2-D Ray-Tracing Technique Associated to a Particle Swarm Optimizer	
<i>Stevan Grubisic, Emanuela Cabral, Walter Pereira Carpes Junior</i>	
PB6.17	488
Accurate Transmission-Path Ray-Tracing Computation for Indoor EM Field Prediction	
<i>Antonino Laudani, Salvatore Coco, Giuseppe Pollicino</i>	

Session PB7: EMC – Electromagnetic Compatibility

13:30-15:00 – Room: Poster Session Room II

PB7.1	490
Study of the Parasitic Effect Caused by Vias in High-Frequency Circuit	
<i>Adaildo Gomes D’Assunção Jr, Glauco Fontgalland, Henri Baudrand</i>	
PB7.2	492
A 3D PEEC Method for the prediction of radiated fields from automotive cables	
<i>Yahyaoui Wissem, Pichon Lionel, Duval Fabrice</i>	
PB7.3	494
Simulation of a Real Overvoltage Transient in a TLM-Modeled Grounding Mesh	
<i>Luiz Henrique Alves de Medeiros, Marcos T. de Melo, Fabio R. L. Silva, Andre A. Almeida, Fabio. N. Fraga</i>	
PB7.4	496
Conservativeness of the Head Tissue Equivalent Liquid for Body-Worn SAR Assessments	
<i>Vikass Monebhurrun</i>	
PB7.5	498
Investigation of Electronic Stirring Chamber Phase-shifting Excitation and Load Effects	
<i>Mario Alves dos Santos Jr, Damien Voyer, Carlos Antonio França Sartori, Djonny Weinzierl, Ronan Perrussel, Christian Vollaire, Laurent Krahenbuhl, Jose Roberto Cardoso</i>	
PB7.6	500
3D Near-field Reconstruction from PCBs by Equivalent Sources Using Legendre Functions	
<i>Lotfi Beghou, Lionel Pichon, Adroaldo Raizer, François Costa</i>	
PB7.7	502
Evaluation of Shielding Effectiveness within Operating Room Using TLM Method	
<i>Wilson Valente Jr., Luciana Firmino, Adroaldo Raizer</i>	
PB7.8	504
Full Wave Solution for Intel CPU with a Heat Sink for EMC Investigations	
<i>Junwei Lu, Boyuan Zhu, David Thiel</i>	

PB7.9	506
Conductor Positions Optimization of a Transmission Line Excitation Chamber	
<i>Avila Sérgio, Santos Jr Mario, Lebensztajn Luiz, Sartori Carlos, Krahenbuhl Laurent, Cardoso José, Weinzierl Djonny</i>	
PB7.10	508
Magnetic Shielding of Apertures Loaded by Resistive Coating	
<i>Marcello D'Amore, Valerio De Santis, Mauro Feliziani</i>	
PB7.11	510
Numerical FEM models for the evaluation of EM fields exposure near welding machines	
<i>Fabrizio Dughiero, Michele Forzan, Elisabetta Sieni</i>	
PB7.12	512
Identification of equivalent multipolar electromagnetic sources by space filtering	
<i>Benjamin Vincent, Olivier Chadebec, Jean-Luc Schanen, Kévin Berger, Ronan Perrussel, Laurent Krähenbühl</i>	
PB7.13	514
Pre-evaluating a SAR Measurement System Performance by Numerical Simulations	
<i>Carlos Antonio França Sartori, Marcelo Perotoni, Antonio Marini de Almeida, José Kleber Cunha Pinto, José Roberto Cardoso, Sérgio Mühlen, Alberto Lisboa Dantas, Mário Leite Pereira Filho</i>	
PB7.14	516
Computer Analysis of Electromagnetic Transients in Grounding Systems	
<i>Rafael Silva Alípio, Marco Aurélio de Oliveira Schroeder, Márcio Matias Afonso</i>	
PB7.15	518
Proposal of Computational Model Validation for EMC Automotive Tests in Vehicles	
<i>Leonardo Lopes Santos Alvarenga, Ricardo Luiz Adriano, José Osvaldo Paulino, Joao Antônio Vasconcelos, Arnaud Christophe Pierre Marie Colin, Claudio Henrique Gomes Santos</i>	
PB7.16	520
Effect of grounding system on Electromagnetic Fields around Building Struck by Lightning	
<i>Bo Zhang, Jinliang He, Rong Zeng, Shuiming Chen</i>	

PB7.17	522
Conservativeness of the SAM Phantom for the SAR Evaluation in the Child's Head	
<i>Vikass Monebhurrun</i>	
PB7.18	524
3D-Modelling of an Aperture Illuminated by HF Electromagnetic Source for EMC Application	
<i>Mohammed djennah, Françoise Rioux</i>	
PB7.19	526
The Dynamic Circuit Model of the Spark Plug for EMI Prediction	
<i>Ya-li ZHENG, Ji-hui YU, Quan-di WANG, Jin JIA</i>	
PB7.20	528
Steady-state Inductive Coupling to the Underground Pipeline Parallel to Overhead Transmission Line above Two-layer Soil	
<i>Lei Qi, Yan Wu, Xiang Cui</i>	
PB7.21	530
A New Stochastic LPP Model for studying ELF Bioelectromagnetic Interaction	
<i>Antonino Laudani, Enrica Calà, Salvatore Coco</i>	

Session OB2: Optimization

15:20-17:10 – Room: Plenary Session Room

OB2.1	532
(Invited) An Enhanced Ellipsoid Method for Electromagnetic Devices Optimisation and Design	
<i>Douglas Alexandre Gomes Vieira, Adriano Chaves Lisboa, Rodney R. Saldanha</i>	
OB2.2	534
Robust Optimization Utilizing the Second-order Design Sensitivity Information	
<i>Dong-Hun Kim, Giwoo Jeung, Dong-Wook Kim, Heung-Geun Kim, David A. Lowther, Jan K. Sykulski</i>	
OB2.3	536
Adapted Output Space-Mapping Technique for a Bi-Objective Optimization	
<i>Stephane Brisset, Tuan-Vu Tran, Pascal Brochet, Fouzia Moussouni</i>	

OB2.4	538
Niching Evolution Strategies for Simultaneously Finding Global and Pareto Optimal Solutions	
<i>Christian Magele, Alice Koestinger, Michael Jaindl, Werner Renhart, Bogdan Cranganu-Cretu, Jasmin Smajic</i>	
OB2.5	540
Design Optimization of Waveguide Filters Using Continuum Design Sensitivity Analysis	
<i>Dong-Hun Kim, Nak-Sun Choi, Giwoo Jeung, Joon-Goo Park, Jin-Kyu Byun</i>	

Wednesday, November 25th

Session OC1: Material Modelling and Numerical Techniques

08:30-10:20 – Room: Plenary Session Room

- OC1.1** 542
(Invited) Evaluation of Electromagnetic Inspection of Hardened Depth of Spheroidal Graphite Cast Iron using 3-D Nonlinear FEM
Yuji Gotoh, Nobuya Sasaguri, Norio Takahashi
- OC1.2** 544
Modelling of Vector Hysteresis in Si-Fe Magnetic Steels and Experimental Verification
Ermanno Cardelli, Edward Della Torre, Antonio Faba
- OC1.3** 546
Size Is in the Eye of the Beholder: Technique for Non-destructive Detection of Parameterized Defects
Flavio Calvano, Pasi Raunonen, Saku Suuriniemi, Lauri Kettunen, Guglielmo Rubinacci
- OC1.4** 548
An Improved Jacobi-Davidson Method for the Computation of Selected Eigenmodes in Waveguides
Bastian Bandlow, Denis Sievers, Rolf Schuhmann
- OC1.5** 550
GPU Accelerated Adams-Bashforth Multirate Discontinuous Galerkin FEM Simulation of High Frequency Electromagnetic Fields
Nico Gödel

Session PC1: Material Modelling I

10:40-12:10 – Room: Poster Session Room I

- PC1.1** 552
Determination of Induction Motor End-Winding Leakage Inductances Using 3-D Non-Conforming FE Meshes
Andrej Stermecki, Oszkár Bíró, Kurt Preis Preis, Siegfried Rainer, Klaus Krischan Krischan, Georg Ofner Ofner

PC1.2	554
Neural FEM for Hysteretic Materials Unbounded Magnetic Field Analysis	
<i>Alessandro Salvini, Salvatore Coco, Antonino Laudani, Francesco Riganti Fulginei</i>	
PC1.3	556
Homogenization of anisotropic laminated stacks taking into account eddy currents	
<i>Slawomir Jan Wiak, Ewa Napieralska-Juszczak, Nabil Hihat, Jean Philippe Lecoq, Krzysztof Komez, Piotr Napieralski</i>	
PC1.4	558
An Anisotropic Vector Hysteresis Model Using Isotropic Vector Play Model	
<i>Tetsuji Matsuo</i>	
PC1.5	560
Influence of Material Dynamic Hysteresis Modelling in Losses Computation	
<i>Thai Phuong Do, Fabien Sixdenier, Laurent Morel, Eric Morin, Laurent Gerbaud, Frederic Wurtz</i>	
PC1.6	562
Interlamination Shorts in Transformer Cores: Estimation of Local Power Dissipation	
<i>Carl A. Schulz, Daniel Roger, Stéphane Duchesne, Jean-Noël Vincent</i>	
PC1.7	564
Modeling of Magnetolectric Effect: A Comparison between Homogenization and Finite Element Techniques	
<i>Romain Corcolle, Laurent Daniel, Frédéric Bouillault</i>	
PC1.8	566
Simple Numeric Modelling of Anomalous Eddy Current Taking Account of Domain Wall Motion in Steel Plate	
<i>Yanhui Gao, Kazuhiro Muramatsu, Koji Fujiwara</i>	
PC1.9	568
Inclusion of Eddy Currents in Laminations in Two-Dimensional Finite Element Analysis	
<i>Jenni Elina Pippuri, Anouar Belahcen, Emad Dlala, Antero Arkkio</i>	
PC1.10	570
Electromagnetic Multi-scale Homogenization of Carbon Fiber Composite Materials	
<i>Guillaume Wasselynck, Didier Trichet, Javad Fouladgar</i>	

PC1.11572
The Effects of Steel Lamination Core Losses on 3D Transient Magnetic Fields	
<i>Dingsheng Lin, Ping Zhou, Qingming Chen, Zol Cendes</i>	
PC1.12574
Analytical calculation of the interactions between two cylinder-shaped magnets	
<i>Jean-Paul Yonnet, Hicham Allag, Benoit Delinchant</i>	
PC1.13576
Numerical Modelling of Superconducting Filaments for Coupled Problem	
<i>Thitipong Satiramatekul, Frederic Bouillault</i>	
PC1.14578
Improved Accuracy of the Classical Eddy-Current Loss-Computation Technique	
<i>Anouar Belahcen, Emad Dlala, Jenni Pippuri</i>	
PC1.15	580
A New 2D Magnetic Reluctivity Model for Rotating Magnetic Fields and Its Application to FEM	
<i>Hee Sung Yoon, Sun-ki Hong, Chang Seop Koh</i>	
PC1.16	582
Measurement and Analysis of Magnetic Properties of Soft Magnetic Composite Material Considering 3-D Reluctivity Tensor	
<i>Yongjian Li, Qingxin Yang, Jianguo Zhu, Youguang Guo</i>	
PC1.17	584
A Model for Specific Losses in Grain-Oriented Steel	
<i>Oszkár Bíró, Ulrike Baumgartner, Yu Chen, Gerald Leber</i>	

Session PC2: Electrical Machines and Drives II

10:40-12:10 – Room: Poster Session Room I

PC2.1	586
Transient Performance of an Induction Motor with the Smith Connection	
<i>Tze-Fun Chan, Loi Lei Lai, Lie Tong Yan</i>	
PC2.2	588
Multi-objective Shape Optimal Design of PMLSM Utilizing Response Surface Method and Grid Computing	
<i>Chang Seop Koh, Hee Sung Yoon, Nyambayar Baatar, Hong-soon Choi</i>	

PC2.3	590
End-Effect Equivalent Method for back-EMF of High Speed SPMSM	
<i>Ki-Yong Nam, Soon-O Kwon, Jeong-Jong Lee, Jung-Pyo Hong</i>	
PC2.4	592
A performance model of an induction motor for transient simulation with a PWM drive	
<i>Derek Dyck, Geoff Gilbert, David A. Lowther</i>	
PC2.5	594
Design of a Dual-Rotor Dual-Output Radial-Flux Motor for Variable Speed Air Conditioners	
<i>Min-Fu Hsieh, Yu-Han Yeh, David G. Dorrell, Samsul Ekram</i>	
PC2.6	596
Vibration Synthesis for Electrical Machines based on Force Response Superposition	
<i>Matthias Boesing, Timo Schoenen, Knut A. Kaper, Rik W. De Doncker</i>	
PC2.7	598
Torque Ripple Analysis Method for Permanent Magnet Synchronous Reluctance Motor	
<i>Ki-Chan Kim, Ju Lee</i>	
PC2.8	600
On the Importance of Incorporating Iron Losses in the Magnetic Field Solution of Electrical Machines	
<i>Emad Dlala, Anouar Belahcen, Antero Arkkio</i>	
PC2.9	602
Efficiency Evaluation of PMASynRM Vs. SynRM Using Coupling FEM & Preisach Modeling	
<i>Tae Won Yun, Yong Hyun Kim, Jung Ho Lee</i>	
PC2.10	604
Optimization of Magnetic Bearing applied to a Ventricular Assist Device	
<i>Luiz Lebensztajn, Everton S. Yoshida</i>	
PC2.11	606
Design of High Performance Line Start Permanent Magnet Synchronous Motor with High Inertia Load	
<i>Jian Li, Byongkuk Kim, Yunhyun Cho</i>	

PC2.12	608
Slit Effect of Laminated Stator Core in Transverse Flux Rotary Machine	
<i>Ji-Young Lee, Seung-Ryul Moon, Do-Hyun Kang, Jung-Pyo Hong</i>	
PC2.13	610
Design and Analysis of a Written-pole Motor Using a Symmetric Field and FE Methods	
<i>Byung-Taek Kim, Dae-Kyong Kim, Byung-Il Kwon</i>	
PC2.14	612
Inductance Calculation and Measurement of Interior Permanent Magnet Synchronous Motor	
<i>Tao Sun, Soon-O Kwon, Jeong-Jong Lee, Geun-Ho Lee, Jung-Pyo Hong</i>	
PC2.15	614
Shape Optimization of a Thomson-coil Actuator for Fast Response Using Topology Modification	
<i>Wei Li, Jiang Lu, Young Woo Jeong, Chang Seop Koh</i>	
PC2.16	616
Optimized Axially Magnetized Permanent Magnet Tubular Actuator: Pole-Piece Shaping	
<i>Laurentiu Encica, Johan Paulides, Koen Meessen, Bart Gysen, Jorge Duarte, Elena Lomonova</i>	
PC2.17	618
Permanent Magnet Wheel Motor for Electric Vehicle Applications	
<i>Konstantinos I. Laskaris, Anastasios G. Vichos, Antonios G. Kladas</i>	
PC2.18	620
Optimized geometrical parameters of a SRM by numerical-analytical approach	
<i>Ammar Bentounsi, Redem Rebbah, Fares Rebbahi, Hind Djeghloud, Hocine Benalla, Soltane Belakehal, Bachir Batoun</i>	
PC2.19	622
Methods for efficient computation and visualization of magnetic flux lines in 3D	
<i>Martin Hafner, Marc Schöning, Marcin Antczak, Andrzej Demenko, Kay Hameyer</i>	
PC2.20	624
Calculation of Copper Losses in Intercell Transformers by 2D FEM simulation	
<i>Bernardo Cougo, Thierry Meynard, François Forest, Eric Labouré</i>	

PC2.21	626
Loss Analysis and Efficiency Evaluations of Synchronous Reluctance Motor Using Coupled FEM & Preisach Modelling	
<i>Il Kyo Lee, Yung Hyun Kim, Jung Ho Lee</i>	

Session PC3: Devices and Applications I

10:40-12:10 – Room: Poster Session Room II

PC3.1	628
A Novel Calculation Method of Distributed Parameters in Transformer Winding	
<i>Chun Zhao, Zhiye Du, Jiangjun Ruan, Ying Peng, Liang Chen</i>	
PC3.2	630
Optimal Regularization for MEG Source Reconstruction by Inverse Methods	
<i>Feng Luan, Chany Lee, Jong-Ho Choi, Hyun-Kyo Jung</i>	
PC3.3	632
Dynamic Force Analysis of Saturated Core HTS FCL under Short-Circuit Operation	
<i>Xu Fang, Jie Qiu, Shuhong Wang, Hongli Xiao, Weizhi Gong, Ying Xin, Jian Guo Zhu, Youguang Guo, Yi Wang, Wei Xu, Xiaoyang Zhang</i>	
PC3.4	634
Adaptive Ablation Treatment Based on Impedance Imaging	
<i>Alessandro Formisano, Ida Maria Vincenza Caminiti, Fabrizio Ferraioli, Raffaele Martone</i>	
PC3.5	636
A contactless dielectrophoretic handling of diamagnetic levitating water droplets in air	
<i>Paul Kauffmann, Pascale Pham, Alain Masse, Thibault Honegger, David Peyrade, Vincent Haguet, Gilbert Reyne</i>	
PC3.6	638
Compact Electromagnetic Bandgap Structures for Notch Band in Ultra-Wideband Applications	
<i>Mihai Dragos Rotaru, Jan K. Sykulski</i>	
PC3.7	640
Microwave Characterization using Least-Square Support Vector Machines	
<i>HACIB Tarik, Acikgoz Hulusi, Le Bihan Yann, Meyer Olivier, Pichon Lionel</i>	

PC3.8	642
Electromagnetic disruption loads on ITER blanket modules	
<i>Maurizio Furno Palumbo, Raffaele Albanese, Roberto Palmaccio, Guglielmo Rubinacci, Pietro Testoni, Fabio Villone</i>	
PC3.9	644
Fast Computations Technique of Forces Acting on Moving Permanent Magnet	
<i>Marek Ziolkowski, Hartmut Brauer</i>	
PC3.10	646
A model to relate SAR to surface field measurements in human phantoms	
<i>Oriano Bottauscio, Mario Chiampì, Luca Zilberti</i>	
PC3.11	648
Design of Railway Wheel Detector Insusceptible to Electromagnetic Noise	
<i>Asuka Otake, Kenta Takayasu, Shinji Wakao, Tamio Okutani, Yasuhito Takahashi, Masahiko Saito, Akihisa Toyoda</i>	
PC3.12	650
Simulation of Internal Myocardium Defibrillation using Macroscopic Anisotropy Models and Finite Element Analysis	
<i>Steve McFee, Maryam Golshayan</i>	
PC3.13	652
Novel Applications of Inductive Method for Measuring Critical Current Density	
<i>Atsushi Kamitani, Teruou Takayama, Soichiro Ikuno</i>	
PC3.14	654
Hybrid generation of subject specific head models	
<i>Robert Szmurło, Jacek Starzyński, Bartosz Sawicki, Stanisław Wincenciak</i>	
PC3.15	656
Modeling a “flying carpet” stable in both the positive and negative z-directions	
<i>Mikhail Kustov, Orphée Cugat, Gilbert Reyne</i>	
PC3.16	658
3D Voltage Driven Finite Element Analyses of Eccentric Rotor Positions of a Novel Hybrid Radial Active Magnetic Bearing	
<i>Erich Schmidt, Matthias Hofer</i>	

PC3.17	660
Contact Parameter Computation and Analysis of Air Circuit Breaker with Permanent Magnet Actuator	
<i>Shuhua Fang, Heyun Lin, Siu-lau Ho, Xianbing Wang, Ping Jin</i>	
PC3.18	662
Reduction of Repulsion Forces on Current-Carrying Contact using 3-D FEM	
<i>Tomohiro Ota, Satoshi Suzuki, Katsuhiro Hirata</i>	
PC3.19	664
Dynamic Analysis Method for Electromagnetic Artificial Muscle Actuator under PID Control	
<i>Yoshihiro Nakata, Hiroshi Ishiguro, Katsuhiro Hirata</i>	
PC3.20	666
Controllable Reactor Simulation using Integral Equation Method	
<i>Zoran Andjelic, David Pusch, Xiaobo Yang</i>	
PC3.21	668
SAR Calculations Using Realistic Phone Models: Uncertainty Due to Positioning	
<i>Vikass Monebhurrun, Azzedine Gati, Man-Fai Wong, Joe Wiart</i>	
PC3.22	670
Antenna Modeling for Inductive RFID Applications Using the PEEC Method	
<i>Peter Scholz, Wolfgang Ackermann, Thomas Weiland, Christian Reinhold</i>	
PC3.23	672
Design and Implementation of a High Frequency Flyback Converter Using New-developed Polymer-bonded Magnetic Cores	
<i>Kai Ding, K.W.E Cheng, Yang Shiyou</i>	
PC3.24	675
Evaluation of Discharge Current by Generalized Energy Method and Integral Ohm's Law	
<i>Se-Hee Lee, Il-Han Park, Francis O'Sullivan, Markus Zahn</i>	

Session PC4: Numerical Techniques II

10:40-12:10 – Room: Poster Session Room II

PC4.1	677
On the equivalence of Finite Element and Finite Integration formulations	
<i>Andrzej Demenko, Jan Sykulski, Rafal Wojciechowski</i>	

PC4.2	679
A Fast Numerical Analysis of Electromagnetic Fields in Large Grounding Systems	
<i>Hongxia Huang, Lin Li</i>	
PC4.3	681
Overlapping Finite Elements for Arbitrary Surfaces in 3D	
<i>Stephane Clenet, Guillaume Krebs, Igor Tsukerman</i>	
PC4.4	683
Basis functions for divergence constraints in the finite element method	
<i>C. M. Pinciuc, A. Konrad, J. D. Lavers</i>	
PC4.5	685
Agglomeration-based algebraic multigrid for linear systems coming from edge-element discretizations	
<i>François Musy, Laurent Nicolas, Ronan Perrussel</i>	
PC4.6	687
A 2D robust FE-FV mixed method to handle strong nonlinearities in superconductors	
<i>Abelin Kameni, Smail Mezani, Frédéric Sirois, Denis Netter, Jean Lévêque, Bruno Douine</i>	
PC4.7	689
A Posteriori Error Estimation and Adaptive Mesh Refinement Controlling in Finite Element Analysis of 3D Steady State Eddy Current Fields	
<i>Jinbiao Li, Dexin Xie, Xiaoming Liu</i>	
PC4.8	691
Auto adaptive interface treatment for the EFGM in electromagnetic problems	
<i>Carlos Alex Sander J. Gulo, Jose Marcio Machado, Gleber Nelson Marques</i>	
PC4.9	693
Automatic treatment of multiply connected regions in Integral Formulations	
<i>Guglielmo Rubinacci, Antonello Tamburrino</i>	
PC4.10	695
Complex Adjoint Variable Method for Finite Element Analysis of Eddy Current Problems	
<i>Hajime Igarashi, Kota Watanabe</i>	

PC4.11	697
New Method Analysis of Non-rotating Magnetoacoustic Tomography with Magnetic Induction	
<i>yang zhang</i>	
PC4.12	699
Combined Spectral-Element, Finite-Element Discretization for Magnetic- Brake Simulation	
<i>Herbert De Gersem</i>	
PC4.13	701
Weight Function Control of Moving Least-Squares Interpolants: Application to Axisymmetric Shielding Current Analysis in HTS	
<i>Soichiro Ikuno, Teruou Takayama, Atsushi Kamitani</i>	
PC4.14	703
Interior Penalty Discontinuous Galerkin Method for the Time-Domain Maxwell's Equations	
<i>Stylianos Dosopoulos, Jin-Fa Lee</i>	
PC4.15	705
A FEM Approach for Analyzing the Corona Ionized Field of Bipolar Bundled Conductors	
<i>Haiyan Yuan, Zhengcai Fu, Junwei Lu</i>	
PC4.16	707
The Solution of Electromagnetic Field Problems using a Sliding Window Gauss-Seidel Algorithm on a Multi-Core Processor	
<i>Hussein Moghnieh, David Lowther</i>	
PC4.17	709
Speeding Up the Process of Building High-Quality Finite-Element Meshes	
<i>Cássia Regina Santos Nunes, Renato Cardoso Mesquita, David Alister Lowther</i>	
PC4.18	711
Extended Boundary-Node Method: Application to Potential Problem	
<i>Ayumu Saitoh, Taku Itoh, Atsushi Kamitani</i>	
PC4.19	713
Reduction of Eddy Current Losses by several Cuts in Conductors	
<i>Arnulf Kost, Matthias Ehrich</i>	

PC4.20	715
Fields and Current Formulation for Radiofrequency Antennas	
<i>Nabil El Alami, Bernard Bandelier, Françoise Rioux-Damidou</i>	
PC4.21	717
A New Method to Solve 3D Magnetodynamic Problems without Assembling an $Ax = b$ system	
<i>João Pedro Assumpção Bastos, Nelson Sadowski</i>	
PC4.22	719
Multiphysics problems via the Cell Method: the role of Tonti diagrams	
<i>Piergiorgio Alotto, Fabio Freschi, Maurizio Repetto</i>	
PC4.23	721
Time--domain geometric eddy--current SA formulation for hexahedral grids	
<i>Ruben Specogna, Lorenzo Codecasa, Patrick Dular, Francesco Trevisan</i>	
PC4.24	723
A finite element method for structures defined by a regular 3D grid of material properties	
<i>Huanhuan Gu, Jean Gotman, Jon Webb</i>	

Session PC5: Material Modelling II

13:30-15:00 – Room: Poster Session Room I

PC5.1	725
Hysteresis Losses' Calculation of Magnetostrictive Ultrasonic Transducer with Jiles-Atherton Hysteresis Model	
<i>Jianbin Zeng, Baodong Bai, Haiquan Zeng</i>	
PC5.2	727
Implementation of an Advanced Eddy-Current Model for Non-Linear Laminated Media	
<i>Anouar Belahcen, Emad Dlala, Jenni Pippuri</i>	
PC5.3	729
Vector Magnetic Hysteresis Modeling of Soft Magnetic Composite Material	
<i>Youguang Guo, Haiyan Lu, Jianguo Zhu, Zhiwei Lin, Jinjiang Zhong, Shuhong Wang</i>	

PC5.4	731
On the Use of Multi-Direction Si-Fe Sheet Sample Magnetic Properties Measured by Epstein Frame in Finite Element Analysis	
<i>Dexin Xie, Qilin Liu, Zhiqiang Ren, Xiaoyan Wang, Yanli Zhang, Zhiguang Cheng</i>	
PC5.5	733
A Study for Harmonic Iron Loss for Electrical Steel under Alternating Magnetic Field	
<i>Sun-Ki Hong, Chang Seop Koh</i>	
PC5.6	735
An Improved Reluctivity Model for Vector Magnetic Properties of Silicon Steels under Distorted Magnetic Flux Density	
<i>Yanli Zhang, Jingguo Yuan, Dexin Xie, Chang Seop Koh</i>	
PC5.7	737
Inrush Currents in a Three-Phase Transformer Taking Into Account Vector Hysteresis	
<i>Jean Vianei Leite, Abdelkader Benabou, Nelson Sadowski</i>	
PC5.8	739
Study of Different FEM Models to Analyze Homogenized Iron Lamination with Electrical Fault	
<i>Juliana Luisa Müller, Abdelkader Benabou, Thomas Henneron, Francis Piriou, João Pedro Assumpção Bastos, Jean-Yves Roger</i>	
PC5.9	741
Three-Phase Transformer Modelling Using the Vector Hysteresis Model and Including the Eddy Current and the Anomalous Losses	
<i>Mauricio Valencia Ferreira da Luz, Jean V. Leite, Abdelkader Benabou, Nelson Sadowski</i>	
PC5.10	743
Iron-Loss Modeling for Rotating Machines: Comparison between Bertotti's Three-Term Expression and 3-D Eddy-Current Analysis	
<i>Katsumi Yamazaki, Noriaki Fukushima</i>	
PC5.11	745
Effect of Temperature Dependence of Magnetic Properties on Heating Characteristics of Induction Heater	
<i>Norio Takahashi, Hiroyuki Kagimoto, Hiroaki Kurose, Daisuke Miyagi, Naoki Uchida, Keiji Kawanaka</i>	

PC5.12	747
Evaluation of Electromagnetic Inspection of Retained Austenite in High Chromium Cast Iron using 3-D Nonlinear FEM Considering Non-Uniform Permeability	
<i>Yuji Gotoh, Akira Nishishita, Nobuya Sasaguri, Norio Takahashi</i>	
PC5.13	749
3-Dimensional Modelling of Magnetostriction in Iron Core with Equivalent Nodal Forces	
<i>Yanhui Gao, Kazuhiro Muramatsu, Koji Fujiwara, Yoshiyuki Ishihara, Shigemasa Fukuchi, Tetsumi Takahata</i>	
PC5.14	751
Tolerance Analysis of NMR Magnets	
<i>Alessandro Formisano, Raffaele Martone</i>	
PC5.15	753
homogenization in electromagnetism: a thermodynamic insight	
<i>Vincent Mazauric</i>	
PC5.16	755
FE Analysis of Plasma Discharge and Sheath Characterization in Dry Etching Reactor	
<i>Gwang-Jun Yu, Young Sun Kim, Se-Hee Lee, Il Han Park</i>	

Session PC6: Electrical Machines and Drives III

13:30-15:00 – Room: Poster Session Room I

PC6.1	757
Permanent-Magnet Synchronous Generator Supplying an Isolated Load	
<i>Tze-Fun Chan, Weimen Wang, Loi Lei Lai</i>	
PC6.2	759
Development of Flux Reversal Linear Synchronous Motor with Multiple Auxiliary Salient Poles	
<i>Shi-Uk Chung, Hong-Ju Lee, Byung-Chul Woo, Ji-Won Kim, Seung-Ryul Moon, Sang-Moon Hwang</i>	
PC6.3	761
Reduction of Cogging Torque for Axial Flux Generator Applied to Small Wind Turbine	
<i>Min-Fu Hsieh, Yu-Han Yeh, David G. Dorrell, Samsul Ekram</i>	

PC6.4	763
Comparison of Magnetic Characteristics according to Stator Core Composition in Transverse Flux Rotary Machine	
<i>Ji-Young Lee, Ji-Won Kim, Byung-Chul Woo, Sang-Ho Lee, Jung-Pyo Hong</i>	
PC6.5	765
Design of the Cage-bars for Single Phase LSPMSM considering the Starting Torque and Magnetic Saturation	
<i>Seung Joo Kim, Won Ho Kim, Kwang Soo Kim, Jong Bin Im, Ju Lee</i>	
PC6.6	767
Analysis of Very Fast Transient Overvoltages and Electric Field Stresses in Conventional Tesla Transformers Using FDTD Method	
<i>Edris Agheb, Ehsan Hashemi, Kaveh Niayesh, Ali Mousavi, Mohsen Faridi</i>	
PC6.7	769
Computational Analysis of Fringing Fields and Forces in the Cylindrical Coordinate System	
<i>Bart. L.J. Gysen, Koen J. Meessen, Johannes J.H. Paulides, Elena A. Lomonova</i>	
PC6.8	771
Field Calculation in the Innovative Transformers with Amorphous Modular Cores	
<i>Dariusz Koterak, Bronislaw Tomczuk, Kazimierz Zakrzewski</i>	
PC6.9	773
Automated Optimization in the Design Process of a Pending Workbench	
<i>Jan Albert, Remus Banucu, Alexander Hafla, Veronika Reinauer, Christian Scheiblich, Wolfgang M. Rucker, Alexander Huf</i>	
PC6.10	775
Effects of Load Variation on Eccentricity Fault Diagnosis in Round Rotor Synchronous Motors	
<i>Bashir Mahdi Ebrahimi, Mohammad Mohammad Etemad Rezaie, Jawad Faiz</i>	
PC6.11	777
Dynamic Characteristics Analysis of Spherical Resonant Actuator Using 3-D FEM	
<i>Satoshi Suzuki, Yoshihiro Kawase, Tadashi Yamaguchi, Shuhei Kakami, Katsuhiro Hirata, Tomohiro Ota</i>	

PC6.12	779
Finite Element Processing Methods to Peripheral Flux Leakage in Axial Field Flux-Switching PM Machines	
<i>Mingyao Lin, Lei Zhang, Xin Li, Haitao Yu</i>	
PC6.13	781
Slotted and Torus PM Generators for Low Speed Direct Drive Applications using an Analytical/Static 2D FEA Design Technique	
<i>David George Dorrell</i>	
PC6.14	783
A General Cuboidal Element for Three-Dimensional Thermal Modeling	
<i>Rafal Wrobel, Phil Mellor</i>	
PC6.15	785
Time-Stepping Finite Element Analysis of a Salient-pole and Round-Rotor Synchronous Generators under Dynamic Eccentricity Fault	
<i>Jawad Faiz, Mojtaba Babaie, Bashir Mahdi Ebrahimi, Jalal Nazarzadeh</i>	
PC6.16	787
Magnetic Forces and Displacement Analysis of Large Scale BLDC Motor by Magneto-Mechanical Formulation	
<i>Pan Seok Shin, Hee Jun Cheong, Sung Hyun Woo, Chang Seop Koh</i>	
PC6.17	789
Optimized Coil Position for Improvement of Holding Torque of the PM - Spherical Motor	
<i>Sung-Hong Won, Dong-Woo Kang, Won-Ho Kim, Sung-Chul Go, Cheol-Jick Ree, Ju Lee</i>	
PC6.18	791
Comparative study of the inductances of an induction motor with rotor eccentricities	
<i>Elkin Ferney Rodriguez Velandia, Jose Andres Santisteban Larrea, Antonio Carlos Ferreira</i>	
PC6.19	793
Development of a Flexible Phase Variable Model for Two-Phase Hybrid Stepping Motor Using Virtual Magnetic Gateway based FEA	
<i>Jiixin Chen, Youguang Guo, Jianguo Zhu, Weinong Fu</i>	

PC6.20	795
Novel Modeling of Flux-barriers in Interior-type PM Synchronous Motor For Pulsation Torque Reduction: Part I. Various Flux-barrier Designs	
<i>Liang Fang, Jeong-Jong Lee, Jung-Pyo Hong</i>	
PC6.21	797
Parametric Finite Element Analyses of a Permanent Magnet Synchronous Machine with an External Rotor	
<i>Erich Schmidt, Marko Susic</i>	
PC6.22	799
2D Exact Analytical Solution of Open Circuit Magnetic Field in Slotted Surface Mounted PM Radial Flux Synchronous Machines	
<i>Yacine Amara, Jacques Raharijaona, Georges Barakat</i>	
PC6.23	801
Quasistatic Electromagnetic Field Computation by Conformal Mapping in Permanent Magnet Synchronous Machines	
<i>Martin Hafner, David Franck, Kay Hameyer</i>	
PC6.24	803
Calculation of Inductances in Intercell Transformers by 2D FEM simulation	
<i>Bernardo Cougo, Thierry Meynard, François Forest, Eric Labouré</i>	

Session PC7: Numerical Techniques III

13:30-15:00 – Room: Poster Session Room II

PC7.1	805
Study on Analysis Method for Ferrofluid	
<i>Yu Okaue, Gaku Yoshikawa, Fumikazu Miyasaka, Katuhiro Hirata</i>	
PC7.2	807
Isogeometric analysis for electromagnetic problems	
<i>Annalisa Buffa, Rafael Vázquez</i>	
PC7.3	809
Nonoverlapping and overlapping decomposition methods in 3D BEM multilayered model for Optical Tomography	
<i>Tomasz Marek Grzywacz, Jan Sikora</i>	

PC7.4	811
Galerkin Projection Method for Sliding Interfaces in Finite Element Analysis of Electrical Machines	
<i>Enno Lange, François Henrotte, Kay Hameyer</i>	
PC7.5	813
Convergence Acceleration of Time-Periodic Electromagnetic Field Analysis by Singularity Decomposition-Explicit Error Correction Method	
<i>Yasuhito Takahashi, Tadashi Tokumasu, Akihisa Kameari, Hiroyuki Kaimori, Masafumi Fujita, Takeshi Iwashita, Shinji Wakao</i>	
PC7.6	815
Efficient Block Gauss-Seidel Preconditioner for 3D Full-Wave Finite Element Analysis	
<i>Toshio Murayama, Shinobu Yoshimura</i>	
PC7.7	817
Numerical Convergence of Method of Moments in the Analysis of Bodies of Revolution	
<i>Ursula Resende, Fernando Moreira</i>	
PC7.8	819
A 3-D FE Particle-in-Cell Parallel code with adaptive load balancing	
<i>Antonino Laudani, Salvatore Coco, Giuseppe Pollicino, Paola Tirrò</i>	
PC7.9	821
Parallel Computing of Magnetic Filed for Rotating Machines on the Earth Simulator	
<i>Tomohito Nakano, Yoshihiro Kawase, Tadashi Yamaguchi, Masanori Nakamura, Noriaki Nishikawa, Hitoshi Uehara</i>	
PC7.10	823
An efficient algorithm for planar circuits design	
<i>Alexandre Serres, Glauco Fontgalland, José Ewerton P. De Farias, Henri Baudrand</i>	
PC7.11	825
MPI Parallelization for Large Electromagnetic Simulations using Curvilinear Finite Elements	
<i>Wolfgang Ackermann, Galina Benderskaya, Thomas Weiland</i>	

PC7.12	827
Multicore Acceleration of CG Algorithms using Blocked-Pipeline-Matching Techniques	
<i>David M. Fernández, Dennis D. Giannacopoulos, Warren J. Gross</i>	
PC7.13	829
A New Approach to the Impedance Method	
<i>Airton Ramos, Daniela O.H. Suzuki</i>	
PC7.14	831
A simplified T- ϕ formulation for eddy current computation in thin CFRP plates	
<i>Hocine MENANA, Mouloud FELIACHI</i>	
PC7.15	833
Preconditioned BICGSTAB Algorithm and its Application to a Moving Linear Electric Motor	
<i>Haitao Yu</i>	
PC7.16	835
An Efficient Two-Level Preconditioner for FEM-BEM Equations based on Lifting	
<i>Fabio Henrique Pereira, Marcio Matias Afonso, Silvio Ikuyo Nabeta</i>	
PC7.17	837
A Comparison of Parallel Finite Element Analysis Using Domain Decomposition	
<i>Kota Watanabe, Kenji Yoneta, Hajime Igarashi</i>	
PC7.18	839
Kernel Regularization for Volume Integral Equations	
<i>Michael V. Davidovich</i>	
PC7.19	841
Error Estimators based on Kriging Interpolation	
<i>Vanessa Gomes Cruz, Luiz Lebensztajn</i>	
PC7.20	843
Investigations on the Accuracy of Maxwell Stress Tensor based Force Calculations	
<i>Ghislain Remy, Guillaume Krebs, Francois Henrotte</i>	

PC7.21	845
Determination of Uniform Magnetizing Current Density With Stable ICCG Convergence Using Simple Technique and Regularization	
<i>Yoshifumi OKAMOTO, Koji FUJIWARA, Yoshiyuki ISHIHARA, Tetsuji MATSUO</i>	
PC7.22	847
Parallel Direct Solver For The Finite Integration Technique in Electrokinetic Problems	
<i>Abdellatif TINZEFTE, Yvonnick Le Menach, julien korecki, Frédéric Guyomarch, francis piriou</i>	
PC7.23	849
Computation of forces using mean and difference potentials	
<i>Antônio Flavio NOGUEIRA</i>	
PC7.24	851
Numerical algorithms for the image reconstruction in electrical impedance tomography	
<i>Stefan Franciszek Filipowicz, Tomasz Rymarczyk, Jan Sikora</i>	

Session PC8: TEAM, Education and Software Methodolgy

13:30-15:00 – Room: Poster Session Room II

PC8.1	853
The Application of System Dynamics in Learning Electromagnetic Contactor Operation	
<i>Paulo Irineu Koltermann, Jéferson Meneguín Ortega, Valmir Machado Pereira, Éder Rodrigues Martins, Luiz Antônio Righi</i>	
PC8.2	855
Educational Software for the Numerical Correction of the Experimental Magnetization Curves	
<i>Valentin IONITA, Emil CAZACU</i>	
PC8.3	857
Application of the Method of Residues in Comparison to TLM Method in a Practical Case	
<i>Sérgio Henrique Lopes Cabral, Sávio Leandro Bertoli</i>	
PC8.4	859
Semi-Analytical Solution of 2-D Rotor Eddy-Current Losses due to the Slotting Effect in SMPMM	
<i>Frédéric Dubas, Christophe Espanet</i>	

PC8.5	861
Effect of Source Replacement on both Iron Loss and Flux in Solid and Laminated Steel Configurations	
<i>Zhiguang Cheng, Norio Takahashi, Behzad Forghani</i>	
PC8.6	863
An Adaptive Equivalent Circuit Method for TEAM Problem 28: An Electrodynamic Levitation Device	
<i>Wei Li, Jiang Lu, Chang Seop Koh</i>	
PC8.7	865
Proposal of a Benchmark for Multi-Level Optimization with 3D Finite Element Model	
<i>Stephane Brisset, Tuan-Vu Tran, Pascal Brochet</i>	
PC8.8	867
Visualization Method of Magnetic Flux Lines with Accurate Allocation Applying Tube System	
<i>So Noguchi, Hideo Yamashita</i>	
PC8.9	869
A Weakly Coupled Parallel 2D Delaunay Refinement Algorithm	
<i>Mauro Massayoshi Sakamoto, José Roberto Cardoso Cardoso, Marcelo Facio Palin Palin, Fabio Henrique Pereira Pereira, Maurício Barbosa de Camargo Salles Salles</i>	
PC8.10	871
The Broad Sense Chain-Making and Chain-Coupling Theorems of Element Grid in 2-D Problems	
<i>Nan Xiong, Kexun Jiang</i>	
PC8.11	873
Analyse of different programming solutions adapted to block matrix type in electromagnetic modelling	
<i>Laurent Santandrea, Yahya Choua, Alejandro Ospina, Yann Le Bihan, Claude Marchand</i>	
PC8.12	875
Simulation of Electric Field Distribution in Polymeric Insulators	
<i>Rosemeri C Fagundes, Walmor C Godoi, Marco A A Vasco, Vitoldo Swinka-Filho, Klaus de Geus, Andre E Lazzaretti</i>	
PC8.13	877
The Cross-Entropy Method and its Application to Inverse Problems	
<i>S.L. Ho, Shiyong Yang</i>	

PC8.14	879
Scalability of Higher-Order Discontinuous Galerkin FEM Computations for Solving Electromagnetic Wave Propagation Problems on GPU Clusters	
<i>Markus Clemens, Nico Gödel, Tim Warburton, Nigel Nunn</i>	

Session OC2: Devices and Applications and Electromagnetic Compatibility

15:20-17:10 – Room: Plenary Session Room

OC2.1	881
(Invited) EMC Modeling of an Industrial Variable Speed Drive with an Adapted PEEC Method	
<i>Vincent Ardon, Jérémie Aimé, Olivier Chadebec, Édith Clavel, Jean-Michel Guichon, Enrico Vialardi</i>	
OC2.2	883
Calculation of Equivalent Circuit Parameters for a High-Frequency RFID Transponder	
<i>Thomas Bauernfeind, Kurt Preis, Oszkar Biro, Florian Hämmerle</i>	
OC2.3	885
Planar Coil Model using Shell Elements Applied to an Eddy-Current Non-Destructive Testing	
<i>Alejandro Ospina, Laurent Santandrea, Yann Le Bihan, Claude Marchand</i>	
OC2.4	887
Numerical Field Calculation in Support of the Hardware Commissioning of the LHC	
<i>Bernhard Auchmann, Stephan Russenschuck</i>	
OC2.5	889
Fault Classification and Detection by Wavelet Based Magnetic Signature Recognition	
<i>Francisco Xavier Sevegnani, Carlos A.F. Sartori</i>	

Thursday, November 26th

Session OD1: Electric Machines and Drives

08:30-10:20 – Room: Plenary Session Room

- OD1.1**891
(Invited) Modeling the dynamic behavior of magnetostrictive actuators
Oriano Bottauscio, Paolo E. Roccato, Mauro Zuca
- OD1.2** 893
Determination of d-q Axis Parameters of Interior Permanent Magnet Machines
Ping Zhou, Dingsheng Lin, Georg Wimmer, Zoltan Cedens
- OD1.3** 895
Simulation of the Winding Overhangs in Permanent Magnet Synchronous Machines
Bogdan Funieru, Andreas Binder
- OD1.4** 897

Abstract—This paper deals with time-domain surface-impedance boundary conditions in computational magnetodynamics considering both magnetic-vector potential and magnetic-field formulation. Based on the resolution of the 1-D eddy-current problem in a semi-infinite slab, the massive conducting region is accounted for by choosing a number of exponentially decreasing trigonometric basis functions covering the relevant frequency range. Herein the method is elaborated for the magnetic-field formulation. Results for both formulations are compared and validated on a two-dimensional test case.

I. INTRODUCTION

SURFACE-impedance boundary conditions (SIBCs) are widely applied in frequency-domain eddy-current problems for considering massive conducting regions. The approach is based on the relation between the tangential components of the electric and the magnetic field at the surface of the conducting region and allows to avoid the discretisation of its volume. The few time-domain extensions proposed to date are mostly based on the fast Fourier transform [1], [2], or on the iterative coupling between the main 3-D finite element (FE) model and a large number of 1-D FE calculations (with classical nodal basis functions) [3].

In [4], the authors proposed a time-domain approach based on the magnetic-vector-potential formulation. This approach is herein extended for the magnetic-field formulation. Results of both formulations will be compared and validated on a 2-D test case.

II. 1-D EDDY CURRENT PROBLEM IN SEMI-INFINITE SLAB

Let us consider a low-frequency eddy-current problem in a bounded domain $\Omega = \Omega_c \cup \Omega_c^C \in \mathbb{R}^3$ with boundary Γ . The conductive and non-conductive parts of Ω are denoted by Ω_c and Ω_c^C , respectively. We are only concerned with linear and homogeneous media, i.e. the conductivity σ (resistivity $\rho = 1/\sigma$) and the permeability μ (reluctivity $\nu = 1/\mu$) are constant scalars in Ω .

The following Maxwell equations and constitutive laws are taken into account:

$$\operatorname{div} \underline{b} = 0, \quad \operatorname{curl} \underline{h} = \underline{j}, \quad \operatorname{curl} \underline{e} = -\partial_t \underline{b}, \quad (1 \text{ a-c})$$

$$\underline{j} = \sigma \underline{e}, \quad \underline{b} = \mu \underline{h}, \quad (2 \text{ a b})$$

where \underline{b} is the flux density (or induction), \underline{h} the magnetic field, \underline{j} the current density and \underline{e} the electric field.

This work was partly supported by the Belgian Science Policy (IAP P6/21).

A. 1-D eddy-current problem and FE model

The 1-D eddy-current problem in a semi-infinite slab ($0 \leq x \leq \infty$, $b(x, t)$ and $h(x, t)$ parallel to the z -axis, $j(x, t)$ and $e(x, t)$ parallel to the y -axis) can be expressed in terms of the z -component of $\underline{h}(x, t)$ denoted by $h(x, t)$:

$$\partial_x^2 h = \sigma \mu \partial_t h \quad \text{with} \quad h(x = \infty, t) = 0, \quad (3)$$

where the boundary condition at infinity ($x = \infty$) ensures the uniqueness of $h(x, t)$. The sinusoidal steady-state solution of (3) at frequency f (pulsation $\omega = 2\pi f$), with boundary condition $h(x = 0, t) = \hat{h} \cos(\omega t + \phi)$, reads

$$h(x, t) = \hat{h} \cos(\omega t + \phi) e^{-x/\delta} \cos(x/\delta) + \hat{h} \sin(\omega t + \phi) e^{-x/\delta} \sin(x/\delta), \quad (4)$$

with δ the skin depth and ϕ an arbitrary phase angle.

The FE discretisation of (3) by means of N basis functions $\alpha_i(x)$, $0 \leq x < \infty$, $1 \leq i \leq N$, leads to a system of first-order differential equations. It reads

$$[S][H(t)] + [M] \partial_t [H(t)] = [V(t)], \quad (5)$$

where $[H(t)]$ is the column matrix that comprises the N degrees of freedom of $h(x, t)$; the only non-zero element (first) of column matrix $[V(t)]$ equals the electromotive force; the elements of $[S]$ and of $[M]$ are given by

$$S_{ij} = \rho \int_0^\infty \partial_x \alpha_i(x) \partial_x \alpha_j(x) dx, \quad (6)$$

$$M_{ij} = \mu \int_0^\infty \alpha_i(x) \alpha_j(x) dx. \quad (7)$$

The associated positive-definite quadratic forms are the instantaneous magnetic energy density $w(t)$ and the instantaneous eddy-current loss density $p(t)$:

$$w = [H]^T [M] [H] \quad \text{and} \quad p = [H]^T [S] [H]. \quad (8)$$

B. Dedicated basis functions

The choice of basis functions is motivated by the solution of the 1-D eddy-current problem (4) [4]. For a given time-domain problem, a set of skin depths δ_k can be preset accounting for the frequency content of the magnetic fields and the accuracy required. We define thus the following $2n$ basis functions:

$$\alpha_{c1}(x) = e^{-x/\delta_1} \cos(x/\delta_1), \quad (9)$$

$$\alpha_{ck}(x) = e^{-x/\delta_k} \cos(x/\delta_k) - \alpha_{c1}(x), \quad 2 \leq k \leq n, \quad (10)$$

$$\alpha_{sk}(x) = e^{-x/\delta_k} \sin(x/\delta_k), \quad 1 \leq k \leq n. \quad (11)$$

Note that all basis functions vanish at the boundary except the first one, i.e. $\alpha_{c1}(x = 0) = 1$.

III. INTEGRATION IN FE MODEL

The SIBC method is applied to a massive subdomain Ω_m of Ω_c . The weak form of the Faraday law (1c) is written as:

$$\partial_t(\mu \underline{h}, \underline{h}')_{\Omega \setminus \Omega_m} + (\rho \text{curl } \underline{h}, \text{curl } \underline{h}')_{\Omega_c \setminus \Omega_m} + \langle n \times e, h' \rangle_{\partial \Omega_m} = 0, \quad (12)$$

where $(\cdot, \cdot)_{\Omega}$ and $\langle \cdot, \cdot \rangle_{\partial \Omega_m}$ denote a volume integral in Ω and a surface integral on $\partial \Omega_m$, respectively, of the scalar product of their arguments; \underline{n} is the outward normal on $\partial \Omega_m$. At the discrete level Whitney edge elements are adopted for (12).

Ignoring the finite depth of Ω_m and the curvature of $\partial \Omega_m$, we can consider a local coordinate system and write the magnetic field in Ω_m as $\underline{h} = \underline{h}_t(y, z) p(x, t)$, with \underline{h}_t tangential to $\partial \Omega_m$ and $p(x, t)$ differentiable with respect to x ($0 \leq x < \infty$). With our time-domain approach, the two volume integrals considered in Ω_m are thus reduced to the following surface integrals:

$$\partial_t(\mu \underline{h}, \underline{h}')_{\Omega_m} = \partial_t \langle \underline{h}_t, \underline{h}'_t \rangle_{\partial \Omega_m} \cdot \mu \int_0^{\infty} p p' dx, \quad (13)$$

$$(\rho \text{curl } \underline{h}, \text{curl } \underline{h}')_{\Omega_m} = \langle \text{curl } \underline{h}_t, \text{curl } \underline{h}'_t \rangle_{\partial \Omega_m} \cdot \rho \int_0^{\infty} \partial_x p \partial_x p' dx, \quad (14)$$

Considering $\alpha_{ck}(x)$ and $\alpha_{sk}(x)$ for the space discretisation of $p(t)$ and $p'(t)$, the integration along the x -axis in (13) and (14) produces the elements of the matrices $[S]$ and $[M]$.

IV. APPLICATION EXAMPLE

The 2-D application example concerns a non-magnetic conducting cylinder (radius $R = 10$ cm; $\sigma = 6 \cdot 10^7$ S/m) inside an inductor (rectangular cross-section) with imposed current. Only one quarter of the geometry is modeled (see Fig. 1). The

Fig. 1. Flux pattern (in phase with imposed sinusoidal current) with $\delta/R = 0.5$ (left) and $\delta/R = 0.1$ (right)

classical magnetic-field (h-)formulation and magnetic-vector-potential (a-)formulation with a very fine discretisation of the cylinder near its surface provide an accurate reference solution. Two typical flux patterns obtained with the a-formulation are depicted in Fig. 1. When applying the SIBC, only the mesh outside the cylinder is effectively considered. A trapezoidal current varying between 1 and -1 at 1 kHz is considered. We adopt a low order approximation of the SIBC with $f_1 = 1$ kHz and further discrete frequencies being odd multiples of f_1 . The induction and the current density in a point at the surface of the cylinder are shown in Fig. 2 for the first fundamental period. Note that the results obtained with the low-order SIBC converge faster ($n = 1$) for the induction with the h-formulation and for the current with the a-formulation.

The magnetic energy and the joule losses in the cylinder have been calculated during the first period with the fine model

Fig. 2. Induction and current density in a point at the surface of the cylinder versus time obtained with dual fine models and time-domain SIBC approaches

(without SIBC) and the low-order SIBC (n equal to 1 and 2). A good convergence of the SIBC results towards the reference results for both formulations is observed in Fig. 3.

Fig. 3. Joule losses and magnetic energy in the cylinder versus time obtained with dual fine models and time-domain SIBC approximations ($n = 1, 2$)

Further results obtained with the two dual formulations on a 3-D application will be included in the full paper.

Abstract: Accurate numerical simulation of eddy-current testing (ECT) experiments usually requires large computational efforts. To avoid time-consuming computations, a natural idea is to build a cheap approximation of the expensive-to-run simulator. In this paper, a kriging-based approximation of an ECT simulator is presented. Kriging is widely used in other domains, but is still quite unexplored in the ECT community. The kriging approximation is built using a random process model of the simulator and a set of simulation results obtained for a number of different input configurations. The resulting approximation might yield almost the same results as those of the simulator.

Keywords: Eddy-current testing; Kriging; simulator approximation

I. INTRODUCTION

Eddy-current testing is well-known for a long time and is applied in a wide range of industrial problems. However, the accurate numerical simulation of the physical phenomenon is still challenging. Finite element and/or integral equation methods are able to provide acceptable accuracy, at a quite high price however, since these methods are implemented using technically complex computer programs that generally necessitate advanced hardware and long computation times. Nowadays, more and more emphasis is put on the *emulation*, or *surrogate modeling* of EM phenomena [1]. This trend leads the electromagnetic community to consider new methods based on mathematical tools from other domains.

Our paper presents an application of *kriging* to eddy-current testing problems. The proposed method provides a way to construct a cheap approximation for a *specific* ECT problem. The main idea is to build a database of ECT configurations, i.e. a set of pairs consisting of a vector of the parameters of a defect and the corresponding output signal, and then to use kriging to predict the output signal at any untried vector of defect parameters. Once the database is built, one does not need the expensive simulator any longer, but only a cheap kriging model.

Kriging is a prediction method appeared in the 60s in the domain of geostatistic. By now, several variants of the method have been developed and a comprehensive literature deals with kriging (see, e.g. [2]). For a recent review of the topic, see [3]. Some applications in electromagnetics are presented for instance in [4]. Also the authors have applied kriging to solve ECT inverse problems in [5]. However, the approach of [5] focuses on the kriging prediction of a *cost-function* (to be minimized in an optimization loop) – now the present paper deals with the use of kriging *directly* on the output signal.

II. THE PROPOSED METHOD

A. The forward prediction problem

The cheap input-output approximation will be built from a database of computer simulations of the ECT problem. To simplify the notation, let us suppose that a vector of output parameters \mathbf{y} is related to a vector of input parameters \mathbf{x} through

$$\mathbf{y} = \mathbf{f}(\mathbf{x}), \quad (1)$$

\mathbf{f} representing the underlying physical phenomena. For eddy-current testing application \mathbf{x} might be the geometrical parameters describing a defect affecting a plate and \mathbf{y} the measured data (coil impedances at different locations above the plate). A possible realization \mathbf{f} is a numerical solution of the corresponding Maxwell's equations.

The proposed method is a two-step approach.

- 1) Compute some corresponding $(\mathbf{x}_i, \mathbf{y}_i), i = 1, \dots, n$ pairs (“samples”) using (1) and store them in a *database* that one will use at the stage 2.
- 2) Fit a kriging interpolator to the samples stored in the database and predict the sought \mathbf{y} output at any arbitrary \mathbf{x} input point.

B. Basics of kriging

The main idea of kriging is to model a real-valued function f by a Gaussian process, the latter being characterized by its mean and its covariance function. The covariance function describes the statistical dependence between two values of the process and it is a scalar function of one parameter under the hypothesis of a *stationary* modeling process. However, the covariance function is not known before f has been observed. Generally, one chooses a class of parameterized covariance functions and tunes the parameters in order to fit the modeling process to the pointwise observations of f .

Once an appropriate covariance function is determined, the prediction $\hat{f}(x)$ of $f(x)$ at any arbitrary x is written as a linear combination of the observations:

$$\hat{f}(x) = \sum_{i=1}^n \lambda_i(x) f(x_i).$$

The $\lambda_i(x)$ weights are computed using the covariance function, by solving a linear system of n equations. The prediction is an *interpolation*, since $f(x_k) = \hat{f}(x_k)$ holds for all $k = 1, 2, \dots, n$. Note that beyond the mere interpolation, kriging provides additional information about the *uncertainty* of the prediction as well.

C. Application to the ECT problem

In (1), the output \mathbf{y} is a vector of size q . It is then appropriate to use an extension of kriging called *co-kriging*

[2] to obtain a prediction model, which takes into account, not only the statistical dependence between the inputs and each component of the vector-valued output, but also the dependence *between* the components of the output vector. Formally, the kriging prediction is

$$\hat{\mathbf{y}}(\mathbf{x}) = \sum_{i=1}^n \Lambda_i(\mathbf{x}) \mathbf{y}_i, \quad (2)$$

with the weighting matrices $\Lambda_i(\mathbf{x})$ of size $q \times q$. The use of n pre-computed samples ($\mathbf{y}_i = \mathbf{y}(\mathbf{x}_i)$, $i = 1, 2, \dots, n$) leads to a linear system of $n \times q$ equations to solve which can be computationally demanding. The hypothesis that all entries of \mathbf{y} have similar statistical behaviour leads to a simpler problem of q distinct kriging models (one for each entry of \mathbf{y}). Due to the assumed statistical similarity of entries, the models are the same and one can then write

$$\hat{\mathbf{y}}^*(\mathbf{x}) = \sum_{i=1}^n \lambda_i(\mathbf{x}) \mathbf{y}_i, \quad (3)$$

using the weighting scalar $\lambda_i(\mathbf{x})$ obtained through the solution of a system of only n linear equations. The common covariance (describing the behaviour of all entries of \mathbf{y}) can be either chosen “by hand” or fitted by maximum likelihood to an appropriate one-dimensional representation of \mathbf{y} (e.g. the first principal component).

The (3) expression is a convenient and computationally cheap interpolator. Beyond the introduction of the method, the main aim of our paper is to examine the validity of the assumptions (leading from the exact (2) to the treatable (3) predictions).

III. ILLUSTRATIVE ECT PROBLEM

In the studied ECT configuration, a volumetric defect (with a $\sigma(\mathbf{r})$ variable conductivity) takes place within a homogeneous, non-magnetic conductive plate (with σ_0 conductivity). An air-cored pancake type coil (probe) scans above the damaged zone, in a plane parallel to the plate. The coil is driven by sinusoidal current and the variations of its impedance at different locations are measured. These locations are placed at the nodes of a rectangular grid, i.e. a surface scan is performed. The defect is assumed to be cuboid-shaped of volume Ω , thus, can be described by a small number of geometrical parameters, such as sizes and positions. The solution of the forward problem is obtained by the classical *volume integral approach* [6]. The electric field at a position \mathbf{r} in the plate is written as a sum of two terms: $\mathbf{E}(\mathbf{r}) = \mathbf{E}^i(\mathbf{r}) + \mathbf{E}^d(\mathbf{r})$ where \mathbf{E}^i is the *incident field* (in a flawless plate), and \mathbf{E}^d is the *defect field*, i.e. the distortion of the field due to the flaw. The current dipole densities \mathbf{P} and \mathbf{P}^i are defined by $\mathbf{P}(\mathbf{r}) = (\sigma(\mathbf{r}) - \sigma_0) \mathbf{E}(\mathbf{r})$ and $\mathbf{P}^i(\mathbf{r}) = (\sigma(\mathbf{r}) - \sigma_0) \mathbf{E}^i(\mathbf{r})$. The interaction of the EM field of the coil with the flaw can be described by an integral equation given by

$$\mathbf{P}(\mathbf{r}) = \mathbf{P}^i(\mathbf{r}) - j\omega\mu_0\sigma_0\chi(\mathbf{r}) \int_{\Omega} \mathcal{G}(\mathbf{r}|\mathbf{r}') \mathbf{P}(\mathbf{r}') dV'. \quad (4)$$

The so-called defect description function $\chi(\mathbf{r})$ is defined as $\chi(\mathbf{r}) = [\sigma(\mathbf{r}) - \sigma_0] / \sigma_0$. $\mathcal{G}(\mathbf{r}|\mathbf{r}')$ is nothing but the classical dyadic Green’s function. Once (4) is solved, the variation

of the coil impedance can be expressed as

$$\Delta Z = -\frac{1}{I_0^2} \int_{\Omega} \mathbf{E}^i(\mathbf{r}) \cdot \mathbf{P}(\mathbf{r}) dV, \quad (5)$$

based on the reciprocity theorem. Here, I_0 denotes the current of the probe coil.

A simple case with two input parameters is chosen to illustrate the method. An OD-type defect (having $\sigma(\mathbf{r}) = 0$ everywhere in Ω) with a known position and width takes place within the plate. The defect is characterized by its length (L) and depth (D , given in % of plate thickness) leading to a 2-dimensional input parameter vector \mathbf{x} . The surface scan of the probe coil is centered on the crack and contains $q = 841$ measurement points and the corresponding q ΔZ complex values (5) are stored in the output parameter vector \mathbf{y} .

The region of interest in the input domain is $0.5 \text{ mm} < L < 3.5 \text{ mm}$ for the length and $10\% < D < 90\%$ for the depth, respectively. In Fig. 1, one can see the input samples (5×5 regularly spaced) and the normalized error of the prediction by (3).

The result is promisingly nice: a very small ($\approx 2\%$) prediction error, by using only $n = 25$ samples (which means that the kriging prediction is made in no time).

Figure 1. Normalized interpolation error (%) in the example. The normalizing term is $\|\mathbf{y}\|_2$ of the largest ($L = 3.5 \text{ mm}$, $D = 90\%$) defect.

IV. CONCLUSION AND FUTURE WORK

A kriging-based approach as a cheap approximation for ECT problems is presented. In the light of the preliminary results, the method is promising. However, a precise examination of the validity of the simplifications is the main task for the future.

Though no theoretical limitation restricts the method to the domain of ECT problems, we described and formalized our approach in the context of a given ECT configuration. However, generality is not narrowed in this way, one can also easily imagine other applications.

Adaptive Parabolic-Elliptic Time Integration Method for Electroquasistatic Problems

Zsolt Badics*

Rhythmia Medical, Inc.

111 South Bedford Street, Burlington, MA 01803, U.S.A.

badics@ieee.org

Abstract—An adaptive parabolic-elliptic time-integration algorithm based on a singly diagonal implicit Runge-Kutta (SDIRK) scheme is described for the FE solution of nonlinear electroquasistatic (EQS) problems. The algorithm uses the nodal charge as the dynamic variable in addition to the scalar potential, thereby achieving superior stability and performance compared to schemes using only the scalar potential. High-order integration is achieved by incorporating the Jacobian into the time integration formula.

I. BACKGROUND

We can often utilize electroquasistatic (EQS) computational models when the inductive effects are negligible compared to the capacitive and conductive phenomena [1]. A brilliant analysis of how to decide if an EQS model is applicable can be found in [2]. There is a wide range of application areas of EQS models: high voltage problems [3], semiconductor substrate coupling modeling [4], thermistor modeling [5], electroquasistatic MEMS micro-machine modeling [6], and biomedical applications [7].

The EQS approximation allows the representation of the electric field by a scalar potential

$$\mathbf{E} = -\text{grad } \Phi \quad (1)$$

and thus yields the following governing equations:

$$\dot{\rho} = \frac{\partial \rho}{\partial t} = -\text{div } \mathbf{J}(\Phi) \quad (2)$$

$$0 = \rho - \text{div } \mathbf{D}(\Phi) \quad (3)$$

$$\mathbf{J}(\Phi) = \bar{\sigma}(\mathbf{E}(\Phi), \mathbf{x}) \mathbf{E}(\Phi) \quad (4)$$

$$\mathbf{D}(\Phi) = \bar{\epsilon}(\mathbf{E}(\Phi), \mathbf{x}) \mathbf{E}(\Phi) + \mathbf{P}_0 \quad (5)$$

We allow anisotropic, nonlinear and spatially varying conductivity $\bar{\sigma}$ and permittivity $\bar{\epsilon}$. It is an algebraic exercise to incorporate permanent polarization, \mathbf{P}_0 , into the algorithm. Therefore, we assume $\mathbf{P}_0=0$ for the rest of the discussion.

The most common solution approach is to eliminate the volumetric charge distribution by plugging (3) into (2)

$$\frac{\partial}{\partial t} [\text{div}(\bar{\epsilon} \text{grad } \Phi)] + \text{div}(\bar{\sigma} \text{grad } \Phi) = 0 \quad (6)$$

and derive a time integration scheme for (6). The main downside of this approach is that the EQS model allows temporal discontinuity in the excitation potential, which can seriously degrade the performance of adaptive variable-step time integration methods. It is also difficult to model problems by (6) when perfect insulator regions or high conductivity contrasts are present.

We find advantageous to develop a time integration scheme directly for the parabolic-elliptic system (2), (3).

II. FORMULATION

For the sake of simplicity, let us derive the time integration method for the Dirichlet problem depicted in Figure 1. (The generalization to more complex arrangements, boundary conditions and excitations is straightforward.) Since the two domains have different material properties, a surface charge density q appears on the interface Σ [2] satisfying

$$\dot{q} = \frac{\partial q}{\partial t} = -(\hat{\mathbf{n}} \cdot \mathbf{J}^+ - \hat{\mathbf{n}} \cdot \mathbf{J}^-) \quad (7)$$

$$0 = q - (\hat{\mathbf{n}} \cdot \mathbf{D}^+ - \hat{\mathbf{n}} \cdot \mathbf{D}^-) \quad (8)$$

Let us split $\Phi = v + v_D$, where $v = 0$ and $v_D = \Phi_D$ on the boundary Γ_D as usual. Thus the weak form of the parabolic-elliptic system (2), (3), (7) and (8) is

$$\int_{\Omega} v' \dot{\rho} + \int_{\Sigma} v' \dot{q} ds = \int_{\Omega} \text{grad } v' \cdot \mathbf{J}(v) + \int_{\Omega} \text{grad } v' \cdot \mathbf{J}(v_D) \quad (9)$$

$$0 = \int_{\Omega} \rho' \rho + \int_{\Sigma} \rho' q ds + \int_{\Omega} \text{grad } \rho' \cdot \mathbf{D}(v) + \int_{\Omega} \text{grad } \rho' \cdot \mathbf{D}(v_D) \quad (10)$$

where v' and ρ' are the weighting functions. We can write the abstract differential algebraic equation (DAE) system (9), (10) in the concise form of an abstract Cauchy problem

$$H\dot{y} = Ky + K_D v_D(t) = F(t, y), \quad y(0) = y_{initial} \quad (11)$$

where $y = [\rho \quad q \quad v]^T$.

Fig. 1. Dirichlet problem with two regions having different materials

III. TEMPORAL DISCRETIZATION

We discretize (11) in time first by utilizing a one-step SDIRK (singly diagonal implicit Runge-Kutta) method. The application of DIRK schemes for electromagnetic problems is proved to be very efficient, especially when the problem is stiff [8], [9], [10]. We follow the Rosenbrock type SDIRK discretization scheme discussed in detail in [11].

Suppose that at time step t_n y is y_n and the selected time step is τ_n . Then, the M -stage SDIRK scheme estimates y_{n+1} at the next time step $t_{n+1} = t_n + \tau_n$ in the form

*The author was with Ansoft Corp. when this research was pursued.

$$y_{n+1} = y_n + \sum_{s=0}^{M-1} m_s Y_{n,s}; \quad Y_{n,s} = [R_{n,s} \quad Q_{n,s} \quad V_{n,s}]^T \quad (12)$$

where the stage variables $Y_{n,s}$ are computed recursively by

$$\begin{aligned} \left[\frac{1}{\tau_n \gamma} H - F_y(t_n, y_n) \right] Y_{n,s} &= F(t_s, y_s) \\ &+ \tau_n \gamma_s F_t(t_n, y_n) - \sum_{j=0}^{s-1} \frac{c_{sj}}{\tau_n} H Y_{n,j}; \quad s = 0, 1, \dots, M-1 \end{aligned} \quad (13)$$

Here F_y is a linear operator representing the Fréchet derivative of F and

$$t_s = t_n + \alpha_s \tau_n, \quad y_s = y_n + \sum_{j=0}^{s-1} a_{sj} Y_{n,j} \quad (14)$$

The coefficients m_s , γ , γ_s , c_{sj} , α_s , and a_{sj} are selected to obtain desired properties [11]. In order to choose optimal time steps adaptively we employ the time step control algorithm described in [11]. Notice that Newton iteration is not required in the nonlinear case when solving (13) because the Jacobian is incorporated directly into the time integration formula.

IV. SPATIAL DISCRETIZATION

We discretize the scalar variables ρ , q , and v of the boundary value problem (13) in space by the finite element method. One troublesome issue is that we have to introduce the surface variable q for all the interfaces where the conductivity is discontinuous. This significantly increases the complexity of the implementation. Fortunately, there is remedy for this problem. The idea is to introduce nodal charges [12] analogously to the nodal forces in mechanical FE models.

Consider the volumetric and surface charge density terms in the weak form (9) and (10). The corresponding charge density terms in the FE discretization of (13) can be replaced by

$$\eta_m = \int_{\Omega} \alpha_m \rho + \int_{\Sigma} \alpha_m q ds \quad (15)$$

where α_m is the shape function and η_m is the nodal charge associated with the FE node m . By utilizing (15) the finite element y vector contains only the nodal charges and the nodal values of the electric scalar potential. Similarly, we can introduce nodal charge stage variables in (12) instead of $R_{n,s}$ and $Q_{n,s}$.

V. VERIFICATION

The method and its efficiency are verified by solving a benchmark problem introduced in [1]. The physical model is depicted in Figure 2.(a) where 100V is switched between the central and ground electrodes. Figure 2.(b) and 2.(c) show potential and electric field plots at $t=0$ and $t \gg \tau_e$, respectively. ($\tau_e = \epsilon/\sigma$ is the charge relaxation time.) The temporal behavior shows good agreement with the control results in [1]. The full paper will present and analyze the performance of the variable time stepping procedure similarly as presented for thermal problems in [11]. The full version will also demonstrate further advantages of our time integration technique by presenting additional examples.

Numerical experimentations on the coupling between PEEC and volume integral method

Tung Le Duc, Olivier Chadebec, Jean-Michel Guichon, Gérard Meunier, Yves Lembeye
Grenoble Electrical Engineering Laboratory, Grenoble-INP / Université Joseph Fourier / CNRS
ENSE³, BP46, 38402 Grenoble, France

Abstract — In order to model ferromagnetic material in quasi-static PEEC method, a coupling with a volume integral equation is proposed. This coupling enables to take advantage of the strong points of each method. The modeling of complex conductor geometry is achieved thanks to PEEC method and magnetic materials are taken into account thanks to a volume integral equation. The coupling is carried out by introducing an impedance matrix (computed with PEEC method in the vacuum) within an integral magnetostatic equation solved by moment method.

I. INTRODUCTION

The PEEC method (Partial Element Equivalent Circuit) is mainly used for the modeling of complex interconnections and can be applied to a large range of devices where the air region is dominant [1] (printed circuits, bus bars...). However, the classical PEEC method does not enable the 3D modeling of ferromagnetic materials widely present in devices (ferromagnetic shielding, disruptive magnetic masses, and cores of inductance). The magnetostatic moments method is well-known and derives from a volume integral equation solved by a point matching approach. It is particularly well adapted to model lightly very simple magnetic materials volume. Like the PEEC method, it does not require the meshing of the air region; on the other hand, it is limited to modeling of magnetostatic effects. Both methods are complementary. A strong coupling of them can be accomplished by modeling non conductive magnetic regions with a method of moments, while PEEC method allows the modeling the contributions of the inductors fed with alternative currents.

II. COUPLING PRINCIPLE

A. Magnetostatic moment method

Let us consider a non conductive magnetic material placed in an inductor field \mathbf{H}_0 . The total magnetic field \mathbf{H} is the sum of \mathbf{H}_0 and \mathbf{H}_{red} , the reaction of the material. A well-known integral volume equation links the local field to the magnetization of the whole material volume V_{mat} :

$$\mathbf{H} = \mathbf{H}_0 + \frac{1}{4\pi} \int_{V_{\text{mat}}} \left(3 \frac{(\mathbf{M} \cdot \mathbf{r})}{r^5} \mathbf{r} - \frac{\mathbf{M}}{r^3} \right) dV \quad (1)$$

where \mathbf{r} is the vector linking the integration point to the point where the field is expressed, V_{mat} the ferromagnetic volume and \mathbf{M} its magnetization. Usually, this integral is solved with a numerical technique. The easier way is to mesh the volume into n elements and to consider that the magnetization is uniform on each of them. Then, thanks to a point matching approach of the linear magnetic material's law at the center of

each element, a linear matrix system is obtained. It remains to solve it, to obtain the magnetization of the whole volume V_{mat} . This method is usually called magnetostatic moment method. This formulation is known to suffer of some inaccuracies in some specific configurations [2]. However, the purpose of this paper is the coupling and very similar methodology can be applied to more sophisticated volume integral formulations.

Let's now assume that the inductor field is created by m unknown alternative currents I flowing in m conductors. In a very similar way to the previous one, we can get a linear system of equations. For instance, the equation associated to magnetic element k is:

$$\frac{\mathbf{M}_k}{\mu_r - 1} = \frac{1}{4\pi} \sum_{i=1}^n \int_{V_{\text{mat}_i}} \left(\frac{(\mathbf{M}_i \cdot \mathbf{r})}{r^5} \mathbf{r} - \frac{\mathbf{M}_i}{r^3} \right) dV_i + \frac{1}{4\pi} \sum_{j=1}^m \int_{V_{\text{cond}_j}} \frac{d\mathbf{l} \times \mathbf{r}}{r^3} I_j dV_j \quad (2)$$

where μ_r is the relative permeability of the material. The second integral term correspond to the Biot and Savart's law integrated on each conductor volume V_{cond_j} . The global matrix system obtained has $6n$ equations (a vector complex equation per element) and $6n+2m$ unknowns (a vector complex magnetization per element plus m complex currents).

B. Inductive PEEC method

Let us consider m volume conductors fed with alternative sources placed in a surrounding air region without any magnetic materials. The well-known PEEC method is particularly reliable to solve this kind of problem. It is based on the determination of partial voltage generated on each conductor by electromagnetic sources. To compute these voltages volume integration on the conductor of the magnetic vector potential created by all the others conductor is provided. For instance, for the conductor k , the expression is [1]:

$$V_{k_cond} = \frac{\mu_0}{4\pi} \frac{j\omega}{s_k} \int_{V_k} \left(\sum_{i=1}^m \frac{I_i}{s_i} \int_{V_i} \frac{1}{r} dV_i \right) dV_k \quad (3)$$

where ω is the angular frequency and S_i is the section of the i -th conductor. This equation links partial voltages of conductors to currents flowing in them. If we write this equation for all conductors, we get a matrix system known as impedance matrix system. By combing these electromagnetic equations with the circuit ones representative of the conductors wiring and adding resistance source effect, it is possible to get a simplified system representative of the device which can be easily coupled with a standard circuit simulator. This inductive PEEC method has already shown its efficiency for the modeling of complex conductor geometries in comparison with FEM.

Let us now consider that linear ferromagnetic materials are present in the surrounding air region. Equation (3) has to be

modified by taking into account the influence of the field created by the material. In fact, like in the first approach, we have to integrate the magnetic vector potential on the volume conductor k . A new voltage has to be added to the previous one, not generated by the current but by the magnetization [3].

$$V_{k_mat} = \frac{\mu_0}{4\pi} \frac{j\omega}{s_k} \int_{V_k} \left(\sum_{i=1}^n \int_{V_i} \frac{\mathbf{M}_i \times \mathbf{r}}{r^3} dV_i \right) \cdot \mathbf{u}_k dV_k \quad (4)$$

Finally, equations (3), (4) and (5) are brought together in a global square $(6n+2m) \times (6n+2m)$ matrix system:

$$\begin{bmatrix} \mathbf{MoM} & \mathbf{BS} \\ \mathbf{L}_M & \mathbf{L}_{standard} \end{bmatrix} \times \begin{bmatrix} \mathbf{M} \\ \mathbf{I} \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{V} \end{bmatrix} \quad (5)$$

where \mathbf{MoM} is the standard moments matrix (first two rearranged term of equation (2)), \mathbf{BS} is the Biot and Savart integral term (last term of (2)), \mathbf{L}_M is the influence of magnetization on conductors in PEEC approach (equation (4)) and $\mathbf{L}_{standard}$ the classical inductive and resistive PEEC matrix. By taking into account circuit equations, it is possible to reduce (5) to get a lighter system and to solve it to get magnetizations and currents in conductors.

III. NUMERICAL EXAMPLES

We consider two numerical examples (Fig.1.). For both, three numerical methods are compared. The first one is the scalar magnetic potential FEM coupled with circuit equations. In this modeling, a special care is given to the mesh around both conductors to ensure accurate results. The second one is a coupling between PEEC to model inductances and FEM to take into account the ferromagnetic material. This approach has already shown its good accuracy with a reduced number of elements in comparison with standard FEM [4]. The last one is the considered coupling.

In the first example, two conductors are considered with a ferromagnetic bar ($\mu_r = 1000$, linear) placed between them (Fig.1, left). The first conductor is fed by a voltage source (1V, 1 kHz). The second one is in short circuit mode. To compare different approaches, we focus on the computed current in the second conductor with different meshes for the three approaches (see table I).

TABLE I. Currents values obtained (A)

FEM			
Nb of elements	230.000	600.000	1.000.000
Current values	-36.25+6,00i	-32.47+7,94i	-32.61+7.87i
FEM/PEEC			
Nb of elements	60.000	150.000	
Current values	-32.60+8,38i	-32.50+8.34	
MoM/PEEC			
Nb of elements	32	126	392
Current values	-35.97+8,95i	-32.94+8.34i	-32.70+8.32i

Whereas the convergence is quickly reached with the FEM/PEEC method, the problem needs a very fine mesh to be accurately solved with FEM. We can see a small difference between both computed values. It can be explained by a small difference in the modelling method used to represent conductors. Results provided by our coupling are very encouraging, the convergence being reached with a very few

number of elements (around 200). Of course, the obtained matrix is fully dense, but the computation time is divided per one hundred in comparison with FEM and ten with FEM/PEEC. Moreover, no specific mesh refinement has been needed.

The second test case is an inductance of microphone converter. It is composed of a complex-shaped conductor and of two ferrite parts (Fig.1. right). In our study, the conductor is fed by a voltage source (1V, 10 kHz) and the ferrite is considered as linear with a permeability of 1000. Values of currents are still compared.

TABLE II. Currents values obtained (A)

FEM 100.000 elements	FEM/PEEC 30.000 elements	MoM/PEEC 2000 elements
14,36 – 1,97i	14,39 – 1,85i	14,43 – 1,68i

Results seem to be not so good for the coupling MoM / PEEC especially if we have a look to the imaginary part of the current. This inaccuracy is mainly due to the small distance between conductors and the magnetic material, leading to important variation of magnetization in the neighborhood of currents. This configuration benefits FEM in comparison with our coupling. A good improvement would certainly be to couple PEEC with a more sophisticated implementation of the volume integral equation.

IV. CONCLUSION

In this paper, we have presented a coupling between PEEC and an integral volume equation. Our approach can be very fast and accurate and enables the introduction of linear magnetic material in PEEC methodology. It is particularly capable for the modeling of complex shapes conductors and relatively simple magnetic material geometry.

Abstract— The paper describes a novel adaptive solution system for electromagnetic field problems. The solution method is based on a meshless approach and thus the pre-processing effort is minimized. The positions of the nodes used for this solution are determined adaptively using a Kohonen Neural Network. The objective of the proposed approach is to obtain an optimal placing of the nodes before adding any new degrees of freedom to reduce the error.

I. INTRODUCTION

The numerical solution of electromagnetic field problems has been a subject of research for almost half a century and it is now possible to simulate the real device to a very high level of accuracy. The most commonly used methods for low frequency electromagnetic systems are based around the finite element technique which has been steadily improved in all its aspects over many years. However, the computational cost is still relatively high and can lead to long execution times, especially if an adaptive system is used to reduce the error. One of the problems with the finite element approach is that it requires the solution domain to be meshed. While great gains have been made in reducing the complexity of solving the resulting linear equations, the mesh generation process is still costly and can be the most time consuming part of certain classes of problems. When adaptation is included, and is implemented by modifying the mesh to add new degrees of freedom, this cost becomes significant. For this reason, attention has been paid to alternate differential approaches usually known as “meshless methods”. These systems, as the name implies, do not need to generate a mesh and thus bypass this drawback of the finite element system. Adaptation can also be implemented in such a system by adding new nodes at points of high error. However, this approach increases the size of the problem and thus the solution time. A better, initial approach to adaptation might be to consider an optimal placement of the starting node set such that the global and local errors in the solution are minimized. This paper proposed that this might be done by considering the nodes of a meshless system to be part of a Kohonen Self Organizing Feature Map – a form of neural network. Using this approach, the nodes of the system can be repositioned to minimize the errors before any new degrees of freedom are added.

II. MESHLESS SOLUTION SYSTEMS

In a meshless system, the field solution is approximated by local shape functions, often, but not always, a form of radial basis function. Each node, through its shape function, is considered to have a domain of influence which could cover the entire problem space or might be limited to a local

neighborhood [3]. The field value at any point in space is then given by summing the contributions of all the nodes within whose domain of influence the point lies. Boundary and interface conditions can be handled through a collocation technique.

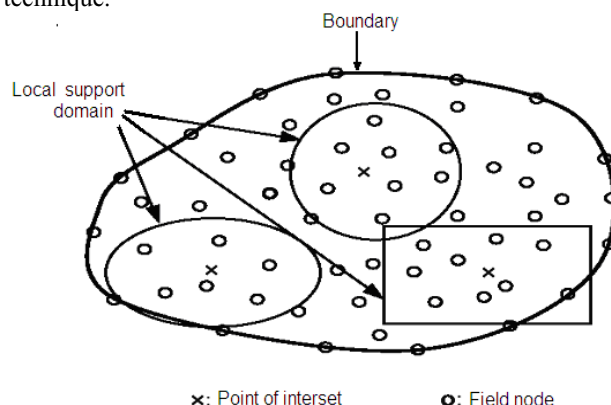

Fig.1. A meshless discretization of an arbitrary domain

A typical radial basis function is the Gaussian given by

$$\Psi(r) = e^{-(\epsilon r)^2} \quad r \in \mathfrak{R} \quad (1)$$

The radius, r , can be expressed in terms of the distance from the center of the function, $x-x_k$. [4]

III. KOHONEN NEURAL NETWORKS

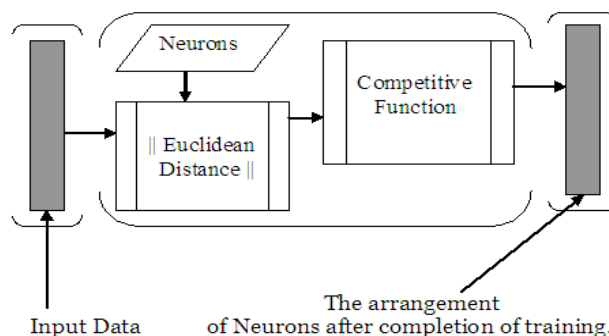

Fig.2. The Kohonen Architecture.

The Kohonen network, also known as self-organizing map is a two-layer unsupervised neural network and has fully interconnected processing units that compete among themselves to be activated or fired[1][2]. It has a strong self-organizing ability, because of which after the training procedure the predefined network grid will follow the structure and distribution of the input points. It is trained iteratively. In each training step one vector x from the input data set is chosen

randomly and the distances between it and all the weight vectors of the Kohonen nodes are calculated using the Euclidean distance. The neuron whose weight vector is the closest to the input vector x is called the Best Matching Unit (BMU) denoted here by b

$$\|x - m_b\| = \min_{i \in N} \{\|x - m_i\|\} \quad (2)$$

N represents the set of Kohonen nodes and $\|\cdot\|$, the Euclidean distance. After this the BMU along with its topological neighbors are moved closer to the input vector in the input space using the following relation.

$$m_i(s+1) = m_i(s) + \alpha(s)h_{bi}(s)[x(s) - m_i(s)] \quad (3)$$

where s denotes time or iteration steps, x is an input vector drawn from the input data set during s , $h_{bi}(s)$ is the kernel function around the winning neuron b and $\alpha(s)$ is the learning rate during s .

IV. THE PROPOSED ALGORITHM

Based on the above, the meshless adaptive algorithm is as shown in Fig. 3.

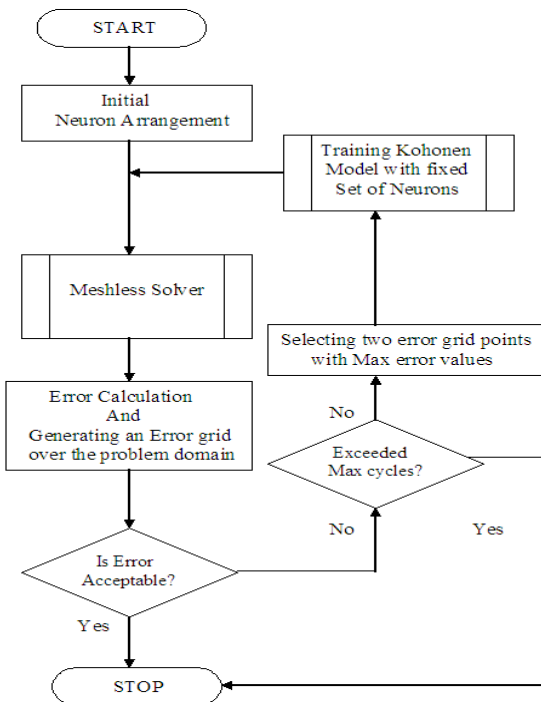

Fig. 3. Flow chart of the proposed algorithm.

The error criterion being used in the present work is relatively simple. The error is estimated by taking the average value of the potential around a particular point and comparing it with the potential computed at that point. Thus an error map is created covering the entire problem domain. The points of maximum error are then identified and the coordinates are used to “train” the Kohonen network and, in the process, the nodes are moved towards the high error positions.

V. INITIAL TESTS

The algorithm has been tested on a very simple problem in order to check out the overall performance and convergence characteristics. The device considered is a parallel plate capacitor. Fig. 4.

Fig.4. A simple parallel plate capacitor

The solution space was populated with 16 nodes which formed the basis of both the meshless solution and the Kohonen network. At each iteration, the problem was solved using the meshless system and the error computed. The nodes were then moved by using the Kohonen network and the process repeated. The results are shown in Fig. 5.

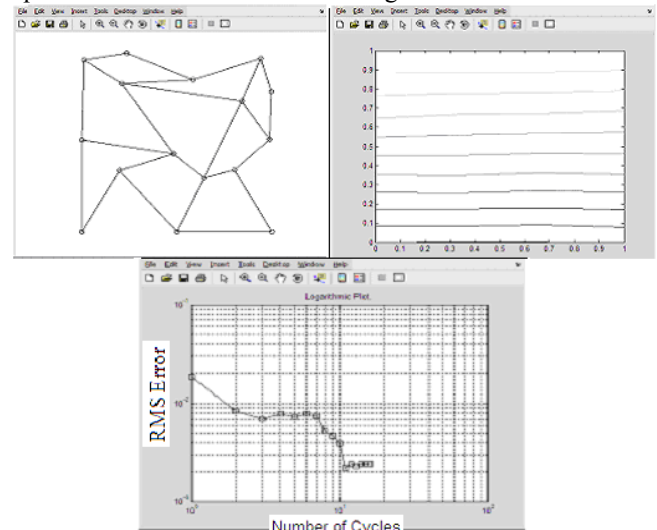

Fig.5. Final positions of the 16 nodes and the field solution and the convergence plot at the bottom.

VI. CONCLUSIONS

An adaptive meshless algorithm using a Kohonen network has been proposed and initial results are shown. The system appears to optimize the positions of the nodes and thus provides the most accurate solution that can be obtained with the given degrees of freedom. The full paper will provide an analysis of the performance of the algorithm and give examples on more complex geometries.

Abstract — The presented work is about the implementation of a vectorial hysteresis model in a Finite Integration Technique (FIT) computation code. This is achieved in the magnetostatic case using the vector potential formulation and with the external electric circuit coupling. The used behaviour law model is the vectorized Jiles-Atherton model with the magnetic flux density as input variable. The proposed approach is illustrated by modelling a coil made of Soft Magnetic Composite (SMC) magnetic core. Comparison with measured global quantities is also done.

I. INTRODUCTION

The numerical study of electromagnetic devices requires knowing the geometrical as well as the physical parameters of the involved system. Geometrical parameters can be easily obtained, whereas the magnetic behaviour law is often approximated as linear or non linear using an average model from the experiment and the hysteresis effect is often neglected. Most of the electrical devices can be studied without the hysteresis phenomena. Nevertheless, for more accuracy, a numerical implementation of the hysteresis phenomena can be required to study specific systems, for example hysteresis motors or systems where the remnant flux has an influence on the global behaviour.

Several hysteresis models exists in the literature, such as the Preisach [1] and the Jiles-Atherton (J-A) [2] models. In this work, we use the vectorized J-A model [3] in its inverse form, i.e. with the magnetic flux density as input variable. The numerical technique used to discretize the mathematical model of the Maxwell's equations is the Finite Integration Technique (FIT) [4]. As the vectorized J-A model provides naturally the differential reluctivity tensor, the magnetic vector potential formulation is written using an Euler approximation of the magnetic behaviour law including the differential reluctivity tensor. The coupling with the external circuit is also presented in order to study a coil with a SMC magnetic core and comparison with the experiment is realised.

II. VECTOR HYSTERESIS MODEL

To take into account rotational fields and anisotropy, a vectorization of the J-A scalar direct model, i.e. with the magnetic field as input variable, has been proposed in [5]. An inverse vector generalisation of the J-A model, proposed in [3], is used in this paper as the vector potential formulation is considered for the numerical model. The input variable of the hysteresis model is the magnetic flux density vector \mathbf{B} and the main equation is [3],

$$d\mathbf{M} = \frac{1}{\mu_0} \left[\mathbf{I} + \bar{\chi}_f \left| \bar{\chi}_f \right|^{-1} \bar{\chi}_f (\mathbf{I} - \bar{\alpha}) + \bar{c} \bar{\xi} (\mathbf{I} - \bar{\alpha}) \right]^{-1} \cdot \left[\bar{\chi}_f \left| \bar{\chi}_f \right|^{-1} \bar{\chi}_f + \bar{c} \bar{\xi} \right] d\mathbf{B} \quad (1)$$

where $\bar{\chi}_f$ is given by $\bar{\chi}_f = \bar{k}^{-1} (\mathbf{M}_{an} - \mathbf{M})$. Vectors \mathbf{M}_{an} and \mathbf{M} are, respectively, the anhysteretic magnetization and the total magnetization. The parameters of the model are described by the third rank tensors \bar{k} , $\bar{\alpha}$ and \bar{c} which terms must be obtained experimentally. \mathbf{I} is the diagonal unity matrix and $\bar{\xi}$ is the diagonal matrix of the anhysteretic functions derivatives with respect to the effective field components [3].

Using $d\mathbf{M}$ obtained from equation (1) and $d\mathbf{H} = \frac{1}{\mu_0} d\mathbf{B} - d\mathbf{M}$, one can write $d\mathbf{H} = \|\partial v\| d\mathbf{B}$, where $\|\partial v\|$ is the differential reluctivity tensor.

III. NUMERIC MODEL

In the magnetostatic case, the Maxwell equation to be solved is,

$$\begin{aligned} \mathbf{Curl} \mathbf{H} &= \mathbf{J} \\ \mathbf{Div} \mathbf{B} &= 0 \end{aligned} \quad (2)$$

where \mathbf{J} is the current density. The constitutive relationship, i.e. the magnetic behaviour law, is such as $\mathbf{H} = \mathbf{f}(\mathbf{B})$. To take into account the vector hysteresis model, the magnetic field is written using the Euler scheme to introduce the differential reluctivity tensor,

$$\mathbf{H}_{t_i} = \|\partial v\| (\mathbf{B}_{t_i} - \mathbf{B}_{t_0}) + \mathbf{H}_{t_0} \quad (3)$$

with t_i and t_0 the current and previous time calculation steps. Using the magnetic vector potential \mathbf{A} , such that $\mathbf{B} = \mathbf{curl} \mathbf{A}$, and using equation (2), we can write the magnetic vector potential formulation. To impose the voltage u , we consider the coupling with the external circuit [6-7]. The coil winding density field \mathbf{N} is defined such as $\mathbf{J} = \mathbf{N}i$ and the voltage expression, using \mathbf{A} and \mathbf{N} , becomes,

$$u = Ri + \frac{d\phi}{dt} = Ri + \mathbf{N} \frac{d\mathbf{A}}{dt} \quad (4)$$

The density field vector \mathbf{N} is constructed with help of sections and numbers of turns of the coil winding [6]. Then, the magnetic vector formulation is,

$$\mathbf{Curl} \|\partial v\| \mathbf{Curl} (\mathbf{A}_{t_i} - \mathbf{A}_{t_0}) = \mathbf{N} i_{t_i} - \mathbf{Curl} \mathbf{H}_{t_0} \quad (5)$$

The finite integration technique [4] is used here to

discretize and solve the problem. The space is discretized using orthogonal elements. For the time discretization, the implicit Euler scheme is used. The operator “*Curl*” became an incidence matrix $[C]$. To construct the material matrix $[dv]$ the series reluctances notions were used by considering field tubes. For each facet, the relation between magnetic induction fluxes through a facet and the field circulation on the dual edges is established. For each time step, the system is solved until the error convergence criterion on A is reached.

IV. SIMULATION RESULT

The studied system consists in a coil with SMC iron core [8]. The current evolution in the winding is calculated using the numerical scheme presented previously. Dimensions of the system and its mesh are reported on figure 1. As the system is axisymmetric, a 2D approach is considered. The mesh is constituted of 480 elements with 525 nodes. By considering the boundary conditions, the number of unknowns is 438.

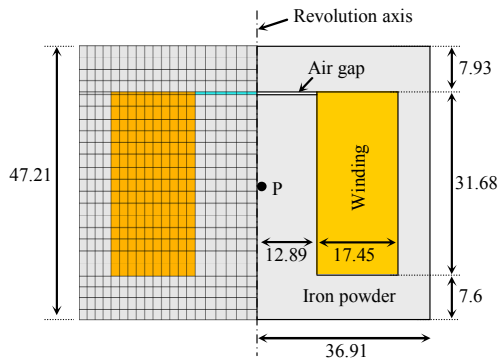

Fig. 1. Dimensions of the studied system (mm) and its mesh.

The coil winding is supplied by a voltage of 90 V RMS at 60 Hz. The system was simulated during 20 periods with 100 time steps per period. The inrush current, due to the magnetic core saturation, is clearly emphasised in figure 2. Figure 3 shows the steady state of the calculated current and the measured one. Despite the small number of elements in the mesh, good accuracy is observed between calculation and measurement.

Fig. 2. Computation inrush current.

The hysteresis loops at three different moments (1st, 10th and 20th periods) at point P (see figure 1), are given in figure 4. During the first period, the hysteresis loop presents the saturation shape due to the inrush current. At the 20th period,

the steady state is reached and the hysteresis loop becomes symmetric.

Fig. 3. Simulated and measured current evolutions.

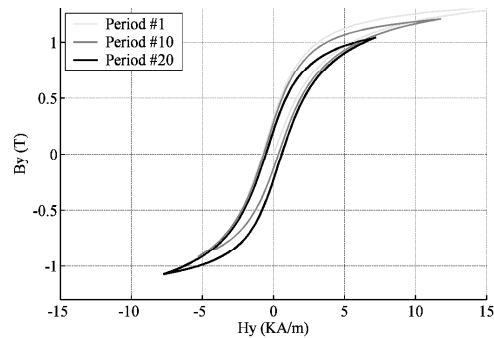

Fig. 4. Hysteresis loops at P.

V. CONCLUSION

A vector hysteresis model has been implemented in the FIT. To validate the numerical model, a coil with SMC core has been studied. The model shows good agreement with the measure for a global quantity, i.e. the current in the winding. The system will be studied in detail to compare the calculated iron losses with the measured ones.

Abstract—In this paper, we study the behavior of the steady-state voltage potentials in a material composed by an interior medium surrounded by a rough thin layer and embedded in an ambient bounded medium. The roughness of the layer is supposed to be ε -periodic, ε being the small thickness of the layer. We present and validate numerically the rigorous approximate transmissions proved by Ciuperca *et al.* in [1]. This paper extends previous works in which the layer had a constant thickness.

I. INTRODUCTION

In the domains with a rough thin layer, numerical difficulties appear due to the complex geometry of the rough layer when computing the steady-state potentials. We present here how these difficulties may be avoided by replacing this rough layer by appropriate transmission conditions. Particularly, we show that considering only the mean effect of the roughness is not sufficient to obtain the potential with a good accuracy.

A. Statement of the problem

Fig. 1. Geometry of the problem.

Let Ω be a smooth bounded domain of \mathbb{R}^2 with connected boundary $\partial\Omega$. For $\varepsilon > 0$, we split Ω into three subdomains: \mathcal{O}^1 , $\mathcal{O}_\varepsilon^m$ and $\mathcal{O}_\varepsilon^0$. \mathcal{O}^1 is a smooth domain strictly embedded in Ω (see Fig. 1). We denote by Γ its connected boundary. The domain $\mathcal{O}_\varepsilon^m$ is a thin oscillating layer surrounding \mathcal{O}^1 . We denote by Γ_ε the oscillating boundary of $\mathcal{O}_\varepsilon^m$: $\Gamma_\varepsilon = \partial\mathcal{O}_\varepsilon^m \setminus \Gamma$. The domain $\mathcal{O}_\varepsilon^0$ is defined by: $\mathcal{O}_\varepsilon^0 = \Omega \setminus (\mathcal{O}^1 \cup \mathcal{O}_\varepsilon^m)$. We also denote by $\mathcal{O}^0 = \Omega \setminus \mathcal{O}^1$. Two piecewise-constant conductivities on the domain Ω have to be defined:

$$\sigma(z) = \begin{cases} \sigma_1, & \text{if } z \in \mathcal{O}^1, \\ \sigma_m, & \text{if } z \in \mathcal{O}_\varepsilon^m, \\ \sigma_0, & \text{if } z \in \mathcal{O}_\varepsilon^0. \end{cases} \quad \tilde{\sigma}(z) = \begin{cases} \sigma_1, & \text{if } z \in \mathcal{O}^1, \\ \sigma_0, & \text{if } z \in \Omega \setminus \mathcal{O}^1. \end{cases}$$

where σ_1, σ_m and σ_0 are given positive constants¹.

Let u^ε and u^0 be defined by:

$$\begin{cases} \nabla \cdot (\sigma \nabla u^\varepsilon) = 0, & \text{in } \Omega, \\ u^\varepsilon|_{\partial\Omega} = g, \end{cases} \quad \begin{cases} \nabla \cdot (\tilde{\sigma} \nabla u^0) = 0, & \text{in } \Omega, \\ u^0|_{\partial\Omega} = g, \end{cases} \quad (1)$$

where g is a sufficiently smooth boundary data. We present how to define the potential u^1 such that u^ε is approached by $u^\varepsilon = u^0 + \varepsilon u^1 + o(\varepsilon^{3/2})$ for ε tending to zero².

II. HEURISTICS OF THE DERIVATION OF THE CONDITIONS

Suppose Γ is a smooth closed curve of \mathbb{R}^2 of length 1 and parameterize it by the curvilinear coordinate $\Gamma = \{\Psi(\theta), \theta \in [0, 1]\}$. Let n be the (outward) normal to $\partial\mathcal{O}^1$. Γ_ε is described by

$$\Gamma_\varepsilon = \{\Psi(\theta) + \varepsilon f(\theta/\varepsilon)n(\theta), \theta \in [0, 1]\},$$

where f is a smooth 1-periodic and positive function, which describes the roughness of the layer.

A. Boundary layer corrector in the infinite strip

The key-point of the derivation of the equivalent transmission conditions consists in taking advantage of the periodicity of the roughness. This is performed by unfolding and upscaling the rough thin layer into the infinite strip $\mathbb{R} \times [0, 1]$.

Define the closed curves \mathcal{C}_1 and \mathcal{C}_0 , which are trigonometrically oriented by

$$\mathcal{C}_0 = \{0\} \times [0, 1], \quad \mathcal{C}_1 = \{(f(y), y), \forall y \in [0, 1]\}.$$

The outward normals to \mathcal{C}_0 and \mathcal{C}_1 equal

$$n_{\mathcal{C}_0} = \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \quad n_{\mathcal{C}_1} = \frac{1}{\sqrt{1 + (f'(y))^2}} \begin{pmatrix} 1 \\ -f'(y) \end{pmatrix}. \quad (2)$$

According to [1] there exists a unique couple (A^0, a^0) where A^0 is a continuous vector field and a^0 is constant such that

$$A^0 \text{ is 1-periodic in } y, \quad \Delta A^0 = 0, \text{ in } \mathbb{R} \times [0, 1], \quad (3a)$$

$$\sigma_0 \partial_n A^0|_{\mathcal{C}_1^+} - \sigma_m \partial_n A^0|_{\mathcal{C}_1^-} = (\sigma_m - \sigma_0) n_{\mathcal{C}_1}, \quad (3b)$$

$$\sigma_m \partial_n A^0|_{\mathcal{C}_0^+} - \sigma_1 \partial_n A^0|_{\mathcal{C}_0^-} = -(\sigma_m - \sigma_0) n_{\mathcal{C}_0}, \quad (3c)$$

$$A^0 \rightarrow_{x \rightarrow -\infty} 0, \quad A^0 - a^0 \rightarrow_{x \rightarrow +\infty} 0, \quad (3d)$$

where the convergences at infinity are exponential. We emphasize that a^0 is not imposed but is a floating potential.

¹The same following results hold if σ_0, σ_1 , and σ_m are given complex numbers with imaginary parts (and respectively real parts) with the same sign.

²The notation $o(\varepsilon^{3/2})$ means that $\|u^\varepsilon - (u^0 + \varepsilon u^1)\|$ goes to zero faster than $\varepsilon^{3/2}$ as ε goes to zero. We refer to Theorem 1.1 of [1] for a precise description of the involved norms and the accuracy of the convergence.

B. Approximate transmission conditions

Our transmission conditions are then obtained with the help of the constant vectors D_1 and D_2 defined by:

$$\begin{aligned} D_1 &= (\sigma_0 - \sigma_m) \left[\int_0^1 f(y) dy n_{C_0} + \int_0^1 A^0(f(y), y) dy \right] \\ &\quad + (\sigma_m - \sigma_1) \int_0^1 A^0(0, y) dy - \sigma_0 a^0, \\ D_2 &= (\sigma_m - \sigma_0) \left[\int_0^1 A^0(f(y), y) f'(y) dy \right. \\ &\quad \left. - \int_0^1 f(y) dy \begin{pmatrix} 0 \\ 1 \end{pmatrix} \right]. \end{aligned}$$

The potential u^1 is then defined by³:

$$\begin{cases} \Delta u^1 = 0, \text{ in } \mathcal{O}^0 \cup \mathcal{O}^1, & u^1|_{\partial\Omega} = 0, \\ [\tilde{\sigma} \partial_n u^1]_{\Gamma} = -\kappa D_1 \cdot \begin{pmatrix} \partial_n u^0|_{\Gamma^+} \\ \partial_t u^0|_{\Gamma^+} \end{pmatrix} + D_2 \cdot \partial_t \begin{pmatrix} \partial_n u^0|_{\Gamma^+} \\ \partial_t u^0|_{\Gamma^+} \end{pmatrix}, \\ [u^1]_{\Gamma} = a^0 \cdot \begin{pmatrix} \partial_n u^0|_{\Gamma^+} \\ \partial_t u^0|_{\Gamma^+} \end{pmatrix}, \end{cases}$$

where ∂_t and ∂_n denote the tangential and the normal derivatives along Γ and κ is the curvature of Γ .

We emphasize that our conditions are different than if we would only consider the mean effect of the roughness. In this case, denoting by \bar{f} the mean of f , the conditions would be (see [1], [3], [4]):

$$[\tilde{\sigma} \partial_n \tilde{u}^1]_{\Gamma} = (\sigma_0 - \sigma_m) \bar{f} \partial_t^2 u^0|_{\Gamma}, \quad [\tilde{u}^1]_{\Gamma} = \frac{\sigma_0 - \sigma_m}{\sigma_m} \bar{f} \partial_n u^0|_{\Gamma^+}.$$

III. NUMERICAL SIMULATIONS

In order to verify the convergence rate stated in Section I, we consider a problem where the geometry and the boundary conditions are ε -periodic. The computational domain Ω is delimited by the circles of radius 2 and of radius 0.2 centered in 0, while \mathcal{O}^1 is the intersection of Ω with the concentric disk of radius 1. The rough layer is then described by $f(y) = 1 + 1/2 \sin(y)$. One period of the domain is shown Fig 2(a). The Dirichlet boundary data is identically 1 on the outer circle and 0 on the inner circle.

The mesh generator *Gmsh* [2] and the finite element library *Getfem++* [5] enables us to compute the four potentials u^ε , u^0 , u^1 and \tilde{u}^1 .

The rough thin layer is supposed slightly insulating. The conductivities σ_0 , σ_1 and σ_m respectively equal to 3, 1 and 0.1. The computed coefficients⁴ issued from Problem (3) are given in Table I.

TABLE I
COEFFICIENTS ISSUED FROM THE SOLUTION TO PROBLEM (3). 3
SIGNIFICANT DIGITS ARE KEPT.

a_1^0	a_2^0	D_1^1	D_2^1	D_1^2	D_2^2
19.3	0	0	0	-0.0499	-3.87

³We denote by $[w]_{\Gamma}$ the jump of a function w on Γ .

⁴The convergences at the infinity in Problem (3) are exponential hence we just have to compute problem (3) for $|x| \leq M$, with M large enough to obtain a^0 with a good accuracy.

Fig. 2. Representation of one period of the domain and the corresponding errors with approximate solutions u^0 and $u^0 + \varepsilon u^1$. $\varepsilon = 2\pi/30$. Do not consider the error in the rough layer because a proper reconstruction of the solution in it is not currently implemented.

The numerical convergence rates for the H^1 -norm in \mathcal{O}^1 of the three following errors $u^\varepsilon - u^0$, $u^\varepsilon - u^0 - \varepsilon u^1$ and $u^\varepsilon - u^0 - \varepsilon \tilde{u}^1$ as ε goes to zero are given Figure 2. As predicted by the theory, the rates are close to 1 for the order 0 and for the order 1 with the mean effect, whereas it is close to 2 for the “real” order 1 equal to $u^\varepsilon - u^0 - \varepsilon u^1$.

Fig. 3. H^1 -Error in the cytoplasm vs ε for three approximate solutions.

Abstract — This paper presents an algorithm dedicated to the determination of shells unknowns magnetization. Thanks to magnetic measurements realized on sensors located very close to ferromagnetic material, an inverse problem is solved enabling the determination of the whole magnetic state of the device. The method is experimentally validated on a mock-up of submarine, the purpose of the study being the prediction of its magnetic anomaly form onboard measurements.

I. INTRODUCTION

Most part of submarines are made of steel. One of the drawbacks using such material is that steel is ferromagnetic. The hull of the submarine, placed in the earth's magnetic field and subjected to important pressure effect, get a static magnetization. This phenomenon is well-known and called magnetostriction. This magnetization creates a local static magnetic anomaly around the submarine and can lead to its detection or localization by magnetic sensors embedded in airplanes or even worse in mines. Therefore, for decades, worldwide marines are looking for reducing this magnetic anomaly by setting up large coils in the whole ships feeding them with adapted currents. Before achieving the reduction of anomaly, it is necessary for the ship to evaluate its own magnetic anomaly. The key point of such system is the identification of the magnetization of the ship's hull and this problem is quite difficult to solve. Indeed, the magnetization can be divided in two parts: an induced one, due to the reversible reaction of the material in the inductor field, and a remanent one due to the magnetic history of the material (which depends on hysteresis, mechanical and thermal constraints). The computation of the induced magnetization is now a well-known problem, however, the remanent part is impossible to evaluate with a deterministic calculation because we have no access to the magnetic past of the material. Moreover, even if we had such knowledge, existing models would be too complex to be applied to 3D geometries. It is then necessary to use magnetic measurements to determine the total magnetization of the hull. Thus, the main goal is to solve an inverse problem (i.e. determination of the sources by knowing the effects) with magnetic sensors placed in the air region closed to the hull.

This problem has already been studied and the magnetization identification has already been achieved when sensors could be located far enough from the sheets and with a simplified mock-up of a surface ship [1], [2]. Some of main results of this problem will be reminded in this paper. However, this method has not been tested yet on realistic

mock-up of a double-hull submarine with an important magnetic sensors number placed between the two hulls.

II. BACKGROUND THEORY

A. Forward modeling

Let us consider a device composed of a ferromagnetic sheet S with a thickness e and placed in an inductor magnetic field \mathbf{H}_0 (the earth's magnetic field, for instance). This sheet has an unknown static magnetization \mathbf{M} which contributes to the global magnetic field. Therefore, field \mathbf{H} is the sum of the inductor field and the field created by the shell itself. The field generated by the ferromagnetic material is directly linked to its magnetization by a classical volume integral equation. For a sheet configuration, it is standard to assume that the magnetization is tangential to the shell and constant through it, its permeability being high and its thickness e being low in comparison with other dimensions. Therefore, the integral equation can be written as follows:

$$\mathbf{H} = \mathbf{H}_0 + \frac{e}{4\pi} \nabla \int_S \frac{\mathbf{M} \cdot \mathbf{r}}{r^3} dS \quad (1)$$

where \mathbf{r} is the vector between the point where \mathbf{H} is expressed and the integration point on the S surface of the shell. For complicated geometries, this equation has of course no analytical solution, it is then necessary to discretized it to get a numerical expression. Lets us consider that surface S is meshed into n surface patches with a uniform magnetization \mathbf{M}_i associated to each of them. Equation (1) becomes:

$$\mathbf{H} = \mathbf{H}_0 + \frac{e}{4\pi} \sum_{i=0}^n \nabla \int_S \frac{\mathbf{M}_i \cdot \mathbf{r}}{r^3} dS_i \quad (2)$$

This equation is a vector one and depends linearly from the \mathbf{M}_i values. Let us remember that the magnetization is tangential to the surface S . Each patches magnetization has then two degrees of freedom. Therefore, equation (3) can be represents as a system of equations:

$$[\mathbf{H}] = [\mathbf{H}_0] + [\mathbf{A}][\mathbf{M}] \quad (3)$$

where \mathbf{H}_0 and \mathbf{H} are vectors of 3 components (each component of the inductor and total field), \mathbf{A} is a $3 \times 2n$ matrix which represents the interaction linking the sources to the field and \mathbf{M} is the $2n$ magnetization vector (2 components per meshed element).

B. Inverse modeling

Let us now imagine that we want to determine \mathbf{M} vector (an image of the magnetization of the sheet projected on it

mesh). A solution is to place magnetic sensors around the shell to have a measurement of \mathbf{H} at a given point of the air region. Let us consider that m tri-axis magnetic sensors are placed around the shell, (3) leads to a Matrix system where \mathbf{H} is measured, \mathbf{H}_0 is known (the position of the device in the earth's magnetic field is known), \mathbf{A} is a $3m \times 2n$ matrix (the coefficient of the matrix can be computed with numerical integration techniques) and \mathbf{M} is searched. To get \mathbf{M} , it remains to solve this system. Unfortunately, this task is not so simple and several aspects can lead to very uneasy resolution process:

-*The system is underdetermined:* If the shell geometry is complicated and the magnetization has important local variations, a very fine mesh is needed to accurately represent the real device. The sensors number being limited, we are faced to a linear system with fewer equations than unknowns.

-*The system has a poor condition number:* This mathematical property leads to an unstable solution. In fact, the measurement vector is associated with a non negligible range of noise and a poor condition number will amplify it during the resolution process to give a divergent solution.

This Inverse problem is said ill-posed. In order to solved it, [1] proposes to add others equations representative of the magnetic behavior of the shell. In our case, it enables to write $2n$ additional equations and to add them to the previous system. The dimension of the research space is therefore considerably reduced and a standard single value decomposition, which returns the solution with the minimal norm generally, succeeds. Let us notice that this approach is efficient if sensors are located sufficiently far enough to ensure a global magnetic observation of the whole device. However, in a real naval application, magnetic sensors have to be placed very close to the hull to get a sufficient signal level and to avoid magnetic disturbance. In this configuration, the solution proposed by [1] failed, returning a non satisfying solution. It is then necessary to use additional a-priori information to select the good solution. It is done by combining the classical approach to a regularization method like proposed in [3]. This kind of method ensures the stability of the solution and improved magnetization identification process.

III. EXPERIMENTAL VALIDATION

A submarine double-hull mock-up of about 3.5 meters long has been designed, built and placed on a railway in a field simulator. It has been instrumented with 75 bi-axis fluxgate sensors and 5 tri-axis ones placed very close to the hull. Above the mock-up, another fluxgate sensor has been placed. By moving the submarine over it, we get a measurement of the anomaly to compare it with the predicted one. Then, the accuracy of the inversion process can be evaluated (Fig.1). Pictures of the experimental set-up are shown on figure 2. The mock-up has been placed in a realistic magnetic state with a strong permanent magnetization.

The whole geometry of the mock-up is meshed into more than 4000 surface elements. So, about 8000 unknowns, fully describing the magnetization, have to be determined. From

sensors; 165 measurement equations are get, the system is then strongly over-determined. To reduce the size of the research space, 4000 equations, representative of the intrinsic magnetic material behavior are added. Then, the matrix system is regularized to finally get a magnetization distribution which seems to be satisfying (Fig.3.). From this magnetization distribution, it is possible, by applying a matrix relation similar to (3) to compute a predicted field on a reference line located outboard the submarine. As it is shown on figure 4, the predicted and the measured field present a very good adequacy.

Abstract — The interaction body force density and total force were evaluated in permanent magnets by using the virtual air-gap scheme incorporating the finite-element method. Until now, the virtual air-gap concept has been successfully applied to calculate a contact force and a body force density in soft magnetic materials. For permanent magnets, however, there have been few research works on a contact force and a force density field. When the generalized methods, methodologies with virtual air-gap scheme, are introduced, one can have an actual total force, but their distribution has an irregularity, which seems to be random distribution of body force density. Inside permanent magnets, however, a smooth pattern was obtained in the interaction body force density, which represents the interacting force field among magnetic materials. To evaluate the interaction body force density, the intrinsic force density should be withdrawn from the total force density. Several analysis models with permanent magnets were tested to verify the proposed methods evaluating the interaction body force density and the contact force, in which the permanent magnet contacts with a soft magnetic material.

I. INTRODUCTION

Virtual air-gap method has been successfully applied to soft magnetic materials for evaluating the force density and global force, especially contact force [1]-[2]. These force calculating methods employing the virtual air-gap scheme have been called as generalized methods such as the generalized magnetic charge force density method (GMC), the generalized magnetizing current force density method (GCM), and the generalized Kelvin force density method (GKV).

Unlike the soft magnetic materials, there have been few research works related to force density and global force in permanent magnets [3]. One might have a difficulty in dealing with permanent magnet because of its permanent magnetization, which is linked to the energy after magnetizing process. To deal with this energy consideration, the intrinsic and interaction forces between a magnet and exterior media were introduced incorporating the virtual work principle [3].

By the same analogy, here, we calculated the interaction body force field inside permanent magnet and contact force, sliding force between a magnet and soft magnetic material, by using the virtual air-gap method. The resultant interaction body force field was quite interesting and seemed to be interpreted as an actual interaction body force density field between a magnet and magnetic materials. In addition to this, the global force including sliding contact force was also successfully evaluated and verified by the conventional magnetic charge and magnetizing current methods.

II. GENERALIZED FORCE CALCULATING METHODS

To model the permanent magnet, the magnetic flux density \mathbf{B} including permanent magnetization can be expressed as

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}_i + \mathbf{M}_0) \quad (1)$$

where μ_0 is the magnetic permeability in air, \mathbf{H} the magnetic field intensity, \mathbf{M}_i the magnetization in soft magnetic materials due to an applied magnetic field, and \mathbf{M}_0 the permanent magnetization in hard magnetic materials.

The GMC, GCM, and GKV were derived by multiplying the equivalent magnetizing sources such as magnetic charge, magnetizing current and magnetic dipole by external applied fields, respectively [1]-[2]. It is important to point out that those external fields have to be obtained after insertion the virtual air-gap at common edge. The resultant external applied fields, \mathbf{H}_{ext} and \mathbf{B}_{ext} , acting on the equivalent sources, therefore, should be included the additional fields and can be expressed as

$$\mathbf{H}_{ext(1\ or\ 2)} = (\mathbf{H}_1 + \mathbf{H}_2) / 2 + \mathbf{H}_{\sigma_m(2\ or\ 1)} \quad (2)$$

$$\mathbf{B}_{ext(1\ or\ 2)} = (\mathbf{B}_1 + \mathbf{B}_2) / 2 + \mathbf{B}_{J_m(2\ or\ 1)} \quad (3)$$

where \mathbf{H}_1 and \mathbf{H}_2 are the magnetic field intensity, and \mathbf{B}_1 and \mathbf{B}_2 are the magnetic flux density acting at the edge of material 1 and 2, respectively. \mathbf{H}_{σ_m} and \mathbf{B}_{J_m} are the magnetic field intensity and flux density produced by the adjacent magnetic charge σ_m or magnetizing current J_m after insertion of the virtual air-gap, respectively.

III. INTERACTION BODY FORCE DENSITY

Energies and force densities of permanent magnet can be divided into three different categories: total magnetic energy and total force density, intrinsic magnetic energy and intrinsic force density, and interaction magnetic energy and interaction force density [3]. The intrinsic force density is obtained when a single magnet in the air and its distribution is supposed to represent the force density on the magnet due to its intrinsic magnetization. The interaction force density represents that the pure interaction force between a magnet and exterior materials. To evaluate the interaction body force density, therefore, the intrinsic force density should be withdrawn from the total force density.

Because the generalized force density methods were calculated in each element inside material, the resultant force field represents a body force density, but this total force density has an irregular pattern [2]. On the contrary, the interaction body force density was obtained in regular pattern after subtracting the intrinsic force density from the total force density.

IV. NUMERICAL RESULTS

Figs. 1(a) and 1(b) represent the effect of different interaction forces between two magnets with x direction of magnetization. The intrinsic body force field has an irregularity as shown in Fig. 2(a), but the interaction body force field, a regularity, which seems to represent an actual body force density field inside the magnet as shown in Fig. 2(b) and Fig. 3.

To verify the sliding contact force, two magnet systems were tested as shown in Figs. 4(a) and 4(b), of which the magnetization had a horizontal and vertical directions, respectively. While the permanent magnets slides into x direction, the resultant forces can be correctly calculated by using the magnetic charge force density method for Model III and the magnetizing current force density method for Model IV. Figs 5(a) and 5(b) show well the trends of solution as we mentioned above. Figs 6(a) and 6(b) represent the resultant distributions of interaction force.

In extended paper, we will present more numerical examples including mechanical deformation and discuss about its physical meanings in detail.

Block-preconditioning for hybrid discretisations in combination with Lagrange-multiplier coupling

Stephan Koch¹, Herbert De Gersem², and Thomas Weiland¹

Abstract—The linear systems of equations arising from hybrid discretizations, e.g., by coupling finite elements (FE) with spectral elements (SE), are sparse and symmetric. However, the use of a saddle-point formulation leads to indefinite algebraic equations. Their solution requires, therefore, the application of appropriate iterative solvers and preconditioners. In order to achieve an acceptable solution time, in particular for transient simulations requiring repetitive solves, an adapted block-preconditioner based on approximations of the Schur complement is applied. The performance regarding the number of iterations of the Krylov subspace method as well as the solution time is compared for different types of preconditioners.

I. INTRODUCTION

In case of technical devices featuring large subdomains in which a particular symmetry holds, such as according to rotation or translation, the application of an anisotropic discretization can lead to a beneficial reduction of the number of degrees of freedom in the numerical model [1]. This approach is based on domain decomposition, whereas the actual model is separated into parts exhibiting symmetry and the surrounding region lacking symmetry (Fig. 1(a)). While for formulations involving scalar potentials the systems of equations remain regular, as, e.g., in [2], introducing the magnetic vector potential to the magnetostatic approximation of the Maxwell equations leads to a consistently singular system due to the nullspace of the curl-operator. This inhibits the use of direct solution strategies, e.g. by LU-factorization. Therefore, iterative methods are required in order to solve the system of equations [3].

II. HYBRID DISCRETIZATION

The magnetostatic formulation in terms of the magnetic vector potential \mathbf{A} introduced in order to represent the magnetic flux density \mathbf{B} as $\mathbf{B} = \nabla \times \mathbf{A}$ reads

$$\nabla \times (\nu \nabla \times \mathbf{A}) = \mathbf{J} \quad (1)$$

with the reluctivity ν and the impressed current density \mathbf{J} . Based on the decomposition of the computational domain into parts with and without symmetry (Fig. 1), discretization is carried out for the respective subdomains separately. While in the non-symmetric region, standard 3D-FE shape functions \mathbf{w}_j^{3D} are applied to discretize \mathbf{A} in the weak formulation of (1), special shape functions accounting for the symmetry present in the model are used for the translatory symmetric region. In contrast to a scalar potential formulation as, e.g., in [1], two sets of vectorial shape functions, $\mathbf{v}_{i,j,q}^{xy}$ and $\mathbf{v}_{i,q}^z$, based

Fig. 1. (a) Idealized model of a long dipole magnet featuring a large domain of symmetry; (b) Cross-section of the magnet serving to establish geometric modeling of reduced order.

on triangular prisms defined by the triangulation of the cross-section in Fig. 1(b) are required to discretize the weak form of (1) inside the domain of symmetry. These are introduced in [2] for the representation of the source field in combination with a magnetostatic formulation in terms of the magnetic scalar potential. Here the two sets of shape functions are used to approximate the primary unknown \mathbf{A} . The discretization leads to two independent systems of equations for the separate domains. These are combined by means of Lagrange multipliers \mathbf{v}_{lg} which guarantee a symmetric coupling by ensuring the tangential continuity of the magnetic field strength \mathbf{H} as well as the normal continuity of the magnetic flux density \mathbf{B} across the interface between both regions. The coupled system reads

$$\begin{pmatrix} \mathbf{K}_{3D} & 0 & -\mathbf{B}_{3D} \\ 0 & \mathbf{K}_{fese} & \mathbf{B}_{fese} \\ -\mathbf{B}_{3D}^T & \mathbf{B}_{fese}^T & 0 \end{pmatrix} \begin{pmatrix} \mathbf{a}_{3D} \\ \mathbf{a}_{fese} \\ \mathbf{v}_{lg} \end{pmatrix} = \begin{pmatrix} \mathbf{j}_{3D} \\ \mathbf{j}_{fese} \\ 0 \end{pmatrix} \quad (2)$$

with the vector of degrees of freedom \mathbf{a} and the vector \mathbf{j} corresponding to the excitation for the non-symmetric part (3D) and the translatory symmetric part (fese), respectively.

III. BLOCK-PRECONDITIONING

In order to ensure an efficient numerical solution of the system (2), an appropriate preconditioner is required, as the condition number of the system matrix is very large especially due to the anisotropic discretization with respect to the direction of symmetry. The approach chosen here accounts for the blockwise structure of the matrix making use of the property

$$\begin{pmatrix} \mathbf{A} & \mathbf{C}^T \\ \mathbf{C} & 0 \end{pmatrix}^{-1} = \begin{pmatrix} \mathbf{T} & -\mathbf{A}^{-1}\mathbf{C}^T\mathbf{S}^{-1} \\ -\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1} & \mathbf{S}^{-1} \end{pmatrix} \quad (3)$$

TABLE I

COMPARISON OF THE ACHIEVED ACCURACY AND THE REQUIRED SOLUTION TIME IN COMBINATION WITH DIFFERENT PRECONDITIONERS USING THE GMRES METHOD LIMITED TO 3000 ITERATIONS WITHOUT RESTARTING. THE DIMENSION OF THE SYSTEM MATRIX IS 30952.

precond type (for \mathbf{A}/\mathbf{S})	iterations	time / s	rel. residual
no precond / -	(3000)	4873	1.7e-1
global Jacobi / -	(3000)	5567	6.7e-3
Jacobi/Jacobi	401	178	2.4e-5
Gauss-Seidel/Gauss-Seidel	187	66	1.7e-5

with $\mathbf{T} = \mathbf{A}^{-1} + \mathbf{A}^{-1}\mathbf{C}^T\mathbf{S}^{-1}\mathbf{C}\mathbf{A}^{-1}$ and the Schur complement $\mathbf{S} = -\mathbf{C}\mathbf{A}^{-1}\mathbf{C}^T$. Taking the upper left (2×2) -block of the system matrix in (2) as \mathbf{A} and $\mathbf{C} = (-\mathbf{B}_{3D}^T, \mathbf{B}_{fese}^T)$, different approximations of the inverse of \mathbf{A} and \mathbf{S} , respectively, are sought. Even though the system matrix is symmetric, the generalized minimal residual method (GMRES) is used in combination with an approximation of the inverse in (3) as a preconditioner. In the full paper the algebraic symmetry will be exploited by using the computationally more efficient minimal residual method (MINRES) which is more efficient with respect to memory consumption due to the three-term recursion scheme. In that case, however, a symmetric positive definite preconditioner must be used [4], [5].

An approximation of the inverse of \mathbf{A} is required to form the sub-blocks of the preconditioning matrix in (3). Moreover, the inverse of the Schur complement \mathbf{S} needs to be built using an appropriate representation of \mathbf{A}^{-1} . Two possibilities are investigated here: First, the exact inverse of \mathbf{A} in (3) is replaced by the reciprocal of the main diagonal, yielding a Jacobi-type preconditioning. The dimension of \mathbf{S} corresponds to the number of degrees of freedom allocated at the interface between the separate domains. Therefore, the size of this matrix remains moderate and explicit inversion can be carried out for sufficiently small numerical models. Secondly, an additive splitting of \mathbf{A} into upper and lower triangular parts leads to Gauss-Seidel preconditioning. Now, the action of the particular blocks of the preconditioning matrix on a given vector is provided by forward and backward substitution at the corresponding occurrences of \mathbf{A}^{-1} .

IV. COMPARISON OF DIFFERENT PRECONDITIONERS

The performance of different types of preconditioners is investigated by solving the system matrix resulting from the hybrid discretization of the schematic magnet model in Fig. 1(a). For the matrix dimension of 30952 the maximum number of GMRES iterations is set to 3000. The results in terms of the achieved accuracy and the required solution time are summarized in Table I. In order to compare the performance to common approaches, the results without any preconditioning as well as for global Jacobi preconditioning are also included. For the latter, the zeros present on the main diagonal of the system matrix are replaced by unity during the construction of the preconditioner. Therefore, the coupling blocks \mathbf{C} are not considered in the preconditioning process. As a consequence, only a slight benefit compared to the absence of any preconditioning is observed as shown

Fig. 2. Convergence history for different types of preconditioners in terms of the relative residual in each iteration step of the GMRES method.

in Fig. 2. In both cases achieving the prescribed accuracy of $1e-6$ is virtually impossible due to the increasing amount of memory for each additional iteration step. Restarting the GMRES iteration discarding the previous search directions does not generally change the situation. However, a significant improvement is observed by considering the coupling blocks of the inverse in (3) in terms of blockwise Jacobi and Gauss-Seidel approximations for \mathbf{A} as a part of \mathbf{T} and \mathbf{S} , respectively. Even though the time required for each iteration is larger in case of the Gauss-Seidel procedure due to the forward and backward substitutions, the number of iterations as well as the solution time is decreased. This is very important especially when considering the hybrid discretization scheme in the time-domain, where the system matrix is solved repeatedly.

V. CONCLUSION

The saddle-point problem resulting from a hybrid discretization in combination with Lagrange multipliers is solved by means of the preconditioned GMRES method. Accounting for the particular structure of the system matrix, superior convergence results in terms of the number of iterations as well as in the solution time are observed using blockwise preconditioning. The beneficial approximation properties of the anisotropic discretization using vectorial shape functions can be exploited in combination with appropriate preconditioners as proposed in this paper.

Abstract— The effect of temperature-dependent thermal conductivity on the magneto-convection in a low Prandtl number liquid is investigated numerically. The liquid is contained in a closed square enclosure with isothermal vertical walls kept at different temperatures. The top and bottom walls are assumed to be insulated. To solve the governing non-linear differential equations (mass, momentum and energy) a finite volume code based on SIMPLER algorithm is utilized. The results for different Rayleigh and Hartmann numbers show that the strength of the magnetic field has significant effects on the flow and temperature fields. The convection becomes stronger as the Rayleigh number increases while the magnetic field suppresses the convective flow and the heat transfer rate. The heat transfer is found to decrease appreciably across the cavity with a decrease in thermal conductivity.

I. INTRODUCTION

The Lorentz force acts against the buoyancy force. This phenomenon is used in material manufacturing industry and turbine blade casting as a control mechanism. Employment of an external magnetic field has increasing applications in material manufacturing industry as a control mechanism since the Lorentz force suppresses the convection currents by reducing the velocities. Study and thorough understanding of the momentum and heat transfer in such a process is important for the better control and quality of the manufactured products. The Garandet et al. [1] proposed an analytical solution to the governing equations of magneto hydrodynamics to be used to model the effect of a transverse magnetic field on natural convection in a two-dimensional enclosure. Al-Najem et al. [2] used the power law control volume approach to determine the flow and temperature fields under a transverse magnetic field in a tilted square enclosure with isothermal vertical walls and adiabatic horizontal walls at Prandtl number of 0.71 and showed that the suppression effect of the magnetic field on convection currents and heat transfer is more significant for low inclination angles and high Grashof numbers. Recently, Pirmohammadi et al. [3] studied the effect of a magnetic field on buoyancy-driven convection in differentially heated square enclosure. They showed that the heat transfer mechanisms and the flow characteristics inside the enclosure depend strongly upon both the strength of the magnetic field as well as the Rayleigh number. It was concluded that the magnetic field considerably decreases the average Nusselt number.

In previous studies the dependency of thermal conductivity on temperature has not been considered. The present study considers laminar natural convection flow in the presence of a longitudinal static magnetic field in a square enclosure heated

from the left wall and cooled from the right wall while the other walls are kept adiabatic. The enclosure is filled with an electrically conducting fluid which its thermal conductivity varies with temperature. The object of the study is to obtain numerical solutions for the velocity and temperature fields inside the enclosure and to determine the effects of the magnetic field strength on the transport phenomena.

II. BASIC EQUATIONS

The geometry and the coordinate system are schematically shown in Fig. 1.

Fig. 1. Geometry of enclosure configuration with magnetic effect.

The non-dimensional governing equations in this study are based on the conservation laws of mass, linear momentum and energy are given as:

$$\frac{\partial U}{\partial X} + \frac{\partial V}{\partial Y} = 0 \quad (1)$$

$$U \frac{\partial U}{\partial X} + V \frac{\partial U}{\partial Y} = -\frac{\partial P}{\partial X} + \text{Pr} \left(\frac{\partial^2 U}{\partial X^2} + \frac{\partial^2 U}{\partial Y^2} \right) \quad (2)$$

$$U \frac{\partial V}{\partial X} + V \frac{\partial V}{\partial Y} = -\frac{\partial P}{\partial Y} + \text{Pr} \left(\frac{\partial^2 V}{\partial X^2} + \frac{\partial^2 V}{\partial Y^2} \right) + Ra \text{Pr} \theta - Ha^2 \text{Pr} V \quad (3)$$

$$U \frac{\partial \theta}{\partial X} + V \frac{\partial \theta}{\partial Y} = \frac{\partial}{\partial X} \left(k^* \frac{\partial \theta}{\partial X} \right) + \frac{\partial}{\partial Y} \left(k^* \frac{\partial \theta}{\partial Y} \right) \quad (4)$$

In the above equations, the primary non-dimensional parameters, the Rayleigh number and the Prandtl number, are defined as:

$$\text{Pr} = \frac{\nu}{\alpha}, \quad Ra = \frac{g\beta(T_h - T_c)H^3}{\alpha\nu}, \quad Ha = B_0 H \sqrt{\frac{\sigma}{\rho\nu}}, \quad k^* = \frac{k}{k_0} \quad (5)$$

Where, ρ is the density, g is the gravitational acceleration, ν is the cinematic viscosity, β is the coefficient of thermal

expansion, k_0 is thermal conductivity in reference temperature and B_0 is the magnitude of magnetic field and σ is the electrical conductivity. Also U , V and θ are non-dimensional velocity components and temperature, respectively. The non-dimensional thermal conductivity of the liquid is assumed to vary linearly with temperature as $k^*=1-\eta\theta$ where η is the temperature coefficient of thermal conductivity.

The local Nusselt number $Nu = -\frac{\partial\theta}{\partial X}$ is computed at the hot wall (Nu) and cold wall (Nu_c). The average Nusselt number is expressed as $\overline{Nu} = \int_0^1 Nu dY$.

III. RESULTS

The accuracy of results is verified with that of Rudraiah and is presented in Pirmohammadi et al [5].

The computations have been done for $Ra = 10^4$ and 10^5 , $\eta=0, 0.25$ and 0.5 , $Ha=0, 15, 30$ and 90 and Pr is fixed at 0.054 corresponding to liquid sodium– potassium alloy. Fig.2 shows the effect of magnetic field and variability of thermal conductivity on temperature field.

It is observed that in the case $\eta=0$ (constant k , i.e. $k = k_0$) and $Ha=0$, as the left wall is maintained at a higher temperature, the adjoining liquid particles experience a drop in their local densities and hence a clockwise rotating buoyancy-induced cell appears and the upper region of the isotherms are pushed towards the cold wall and the lower region towards the hot wall. This results in a simple clockwise rotating convection cell. When η is increased to 0.5 (varying k , i.e. $< k_0$) the isotherms are attracted towards the hot wall as such without any change in their qualitative shape and the formation of thermal boundary layer is clear [4], showing that smaller quantity of heat is propagated from the hot wall to the cold wall across the cavity compared to $\eta=0$ case. By applying

(a) $\eta=0$ and $Ha=0$

(b) $\eta=0.5$ and $Ha=0$

(c) $\eta=0.5$ and $Ha=90$

Fig.2 isotherms for $Ra=10^5$

magnetic field ($Ha=90$) the Lorentz force acts against the buoyancy force and convection heat transfer suppresses. Also it is shown that the temperature stratification in the core diminishes and the thermal boundary layers at the two side walls disappear. This is due to the retarding effect of the Lorentz force. For a sufficiently large Ha , the convection is completely suppressed as in the case of a small Ra .

We observe that the effect of η is to increase the \overline{Nu} from Table I. \overline{Nu} gives the relative measure of the total heat transfer rate to the conductive heat transfer rate. This shows that the retardation of conductive mode of heat transfer is more compared to that of convective mode near the hot wall, even though the heat transfer across the cavity from the hot to cold wall gets reduced by both conduction and slower convection for an increasing η . Also it can be seen that \overline{Nu} decreases with an increase of Hartmann number. This shows that the convection in the enclosure is suppressed due to the introduction of the magnetic field.

TABLE I
EFFECT OF η AND Ha ON AVERAGE NUSSLETT NUMBER

Ra	η	Ha	\overline{Nu}	\overline{Nu}_c

Abstract — This paper deals with large-scale 3D non-linear magnetostatic analysis by Hierarchical Domain Decomposition Method (HDDM). In magnetostatic numerical analysis, the computational object is always made in a complicated way at a large scale, and computational time is always very large. But, with the development of computational capabilities, it is now possible to focus our attention on the computational time without worrying about the amount of memory. In this paper, we reexamine the solution strategy for Finite Element Analysis (FEA) in the subdomain problems. Because the finite element equation of the A method that neglects the Lagrange multiplier p is singular, it has been solved by the Conjugate Gradient (CG) method in past researches. To solve it by the direct method, the A method that doesn't neglect the Lagrange multiplier p is considered. In this method we can expect to analyze more complex objects in relatively short time.

I. INTRODUCTION

There are many machines or devices where the electromagnetic phenomena are applied such as a computer, a cell phone, a transformer, and an MRI, etc. In order to analyze these engineering or physical phenomena, computer simulation is a reliable and yet economical approach.

Moreover, a computational object tends to be large and complicated for numerical analysis recently. In addition, subdivision of the mesh is performed for the improvement of accuracy. Therefore, large-scale computations are increasingly important in electromagnetic field problems. To meet this requirement, we have already introduced Hierarchical Domain Decomposition Method (HDDM) [1][2] together with the data handling type "Parallel processor mode (P-mode)" [3][4] to 3D non-linear magnetostatic problems using the Newton method to solve the simultaneous non-linear equations and the A method with the continuity of the electric current density that uses the magnetic vector potential A as an unknown function [5]. To verify the accuracy of our analysis, Testing Electromagnetic Analysis Methods (TEAM) Workshop Problem 20 was analyzed changing its Degrees of Freedom (DOF) several times up to 50 million DOF. The computations were performed with a PC cluster that consists of 32 PC. As a result, a non-linear magnetostatic problem with 50 million DOF was successfully solved in about 8.5 hours [6].

The possibility of large-scale analysis in 3D non-linear magnetostatic problems has been shown. However, we have to reduce the number of iterations and computation time. In this paper, to reduce computation time, the solution strategy of Finite Element Analysis (FEA) in subdomains is reexamined.

Usually, FEA in subdomains is performed by the direct method. However, because the finite element equation that we employ is singular, it is solved by the ICCG method, namely

Conjugate Gradient method that uses the shifted incomplete Cholesky factorization as the preconditioner. If the direct method is applied for solving FEA in subdomains, the computation time seems to be reduced by storing matrices that are results of the LU decomposition on main memory. Moreover, because the accuracy of the solutions in subdomains is improved by solving with the direct method, the characteristic of convergence of the interface problem can be improved, too. Therefore, to solve FEA in subdomains by the direct method, we consider the A method that doesn't neglect the Lagrange multiplier p in subdomains.

II. ITERATIVE DOMAIN DECOMPOSITION METHOD

We consider 3-D non-linear magnetostatic problems using the A method and the Newton method, see [5]. Then, we introduce an iterative domain decomposition method to this method. Let us denote the finite element equations of the A method by the matrix form as follows:

$$Ku = f \quad (1)$$

where K denotes the coefficient matrix, u the unknown vector, and f the known vector.

The polyhedral domain Ω is partitioned into the non-overlapping subdomains. Then the linear system (1) is rewritten as follows:

$$\begin{pmatrix} K_{II} & K_{IB} \\ K_{IB}^T & K_{BB} \end{pmatrix} \begin{pmatrix} u_I \\ u_B \end{pmatrix} = \begin{pmatrix} f_I \\ f_B \end{pmatrix} \quad (2)$$

where the subscripts I, B correspond to the nodal points in the interior of subdomains and on the interface boundary.

At first the unknown vector u_B is obtained from the algorithm based on the CG method to (2), see [5]. After solving u_B , the unknown u_I is obtained from:

$$K_{II}u_I = f_I - K_{IB}u_B. \quad (3)$$

The vector u_I can be solved independently in each subdomain. Hence we can get the unknown u in the whole domain.

In the past, the vector u_I was solved by the ICCG method, because the finite element equation of the A method that neglects the Lagrange multiplier p is singular. In this paper, to solve FEA in subdomains by the direct method, the A method that doesn't neglect the Lagrange multiplier p is considered in subdomains.

In the actual parallel computing in the next section, we adopt HDDM with "Parallel processor mode (p-mode)".

III. NUMERICAL EXAMPLES

In this section, TEAM Workshop Problem 20 [7] is considered, which consists of a center pole, a yoke and a coil.

The center pole and the yoke are made of SS400, and the coil is made of polyimide electric wire. The electric current in the coil is 1,000 [A]. The magnetic reluctivity is a positive constant in each element such that in the region of air and coil, the value is $1/(4\pi \times 10^{-7})$ [m/H]. TABLE I shows numbers of elements, DOF and subdomains.

TABLE I
NUMBERS OF ELEMENTS, DOF AND SUBDOMAINS

	elements	DOF
Model (1)	440,634	527,319
Model (2)	1,033,404	1,227,859
Model (3)	1,786,748	2,114,436
Model (4)	38,052,061	44,440,020
Model (5)	50,254,629	58,650,613

TABLE II
COMPUTATION TIME, SPEED-UP RATIO AND AMOUNT OF MEMORY PER CPU

	method	computation time [s]	speed-up previous/new	memory per CPU [MB]
Model (1)	previous	230	1.60	25.3
	new	144		60.7
Model (2)	previous	715	1.49	59.3
	new	481		142
Model (3)	previous	1,402	1.52	102
	new	920		246

Fig. 1. History of residual norms (Model (4)).

Fig. 2. History of residual norms (Model (5)).

A. Comparison the new method with the previous method

In this section, we compare the new method (solving by the direct method with Lagrange multiplier p) with the previous method (solving by ICCG method) by solving Model (1)-(3). A simplified block diagonal scaling is used as the preconditioner in the CG procedure on the interface. Each process is stopped when the residual norm becomes less than 10^{-4} . The Newton iteration is stopped by $\|u_b^{n+1} - u_b^n\| / \|u_b^{n+1}\| < 10^{-5}$.

FEAs in subdomains of the previous method are solved by the shifted ICCG method (the shift value is 1.2) and it is stopped when the preconditioned residual norm becomes less than 10^{-9} . Computations were performed by a PC cluster that consisted of 8 CPUs of Intel Core2Duo E6600 (2.4GHz). TABLE II shows computation time, speed-up ratio and amount of memory per CPU versus method cases. In any Model (1)-(3), the new method needs much memory than the previous method by about twice, because the matrices that are results of the LU decomposition are stored on main memory. However, the computation times of the new method are reduced and speed-up ratios are 1.5-16.

B. Characteristics of convergence of the interface problem

To investigate characteristics of convergence of the interface problem, the CG procedure on the interface is iterated up to 4,000 times or is stopped when the relative residual norm become less than 10^{-8} . In this section, Model (4) and (5) are computed. Computations were performed by a PC cluster that consisted of 28 CPUs of Intel Core2Duo E6600. Fig. 1 and Fig. 2 show the histories of residual norms. It is clear that the characteristic of convergence of the new method is better than that of the previous method. Moreover, the residual norms of the previous method have diverged after reaching the minimum residual nom. However, those of the new method have become small smoothly.

IV. CONCLUSIONS

To solve FEA in subdomains by the direct method, the A method that doesn't neglect the Lagrange multiplier p is considered in subdomains. Because the direct method is used in subdomains, the amount of memory of the new method is about twice as much as that of the previous method. However, the computation time of the new method is about 0.65 times as long as that of the previous method by storing matrices that are results of the LU decomposition on main memory. Moreover, the characteristic of convergence of the interface problem is improved. As present work, we are trying to analyze the model with 100 million DOF.

Abstract—The aim of this paper is to introduce a **Discrete Geometric Approach to solving 2D non-linear magnetostatic problems**. In particular, an efficient algorithm will be presented to solve magnetostatics in isotropic non-linear media by means of a Newton-Raphson scheme, in which the Jacobian is calculated analytically. Results on a reference configuration (TEAM Workshop Problem 25) are reported and discussed.

Index Terms—Discrete Geometric Approach, Non-linear Magnetostatics, TEAM Workshop Problem 25

I. INTRODUCTION

We focus on a Discrete Geometric Approach (DGA) based on the geometric structure behind Maxwell's equations [1], [2] to solving non-linear magnetostatic problems in two-dimensional domains. An efficient Newton-Raphson scheme will be presented in which the elements of the Jacobian matrix can be calculated analytically in the case of isotropic non-linear media. As an application, the optimal design of a die press model (TEAM Workshop Problem 25 [3]) is carried out.

II. DISCRETE GEOMETRIC APPROACH

In a 2D domain of interest D , a pair of interlocked cell complexes (\mathcal{K} , $\tilde{\mathcal{K}}$) [1], [4] is introduced, where \mathcal{K} is simplicial and $\tilde{\mathcal{K}}$ is obtained from it using the barycentric subdivision, see Fig. 1. The interconnections between the pairs (edge e , node n), (face f , edge e) of \mathcal{K} are described by the incidence matrices \mathbf{G} , \mathbf{C} respectively; we denote with $\tilde{\mathbf{C}}$ the incidence matrix between pairs (dual faces \tilde{f} , dual edges \tilde{e}) of $\tilde{\mathcal{K}}$ and $\tilde{\mathbf{C}} = \mathbf{C}^T$ holds. The edge and face vectors will be denoted in roman type.

Fig. 1. A restriction of the primal and dual cell complexes is shown within a single volume v .

Next, we consider the integrals of the field quantities involved in the magnetostatic problem with respect to the

oriented geometric elements of $\mathcal{K} - \tilde{\mathcal{K}}$, yielding the Degrees of Freedom (DoF) arrays. There is a precise association between the DoFs and the geometric elements of \mathcal{K} and $\tilde{\mathcal{K}}$ [5]. We denote by Φ the array of magnetic fluxes associated with primal faces f , by \mathbf{F} the array of magneto-motive forces (m.m.f.s) associated with dual edges \tilde{e} , by \mathbf{I}_s the arrays of electric source currents across dual faces \tilde{f} , and by \mathbf{A} the array of circulations of the magnetic vector potential on primal edges e .

Maxwell's laws can be written *exactly* as topological balance equations between DoFs arrays, as

$$(\mathbf{C}^T \mathbf{F})_e = (\mathbf{I}_s)_e, \quad e \in D \quad (1)$$

$$(\Phi)_f = (\mathbf{C}\mathbf{A})_f, \quad f \in D \quad (2)$$

where (1) is the Ampère's Law, (2) involves the array \mathbf{A} in such a way that Gauss' Law $\mathbf{D}\Phi = 0$ is satisfied identically (since $\mathbf{D}\mathbf{C} = 0$). The discrete counterpart of the constitutive law $\mathbf{H} = \nu\mathbf{B}$ can be written as

$$\mathbf{F} = \nu \Phi, \quad (3)$$

where the matrix ν is a square symmetric matrix which can be efficiently constructed in a pure geometric way. In fact, considering the cell v_k , the Gauss' law, since $f_1 + f_2 - f_3 = 0$, is always verified for an element-wise constant field \mathbf{B}

$$\Phi_1 + \Phi_2 - \Phi_3 = \mathbf{B} \cdot \mathbf{f}_1 + \mathbf{B} \cdot \mathbf{f}_2 - \mathbf{B} \cdot \mathbf{f}_3 = 0. \quad (4)$$

The three fluxes are dependent and only two are used to produce the \mathbf{B} field by

$$\begin{bmatrix} f_{1x} & f_{1y} \\ f_{2x} & f_{2y} \end{bmatrix} \begin{bmatrix} B_x \\ B_y \end{bmatrix} = \begin{bmatrix} \Phi_1 \\ \Phi_2 \end{bmatrix}. \quad (5)$$

Inverting this linear system and using the fact that $f_{iy} = e_{ix}$ and $f_{ix} = -e_{iy}$

$$\mathbf{B} = \frac{1}{2S} \begin{bmatrix} e_{2x} & -e_{1x} \\ e_{2y} & -e_{1y} \end{bmatrix} \begin{bmatrix} \Phi_1 \\ \Phi_2 \end{bmatrix}, \quad (6)$$

where S is the area of v_k . The local constitutive matrix ν^k , for an isotropic medium, can be obtained by

$$\mathbf{F}^k = \nu^k \Phi^k = \begin{bmatrix} \tilde{e}_1 \\ \tilde{e}_2 \\ \tilde{e}_3 \end{bmatrix} \nu \frac{1}{2S} \begin{bmatrix} e_{2x} & -e_{1x} & 0 \\ e_{2y} & -e_{1y} & 0 \end{bmatrix} \Phi^k, \quad (7)$$

Substituting (2) and (3) in (1), the set of algebraic equations governing the magnetostatic problem can be derived

$$\mathbf{C}^T \nu \mathbf{C} \mathbf{A} = \mathbf{I}_s. \quad (8)$$

A. Non linear case

In the presence of non-linear (ferromagnetic) media, the following set of non-linear equations has to be solved

$$\mathbf{C}^T \boldsymbol{\nu}(\mathbf{A}) \mathbf{C} \mathbf{A} = \mathbf{I}_s. \quad (9)$$

An iterative scheme is needed to nullify the vector

$$\mathbf{f}(\mathbf{A}) = \mathbf{C}^T \boldsymbol{\nu}(\mathbf{A}) \mathbf{C} \mathbf{A} - \mathbf{I}_s. \quad (10)$$

At the n -th step of the iterative process we get

$$\begin{aligned} \mathbf{W}^n \mathbf{h}^n &= -\mathbf{f}(\mathbf{A}^n) \\ \mathbf{A}^{n+1} &= \mathbf{A}^n + \mathbf{h}^n \end{aligned} \quad (11)$$

where \mathbf{h}^n is the correction vector used to determine the new estimate \mathbf{A}^{n+1} and \mathbf{W}^n is the Jacobian matrix or a non-singular matrix which approximates it, if a Newton-Rapshon or a Broyden method are adopted respectively. The advantage of the Broyden method is that the Jacobian matrix needs not to be recomputed at each iteration; on the other hand the order of convergence is lower (in between 1 and 2).

B. Computation of the Jacobian

The element (i, j) in the Jacobian matrix can be written as

$$\mathbf{W}_{i,j} = \frac{\partial \mathbf{f}_i}{\partial A_j} = [\mathbf{C}^T \boldsymbol{\nu}(\mathbf{A}) \mathbf{C}]_{i,j} + \left(\mathbf{C}^T \frac{\partial \boldsymbol{\nu}(\mathbf{A})}{\partial A_j} \mathbf{C} \mathbf{A} \right)_i. \quad (12)$$

For the primal edges e not belonging to the ferromagnetic region the second addendum of (12) vanishes while the first one is independent of \mathbf{A} . It is convenient to compute the contribution \mathbf{W}^k to the Jacobian \mathbf{W} due to the cell v_k . For isotropic non-linear media, the reluctivity matrix is scalar and the constitutive matrix $\boldsymbol{\nu}^k$ can be rewritten as $\boldsymbol{\nu}^k(\mathbf{A}) = \mathbf{m}^k \nu^k(\mathbf{A}^k)$, where \mathbf{m}^k is the matrix $\boldsymbol{\nu}^k$ calculated by swapping the reluctivity ν^k with the pure number 1. The contribution of v_k to the Jacobian becomes

$$\mathbf{W}_{i,j}^k = [\mathbf{K}^k]_{i,j} \nu^k(\mathbf{A}^k) + (\mathbf{K}^k \mathbf{A}^k)_i \frac{\partial \nu^k(\mathbf{A}^k)}{\partial A_j^k}, \quad (13)$$

where $\mathbf{K}^k = \mathbf{C}^{kT} \mathbf{m}^k \mathbf{C}^k$ is a constant matrix. The derivative in (13) becomes

$$\frac{\partial}{\partial A_j^k} \left(\frac{1}{\mu^k(\mathbf{A}^k)} \right) = -\frac{1}{(\mu^k)^2} \frac{\partial \mu^k}{\partial B^k} \frac{\partial B^k}{\partial A_j^k}, \quad (14)$$

where B^k is the amplitude of the induction field in v_k , $\frac{\partial \mu^k}{\partial B^k}$ is the slope of the permeability curve. By substituting (2) in (6) with $f = \{1, 2\}$, we write the components of \mathbf{B} in terms of \mathbf{A}^k by defining two vectors \mathbf{k}_x and \mathbf{k}_y , such that

$$B_x = \mathbf{k}_x \cdot \mathbf{A}^k, B_y = \mathbf{k}_y \cdot \mathbf{A}^k \quad (15)$$

holds. The amplitude B^k can thus be computed by

$$B^k = \sqrt{(\mathbf{k}_x \cdot \mathbf{A}^k)^2 + (\mathbf{k}_y \cdot \mathbf{A}^k)^2}. \quad (16)$$

Using these equations, the $\frac{\partial B^k}{\partial A_j^k}$ term can be calculated analytically as

$$\frac{\partial B^k}{\partial A_j^k} = \frac{(\mathbf{k}_x \cdot \mathbf{A}^k) k_{xj} + (\mathbf{k}_y \cdot \mathbf{A}^k) k_{yj}}{\sqrt{(\mathbf{k}_x \cdot \mathbf{A}^k)^2 + (\mathbf{k}_y \cdot \mathbf{A}^k)^2}}, \quad (17)$$

where k_{xj} and k_{yj} represent the values in the j -th column of \mathbf{k}_x and \mathbf{k}_y respectively. Finally (17) can be rewritten as

$$\frac{\partial B^k}{\partial A_j^k} = \frac{B_x k_{xj} + B_y k_{yj}}{B^k}, j = 1, \dots, 3. \quad (18)$$

III. PROBLEM DESCRIPTION AND RESULTS

As a test problem, the TEAM Workshop Problem 25 [3] has been considered. A detail of the two-dimensional benchmark geometry is shown in Fig.2. The die molds are set to form a radial flux density distribution. The shape of the inner die mold is assumed as a circle; the inside shape of the outer die mold is represented by an ellipse and a line parallel to the x -axis. Then, the radius R_1 of the inner die, the long and short axes (L_2, L_3) of ellipse and the dimension L_4 are chosen as design variables with specified upper and lower bounds.

Fig. 2. TEAM Workshop problem 25: enlarged view of the die press model.

The developed 2D numerical code based on the DGA is coupled to a hybrid optimization approach which combines parallel genetic algorithms for global minimum search and a deterministic algorithm for local refinement.

In Fig.2 the magnetic flux density distribution is shown, evaluated for the final (optimal) shape of die molds obtained using the numerical code developed based on the proposed DGA. The maximum errors of the of the flux density in P_i are $\varepsilon_B^{max} = 0.87\%$ in terms of amplitude and $\varepsilon_\theta^{max} = 1.1$ deg in terms of direction.

The main features of the hybrid search algorithm and the results of the investigations on number of mesh elements, iterations, CPU time, accuracy, will be described in detail in the full paper.

Optimal Selection of the Integration Surface in the Hybrid FEM-DBCI Method

Giovanni Aiello, Salvatore Alfonzetti, and Nunzio Salerno

Dip. Ing. Elettrica, Elettronica e dei Sistemi, Università di Catania – Viale A. Doria, 6 – I-95125 Catania– Italy

Abstract — In this paper the optimal placement of the integration surface for the integral equation in the hybrid FEM-DBCI method is achieved by selecting it as lying in the middle of the tetrahedral or hexahedral finite elements. Better accuracy is obtained with respect to the case in which the integration surface lies along the element faces. Some numerical examples are provided.

Index Terms— Finite Element Method, Integral Equations, Open Boundary Problems.

I. INTRODUCTION

FEM-DBCI (Finite Element Method - Dirichlet Boundary Condition Iteration) is a numerical method devised by the authors to solve a variety of static and quasi-static electromagnetic field problems in unbounded domains [1-4]. FEM-DBCI, like the well-known FEM-BEM (Boundary Element Method) [5-6], is a hybrid method in which the differential equation, which governs the interior problem, is coupled with an integral one which expresses the unknown boundary condition on the fictitious truncation boundary Γ_F .

The integral equations of the two methods make use of the free-space Green function, but while the integration surface and truncation boundary coincide in FEM-BEM, FEM-DBCI uses another closed surface, say Γ_M , strictly enclosed by Γ_F and containing all relevant parts of the system. The resulting global algebraic systems are partly sparse and partly dense; however, the FEM-DBCI integral equation is explicit with respect to the boundary unknowns and this property allows a simple iterative solution of the global system: assuming an initial guess for the Dirichlet condition on the truncation boundary Γ_F , the sparse FEM equations are solved by means of the conjugate gradient (CG) solver; the dense equations are then used to improve the Dirichlet condition on Γ_F ; the procedure is iterated until convergence is reached. This solution strategy is efficient because the CG is only applied to the sparse equation, and the dense equation is only used a few times. An improvement on this solving method is obtained by means of the Generalized Minimal Residual (GMRES) method, as described in [7]. A detailed comparison between FEM-BEM and FEM-DBCI is made in [8], concluding that the former is more accurate than the latter but more time-consuming.

Recently the authors showed that a notable improvement in the accuracy of FEM-DBCI is obtained in a mesh of triangular elements by selecting the integration curve as constituted by segments connecting the middle points of triangle sides [9]. The improvement is obtained with respect to the standard

selection of the integration curve as made of triangular element sides.

In this paper it is shown that a similar improvement is obtained in a mesh of tetrahedral elements. The paper is organized as follows: In the next section a brief description of the FEM-DBCI method is given, by referring, for sake of simplicity, to a simple electrostatic problem. In Section III the proposed improvement is highlighted. A simple system is numerically analyzed in Section IV.

II. FEM-DBCI FOR ELECTROSTATIC PROBLEMS

Consider a three-dimensional electrostatic system made of distributed and/or lumped charges, voltage conductors and non-homogeneous objects embedded in air. In order to compute the electrical potential v , a closed truncation boundary Γ_F is introduced enclosing all the conductors, all the dielectric objects and some distributed charges, but possibly leaving out some other distributed and/or lumped charges (external charges). In the bounded domain D delimited by $(F$, the Poisson equation holds:

$$-\nabla \cdot (\epsilon \nabla v) = \rho \quad (1)$$

where ϵ is the electric permittivity and ρ the charge density. The unknown Dirichlet condition on Γ_F is expressed through:

$$v(\mathbf{r}) = v_{\text{ext}}(\mathbf{r}) + \iint_{\Gamma_M} \left(v(\mathbf{r}') \frac{\partial G(\mathbf{r}, \mathbf{r}')}{\partial n'} - G(\mathbf{r}, \mathbf{r}') \frac{\partial v(\mathbf{r}')}{\partial n'} \right) dS' \quad (2)$$

where Γ_M is a closed surface enclosing all the conductors and dielectric non-homogeneities but strictly enclosed by Γ_F , \mathbf{n}' is its outward normal unit vector and v_{ext} is due to the external charges. By discretizing the domain D by means of tetrahedral finite elements, equations (1) and (2) read as follows [1]:

$$\mathbf{A}\mathbf{V} = \mathbf{B}_0 - \mathbf{A}_F \mathbf{V}_F \quad (3)$$

$$\mathbf{V}_F = \mathbf{V}_{F0} + \mathbf{H}\mathbf{V} \quad (4)$$

where \mathbf{A} is a standard FEM matrix (symmetric and positive definite), \mathbf{V} is the vector of unknown nodal values inside the domain, \mathbf{B}_0 and \mathbf{V}_{F0} are due to source and conductor potentials, \mathbf{A}_F is a rectangular matrix of coefficients similar to \mathbf{A} , \mathbf{V}_F is the vector of nodal field values on Γ_F , and \mathbf{H} is a rectangular matrix in which null entries appear for the nodes of the elements not adjacent to the integration surface Γ_M . The integrals in (2) are performed by means of the Gauss method with a variable number of Gauss points according to ratio of the distance of the node on Γ_F from a point on Γ_M to the mean radius of the subpart of Γ_M . The system (3)-(4) is solved iteratively. Starting with an initial guess for the potential on Γ_F (for example $\mathbf{V}_F = \mathbf{0}$), equation (3) is solved for \mathbf{V} . Equation (4)

is then used to improve V_F . The procedure is iterated until convergence takes place.

III. SELECTING THE INTEGRATION SURFACE

The most simple way to select the integration surface Γ_M in a tetrahedral mesh is to build it by means of triangular faces of tetrahedral elements (see triangles ABD and BCD in Fig. 1, where capital letters denote the element vertices and small letters denotes the middle points of edges). In this way, however, accuracy is not well balanced between v and $\partial v/\partial n$ in (2). No accuracy problems arise in evaluating G and $\partial G/\partial n$, because the Green function is known analytically. In fact, the first term is much more accurate than the second one, since the numerical derivative $\partial v/\partial n$ is maximally erroneous on the tetrahedral faces, where v is maximally correct because of the presence of several nodes on the element face itself.

To improve the accuracy of the integral equation, one can select the integration surface as constituted by sub-surfaces internal to the tetrahedra and connecting the middle points of their edges (see fig.1). Note that two kinds of sub-surfaces arise: triangles and quadrangles (it is simple to show that the four points b, d, f, and h in fig. 1 are coplanar).

In this way the accuracy of the derivative $\partial v/\partial n$ is maximized, whereas the accuracy of the field variable v is not greatly decreased, so that a global improvement in the accuracy of the integral equation and the whole solution is expected. In order to verify this, in the next sections an example is provided for which analytical solutions is known.

IV..A VALIDATION EXAMPLE

The example concerns the computation of the electrostatic potential v near a conducting sphere of radius R , voltaged at V_0 , embedded in a homogeneous unbounded dielectric medium of permittivity ϵ_0 . By selecting the origin of a Cartesian reference frame in the center of the sphere, the problem exhibits the analytical solution:

$$v^*(x, y, z) = \frac{R}{\sqrt{x^2 + y^2 + z^2}} V_0 \quad (5)$$

Fig. 1- Two different choices for the integration surface Γ_M in a tetrahedral mesh (tetrahedra: ABDE, CDBG, FGBE, HGED, EGBD); first choice: triangles ABD and BCD; second choice triangles abh, bcd, def, fgh and quadrangle bdfh.

Fig. 2- Tetrahedral mesh of the example.

The analysis can be restricted to the first octant only, by imposing homogeneous Neumann conditions on the coordinate planes. The unbounded domain is truncated by a spherical fictitious boundary Γ_F of radius $R+d$, with $d=1.2 R$. The mesh was made of 8640 first-order tetrahedra, with two layers of elements in the radial direction (see Fig. 2). Selecting Γ_M coinciding with the conductor surface, the relative error between the computed solution and the analytical one is 2.8 per cent, having set the convergence tolerance to 0.1 per cent. Selecting Γ_M at a distance of $d/4$ from the conductor (that is in the middle of the first layer of tetrahedra), the relative error decreases to 0.8 per cent. More details and examples will be provided in the full paper.

Abstract — In this paper, an approach based on the double Lagrange multipliers is developed in the finite element method in order to impose complex periodic or anti-periodic boundary conditions. The magnetostatic equations are solved using the vector or scalar potential formulations. In order to show the possibilities of the proposed approach, an example of application is studied and the results are discussed.

I. INTRODUCTION

To model an electromagnetic device, the finite element method is currently used today. In order to reduce the mesh of the studied domain, the geometric symmetries of the system are generally considered. Then, only one part of the device is modelled. The reduction of the domain can introduce periodic or anti-periodic conditions on the fields. To impose these conditions, a simple method consists to build a same mesh on the boundaries where the conditions are applied. In the device with a simple geometry, same meshes on two boundaries can be easily fixed. In the case of complex structures, this method is not rather flexible and becomes difficult to implement. In order to avoid this difficulty, a technique based on the double Lagrange multipliers method can be used [1][2]. By using this approach, the meshes on the boundaries with periodic or anti-periodic conditions can be different. The continuity of the fields is obtained by imposing supplementary relations.

In this communication, the double Lagrange multipliers approach is introduced in the case of magnetostatic problems. In first, the magnetostatic problem is presented. Then, the double Lagrange multipliers approach is developed in the scalar and vector potential formulations to impose the periodic or anti-periodic boundary conditions. At last, an application based on the simplified structure of a claw pole electrical machine is analyzed.

II. MAGNETOSTATIC PROBLEM

Let's consider a domain D with its boundary Γ divided into four parts such that $\Gamma = \Gamma_{S1} \cup \Gamma_{S2} \cup \Gamma_B \cup \Gamma_H$ and $\Gamma_{S1} \cap \Gamma_{S2} \cap \Gamma_B \cap \Gamma_H = \emptyset$ (Fig. 1). In the case of a magnetostatic problem, Maxwell's equations and the behaviours law are given by:

$$\text{div } \mathbf{B} = 0 \quad \text{with } \mathbf{B} \cdot \mathbf{n}|_{\Gamma_B} \quad (1)$$

$$\text{curl } \mathbf{H} = \mathbf{J} \quad \text{with } \mathbf{H} \times \mathbf{n}|_{\Gamma_H} \quad (2)$$

$$\mathbf{B} = \mu \mathbf{H} \quad (3)$$

with \mathbf{n} the outward normal of Γ , \mathbf{B} the magnetic flux density, \mathbf{H} the magnetic field, \mathbf{J} the current density supposed to be known in stranded inductors and μ the magnetic permeability. The boundaries Γ_{S1} and Γ_{S2} are used to impose

a periodic or anti-periodic condition on the fields. These conditions can be expressed such that:

$$\mathbf{B} \cdot \mathbf{n}|_{\Gamma_{S1}} = \alpha \mathbf{B} \cdot \mathbf{n}|_{\Gamma_{S2}} \quad \text{and} \quad \mathbf{H} \times \mathbf{n}|_{\Gamma_{S1}} = \alpha \mathbf{H} \times \mathbf{n}|_{\Gamma_{S2}} \quad (4)$$

with α a scalar value equal to 1 or -1 . This one depends on the periodic or anti-periodic condition between Γ_{S1} and Γ_{S2} .

Fig. 1 Definition of the studied domain

III. POTENTIAL FORMULATIONS

In the scalar potential formulation, a source field \mathbf{H}_s is introduced such that $\text{rot } \mathbf{H}_s = \mathbf{J}$ with $\mathbf{H}_s \times \mathbf{n} = 0$ on Γ_H , Γ_{S1} and Γ_{S2} . From (2.a), a scalar potential Ω can be introduced and the magnetic field can be rewritten such that $\mathbf{H} = \mathbf{H}_s - \text{grad } \Omega$ with $\Omega = Cst$ on Γ_H . Equation to solve in the studied domain is given by the weak formulation of (1.a) such that:

$$(\mu \text{ grad } \Omega, \text{ grad } \psi)_D + \langle \mathbf{B} \cdot \mathbf{n}, \psi_{S1} \rangle_{\Gamma_{S1}} + \alpha \langle \mathbf{B} \cdot \mathbf{n}, \psi_{S2} \rangle_{\Gamma_{S2}} = (\mu \mathbf{H}_s, \text{ grad } \psi)_D \quad (5)$$

with ψ a test function chosen in the same space than Ω and ψ_{S1} and ψ_{S2} the restriction of ψ on Γ_{S1} and Γ_{S2} . On Γ_B and Γ_H , the surface integrals vanish by (1.b) and (2.b). To impose a periodic or anti-periodic condition on Γ_{S1} and Γ_{S2} , the double Lagrange multipliers method can be introduced. The Lagrange multipliers can be expressed on Γ_{S1} or Γ_{S2} . We define the multipliers λ_{B1} and λ_{B2} on Γ_{S1} such that $\mathbf{B} \cdot \mathbf{n}|_{\Gamma_{S1}} = \lambda_{B1} + \lambda_{B2}$ [1]. The test function associated with the multipliers is chosen equal to ψ_{S1} . The geometric transformation T between Γ_{S1} and Γ_{S2} is defined in order to project the test function ψ_{S2} on Γ_{S1} . The final equation system to solve can be written such that:

$$\begin{aligned} & (\mu \text{ grad } \Omega, \text{ grad } \psi)_D + \langle \lambda_{B1}, \psi_{S1} \rangle_{\Gamma_{S1}} + \langle \lambda_{B2}, \psi_{S1} \rangle_{\Gamma_{S1}} \\ & + \alpha \langle \lambda_{B1}, T\psi_{S2} \rangle_{\Gamma_{S1}} + \alpha \langle \lambda_{B2}, T\psi_{S2} \rangle_{\Gamma_{S1}} = (\mu \mathbf{H}_s, \text{ grad } \psi)_D \\ & \langle \Omega_{S1} + \alpha T\Omega_{S2}, \psi_{S1} \rangle_{\Gamma_{S1}} + \langle \lambda_{B1} - \lambda_{B2}, \psi_{S1} \rangle_{\Gamma_{S1}} = 0 \\ & \langle \Omega_{S1} + \alpha T\Omega_{S2}, \psi_{S1} \rangle_{\Gamma_{S1}} + \langle -\lambda_{B1} + \lambda_{B2}, \psi_{S1} \rangle_{\Gamma_{S1}} = 0 \end{aligned} \quad (6)$$

with Ω_{S1} and Ω_{S2} the restriction of Ω on Γ_{S1} and Γ_{S2} . The two last equations are introduced to insure the continuity of

the scalar potential on Γ_{S1} and Γ_{S2} . For a periodic condition, these last relations impose the equality of Ω on Γ_{s1} and Γ_{s2} . To discretize Ω , ψ , λ_{B1} and λ_{B2} , nodal shape functions are used.

In the vector potential formulation, a potential \mathbf{A} is introduced by using (2.a) and the magnetic flux density can be rewritten such that $\mathbf{B} = \text{curl } \mathbf{A}$ with $\mathbf{A} \times \mathbf{n} = 0$ on Γ_B . From (2.a), the weak formulation is given by:

$$(\mu^{-1} \text{curl } \mathbf{A}, \text{curl } \psi)_D + \langle \mathbf{H} \times \mathbf{n}, \psi_{s1} \rangle_{\Gamma_{s1}} + \alpha \langle \mathbf{H} \times \mathbf{n}, \psi_{s2} \rangle_{\Gamma_{s2}} = (\mathbf{J}, \psi)_D \quad (7)$$

with ψ a test function and ψ_{s1} and ψ_{s2} its restriction on Γ_{S1} and Γ_{S2} . A similar approach to the scalar formulation is used to impose a periodic or anti-periodic condition. Then, we define λ_{H1} and λ_{H2} the Lagrange multipliers on Γ_{S1} such that $\mathbf{H} \times \mathbf{n}|_{\Gamma_{s1}} = \lambda_{H1} + \lambda_{H2}$. The final equation system to solve is given by:

$$\begin{aligned} & (\mu^{-1} \text{curl } \mathbf{A}, \text{curl } \psi)_D + \langle \lambda_{H1}, \psi_{s1} \rangle_{\Gamma_{s1}} + \langle \lambda_{H2}, \psi_{s1} \rangle_{\Gamma_{s1}} \\ & + \alpha \langle \lambda_{H1}, \mathbf{T} \psi_{s2} \rangle_{\Gamma_{s1}} + \alpha \langle \lambda_{H2}, \mathbf{T} \psi_{s2} \rangle_{\Gamma_{s1}} = (\mathbf{J}, \psi)_D \\ & \langle \mathbf{A}_{s1} + \alpha \mathbf{T} \mathbf{A}_{s2}, \psi_{s1} \rangle_{\Gamma_{s1}} + \langle \lambda_{H1} - \lambda_{H2}, \psi_{s1} \rangle_{\Gamma_{s1}} = 0 \\ & \langle \mathbf{A}_{s1} + \alpha \mathbf{T} \mathbf{A}_{s2}, \psi_{s1} \rangle_{\Gamma_{s1}} + \langle -\lambda_{H1} + \lambda_{H2}, \psi_{s1} \rangle_{\Gamma_{s1}} = 0 \end{aligned} \quad (8)$$

with \mathbf{A}_{s1} and \mathbf{A}_{s2} the restriction of \mathbf{A} on Γ_{S1} and Γ_{S2} . Edge shape functions are used to discretize the vector potential and the Lagrange multipliers.

IV. APPLICATION

The studied structure is based on a simplified claw pole electrical machine (Fig. 2). The rotor is composed by two half claws and the stator by three windings. These ones are supplied by a three phase current source. The mesh is constituted by 5663 nodes and 28786 tetrahedrons. An anti-periodic condition, according to an axis, is applied on two boundaries (Fig. 3). This structure has been solved by both potential formulations. For the scalar and vector formulation, the number of unknowns is equal to 6525 and 36090. In Fig. 4, the distribution of the magnetic flux density trough a section obtained by the scalar potential formulation is presented for a given time step. In Fig. 5, the magnetic energy waveform in function of time obtained by both formulations is presented. The shapes of the curves are similar. The different between the maximal values is due to the discretization of the mesh in the air gap [3]. In term of solution, the matrix systems are solved by the minimum residual method with a SSOR (Successive Over Relaxation) preconditionner. The iteration method requires 3% of unknown number to obtain the solution with the scalar formulation and 12% with the vector formulation.

V. CONCLUSION

The double Lagrange multipliers method has been introduced in the scalar and vector potential formulations in order to impose the periodic and anti-periodic conditions. The studied example shows the possibilities of the proposed model for a complex geometry with anti-periodic conditions.

Analysis of the Ionized Field under HVDC Transmission Lines Including Wind's Effect Based on Finite Element Method

E-mail: tiebinglu@yahoo.com

Abstract: The corona generated from HVDC transmission lines can affect the environment nearby. Based on the upstream finite element method, an iterative algorithm to analyze the ionized field and the ion current density at the ground level generated from the bundled conductors of bipolar lines is modified. The algorithm is proved to be convergent efficiently. The effect of wind is taken into account. A unipolar line in the presence of wind is calculated and the validities are testified by comparing with measurement results. Finally, bipolar lines can be analyzed by the method.

I. INTRODUCTION

In order to set up a strong and steady power system in China, ± 800 kV ultra HVDC transmission lines system is building. But the ionized field and the ion current density at the ground level due to the corona have to be analyzed in advance to make sure the environment friendly.

Because of the ions existing in the space, the ionized field is very difficult to be calculated [1]. However, the problem has been considered by a number of researchers over the past several decades [2-6]. Based on Deutsch's assumption, Sarma et al. [2] firstly proposed an analytical equation to solve the ionized fields of unipolar line. Obviously, it is not valid when wind is present. Janischewskyj and Gela [3] proposed a numerical method by using the finite element method. Furthermore, Takuma et al. [4] proposed the upstream finite element method. The stability and convergence can be improved effectively. They assumed that the space charge density remains constant around the surface of the conductors. As a matter of fact, the assumption of the constant charge density is not quite true, especially in the presence of wind. Z.Al-Hamouz [5] suggested a method to solve the ion current density based on a finite element mesh which fits the flux tubes of the field. Fortin et al. [6] proposed a similar approach to calculate the ionized electric field of bundled bipolar conductors by treating the conductors in the bundles individually.

In this paper, an iterative method based on upstream FEM is modified to analyze the ionized electric field and the ion current density under the HVDC lines and the effect of wind is included. Different from [4], the assumption that the space charge density remains constant around the surface of the conductors is waived to avoid empirical factor. The algorithm is proved to be convergent efficiently. The effect of wind is taken into account. The validities of the method are testified by comparing with measurement results.

II. METHODOLOGY OF BIPOLAR LINES

Under some assumptions, for the bipolar lines with the effect of wind, the potential φ , the ionized field \vec{E}_s , the space charge density ρ_+ and ρ_- , the current density \vec{j}_+ and \vec{j}_- are defined by the following equations [1]:

$$\nabla^2 \varphi = -(\rho_+ - \rho_-) / \varepsilon_0 \quad (1)$$

$$\vec{j}_+ = \rho_+ (K_+ \vec{E}_s + \vec{w}) \quad (2)$$

$$\vec{j}_- = \rho_- (K_- \vec{E}_s - \vec{w}) \quad (3)$$

$$\nabla \cdot \vec{j}_+ = -R_i \rho_+ \rho_- / e \quad (4)$$

$$\nabla \cdot \vec{j}_- = R_i \rho_+ \rho_- / e \quad (5)$$

$$\vec{E}_s = -\nabla \varphi \quad (6)$$

where K is the ionic mobility within the corona area, R_i is the ion recombination coefficient. The subscript + is for positive and - for negative, and \vec{w} is the wind velocity vector and e is the charge of the electron.

Because FEM only can be applied in a limited region, an artificial boundary far from the lines must be placed, where the potential is equal to the value of the charge-free field obtained by Charge Simulation Method (CSM).

The iterative process is started by assuming initial values of charge density at grid nodes. The space-charge density at the conductor surface can be gained from [7]. Equations (1) and (6) are used to compute values of ionized field. Based on (2)-(5), we can get:

$$\nabla \rho_+ \cdot \vec{v}_+ = -\frac{K_+}{\varepsilon_0} \rho_+^2 + \left(\frac{K_+}{\varepsilon_0} - \frac{R}{e} \right) \rho_+ \rho_- \quad (7)$$

$$\nabla \rho_- \cdot \vec{v}_- = -\frac{K_-}{\varepsilon_0} \rho_-^2 + \left(\frac{K_-}{\varepsilon_0} - \frac{R}{e} \right) \rho_- \rho_+ \quad (8)$$

where $\vec{v}_+ = K_+ \vec{E}_s + \vec{w}$, $\vec{v}_- = -K_- \vec{E}_s + \vec{w}$ are the mobility velocity vector of positive and negative ions, respectively.

In order to calculate (7) and (8), the upstream FEM is applied [4]. The nodes are calculated one by one from their upstream elements from the surface of the conductor until all of the nodes have been calculated.

The charge density in the element ijm can be described by the following interpolating function:

$$\rho(x, y) = N_i \rho_i + N_j \rho_j + N_m \rho_m = [N] [\rho] \quad (9)$$

If b, c are functions of corresponding coordinates:

$$\begin{aligned} b_i &= y_j - y_m & b_j &= y_m - y_i & b_m &= y_i - y_j \\ c_i &= x_m - x_j & c_j &= x_i - x_m & c_m &= x_j - x_i \end{aligned}$$

we can obtain:

$$\frac{\partial \rho}{\partial x} = \left[\frac{\partial N}{\partial x} \right] [\rho] = \frac{1}{2\Delta} \begin{pmatrix} b_i & b_j & b_m \end{pmatrix} [\rho] \quad (10)$$

$$\frac{\partial \rho}{\partial y} = \left[\frac{\partial N}{\partial y} \right] [\rho] = \frac{1}{2\Delta} \begin{pmatrix} c_i & c_j & c_m \end{pmatrix} [\rho] \quad (11)$$

$$\begin{aligned} \nabla \rho_{i+} \cdot \vec{V}_{i+} &\approx \frac{\partial \rho}{\partial x} V_{x+} + \frac{\partial \rho}{\partial y} V_{y+} \\ &= \frac{1}{2\Delta} (b_i \rho_{i+} + b_j \rho_{j+} + b_m \rho_{m+}) V_{x+} + \frac{1}{2\Delta} (c_i \rho_{i+} + c_j \rho_{j+} + c_m \rho_{m+}) V_{y+} \end{aligned} \quad (12)$$

Equation (7) and (8) can be changed as:

$$A_+ \rho_{i+}^2 + B_+ \rho_{i+} + C_+ = 0 \quad (13)$$

where

$$\begin{aligned} A_+ &= \frac{K_+}{\epsilon_0}, \\ B_+ &= \frac{(b_i V_{x+} + c_i V_{y+})}{2\Delta} - \left(\frac{K_+}{\epsilon_0} - \frac{R}{e} \right) \rho_{i-}, \\ C_+ &= \frac{(b_j V_{x+} + c_j V_{y+}) \rho_{j+}}{2\Delta} + \frac{(b_m V_{x+} + c_m V_{y+}) \rho_{m+}}{2\Delta} \\ \Delta &= \frac{1}{2} (b_i c_j - b_j c_i) \end{aligned}$$

The larger solution can be looked as the final result, thus the calculation is stable. Next, the obtained charge density is used to calculate the ionized field in (1), so the iteration continues until the satisfied result is obtained.

III. VALIDITY

Fig. 1 shows the calculated results of a $\pm 200\text{kV}$ unipolar test line in the presence of wind with 0.25cm in radius and 2m in height. The relevant measurements in [8] are also shown in Fig. 1 as separate stars and circles. The star * is for the results without wind, and the circle o is for the results with 8m/s wind velocity. The calculated curves agree reasonable with measurement results.

Fig.1 Comparison between the measurement and calculation

IV. APPLICATIONS

The proposed method is applied to an operating HVDC lines in the present of wind of 1m/s and 3m/s respectively. The unipolar line is energized at 500kV with a $4 \times 1.185\text{cm}$ and a 45cm spacing conductor bundle at height of 12.5m . The distributions of ionized electric field and the ion current density at the ground level are shown in Fig. 2. The results show that the ionized field can be influenced by wind

obviously. Both of the maximum of electric field and current density shift to the downwind side, increasing down the wind and decreasing against the wind. And the effect of wind on ion current density is stronger than that on ionized field. Both of the field and current curves became wider down the wind. This trend is visible when wind velocity increases from zero to 3m/s . However, if the velocity is increased to 6m/s or more, the field strength almost doesn't increase any longer. The explanation of the results and the case of bipolar lines will be included in the final version

Fig. 2 Effect of winds on ionized field and ion current density

V. CONCLUSIONS

The charge generated from corona conductors of HVDC transmission lines can enhance greatly the electric field in the space and on the ground plane. An upstream FEM-based approach can effectively calculate the ionized field and ion current density e . The influence of wind can be taken into account. The validity of the method is testified. And the rapidity of convergence is satisfying. Then, the influence of wind on one unipolar line is analyzed. The tendency can be explained corresponding to the physical fact.

This project is partly supported by National Nature Science Foundation of China under grant No. 50677016.

Abstract — An innovative 3-D Finite Elements approach for the computation of the self-consistent unbounded magnetic field of electron beams is presented for the analysis of electron guns. The solution of the whole problem is obtained by solving iteratively a Vlasov-Maxwell equation together with the relativistic dynamical equations of motion, by assuming stationary conditions. The self-consistent unbounded magnetostatic field is computed by using an edge elements curl-curl formulation for the magnetic vector potential \mathbf{A} , and by adopting a fictitious boundary iterative algorithm to overcome the problem of boundary conditions assignment. An example of application to the spread of relativistic beam is given in order to better illustrate the procedure.

I. INTRODUCTION

In the design process of electron guns the electromagnetic analysis is a critical issue in order to achieve the desired electron beam characteristic. In fact, the adoption of more complex geometries and the insertion of appropriate control grids allow the designer to obtain a better performance, but, on the other hand, require the use of dedicated tools to carry out the electromagnetic analysis. For this reason some numerical analysis tools, most of them based on the Finite Element Method (FEM), have been set up [1], but they do not address satisfactorily the self-consistent magnetic field (SCMF). In fact, although high focusing magnetic fields (about 100 times the self consistent component) are usually used for these devices in the focusing region, the influence of SCMF is important above all in the electron gun region, where the focusing magnetic fields vanish. Several approaches were developed to model self-consistent magnetic field: some apply directly the Ampere's law to obtain only the angular component (in a cylindrical symmetric system) of the magnetic field, others solve numerically the whole magnetic problem by using the magnetic vector potential, taking into account all the three components (angular, radial and axial) of the magnetic field. In the latter case a tricky problem is the assignment of the boundary conditions for the magnetic vector potential \mathbf{A} .

In this paper we present an innovative scheme for the treatment of the self-consistent unbounded magnetic field in 3D Finite Elements code for the analysis of electron guns. The solution of the whole problem is obtained by solving iteratively a Vlasov-Maxwell equation together with the relativistic dynamical equations of motion [2], by assuming stationary conditions. In particular in order to model efficiently the self-consistent unbounded magnetostatic field a curl-curl formulation for the magnetic vector potential \mathbf{A} has been employed, and a fictitious boundary iterative algorithm has been adopted to overcome the problem of boundary conditions

assignment. On the fictitious boundary the \mathbf{A} components are initially guessed and successively updated according to the magnetic vector potential and current density distributions obtained in the preceding iteration step. This treatment closely follows an analogous approach, successfully used for the solution of uncoupled electromagnetic problems in unbounded domains [3].

II. 3-D FE ANALYSIS OF ELECTRON GUN

The dynamics of a set of charged particles subject to an electromagnetic field in collisionless conditions can be described by means of the Vlasov equation for the particle distribution function $f(t, \mathbf{x}, \mathbf{p})$, defined in the phase space $(\mathbf{x}, \mathbf{p}) \in \mathfrak{R}_x \times \mathfrak{R}_p$ and time t ,

$$\frac{\partial f}{\partial t} + \frac{\mathbf{p}}{m} \cdot \nabla_x f + q(\mathbf{E} + \frac{\mathbf{p}}{m} \times \mathbf{B}) \cdot \nabla_p f = 0 \quad (1)$$

where \mathbf{p} is the particle momentum, m and q are the particle mass and charge respectively. The electric field \mathbf{E} and magnetic field \mathbf{B} satisfy the Maxwell equations, for which the charge and current densities

$$\rho(t, \mathbf{x}) = q \int_{\mathfrak{R}_p} f(t, \mathbf{x}, \mathbf{p}) d\mathbf{p}, \quad \mathbf{J}(t, \mathbf{x}) = q \int_{\mathfrak{R}_p} \frac{\mathbf{p}}{m} f(t, \mathbf{x}, \mathbf{p}) d\mathbf{p} \quad (2)$$

are the source terms.

The Vlasov equation together with the Maxwell equations constitutes a system of coupled equations called Vlasov-Maxwell system. This coupled problem is usually solved by using Particle-in-Cell (PIC) approaches, in which the electron beam is represented by a reasonable number of macro-particles, subject to the dynamic equations and sources of the electromagnetic field. In addition, it is often possible to consider a stationary solution for this particle model: in this case the self consistent electric field \mathbf{E} is the solution of a Poisson equation, including the space-charge density as a source, while the self-consistent magnetic field \mathbf{B} can be calculated from the field equations for the magnetic vector potential, including the beam current density as a source. In particular we use a FE approach to perform the fully 3-D steady-state analysis. The resulting discretized problem consists of three set of equations: the first is an FE linear algebraic system regarding the spatial distribution of the unknown potential values originated by a nodal formulation of the Poisson equation for the electrical scalar potential, the second is an FE linear algebraic system regarding the spatial distribution of the unknown magnetic potential vector \mathbf{A} originated by an edge element discretization of a curl-curl

formulation for the magnetostatic problem; the other regards the trajectories computation of all the discrete particles used in the model. The solution of the whole system is carried out by following an iterative scheme which alternates the tracing of the electron trajectories and the computation of space charge distribution with the solution of the electrostatic and magnetostatic problems. These steps are repeated until convergence is reached, when the “distance” between two consecutive solutions is less than a user-specified end-iteration tolerance: in this situation a fixed point for the solution is approached and the current flow and electromagnetic field distribution can be assumed self-consistent.

Hereafter, we discuss briefly the aspects concerned with the solution of the unbounded magnetic problem, the solution of the other problems have been illustrated in [3]. A curl-curl formulation for the magnetic vector potential \mathbf{A} in an unbounded domain is used:

$$\nabla \times \nabla \times \mathbf{A} = \mu_0 \mathbf{J} \quad (3)$$

This equation is considered in a bounded domain Ω_M delimited by a fictitious boundary and enclosing all the magnetic sources (that is all particles current-carrying), which might be the same domain Ω of the electrical problem or smaller ($\Omega_M \subseteq \Omega$), since the electron beam usually does not sit in the whole electron gun geometry. In this way the solution of the unbounded problem is converted into the iterative solution of a sequence of bounded Dirichlet magnetic problems. In Ω_M the discretized vector potential is expressed inside each mesh element by using edge elements, in order to avoid spurious solutions. A congruent distribution of 3-D current density is a fundamental aspect for the convergence: the source current density is obtained directly after tracing the electron trajectories by following a suitable deposition and accumulation scheme. As regards the boundary conditions on the fictitious boundary, they are initially guessed and successively updated according to the magnetic vector potential and current density distributions obtained in the preceding iteration step. In particular the boundary values of magnetic potential field can be derived by exploiting its Laplacian behaviour in a region not containing sources by means of the Green's function. In fact, for a generic harmonic function H in the external homogeneous unbounded region one has:

$$\mathbf{H}(\mathbf{r}_F) = - \int_{\Gamma} \left[\frac{\partial \mathbf{H}(\mathbf{r})}{\partial \mathbf{n}} G(\mathbf{r}, \mathbf{r}_F) - \frac{\partial G(\mathbf{r}, \mathbf{r}_F)}{\partial \mathbf{n}} \mathbf{H}(\mathbf{r}) \right] ds \quad (4)$$

where: Γ is an arbitrary surface contained in Ω_M enclosing the whole electron beam; \mathbf{n} is the unit vector normal to Γ , oriented toward Ω_M ; \mathbf{r} and \mathbf{r}_F are point vectors relative to Γ and $\partial\Omega_M$, respectively and G is the 3-D Green's function for free space. Since in the FEM approximation, the surface curve Γ is conveniently selected as constituted by finite element sides, equation (5) can be rewritten for each boundary “unknown” \mathbf{A}_F in the form:

$$\mathbf{A}_F = \mathbf{R}_M \mathbf{A} \quad (5)$$

where \mathbf{R}_M is a rectangular matrix of purely geometrical coefficients. The solution of the discretized equations (3) and (5) are well suited to be solved iteratively, arbitrarily guessing at the beginning the magnetic vector potential on the boundary $\partial\Omega_M$.

III. AN EXAMPLE OF APPLICATION TEST

In order to evaluate the accuracy and the computational performance of the proposed procedure a test regarding the spreading of a relativistic beam is hereafter presented. In particular we consider the evolution of an axisymmetric relativistic laminar electron beam inside a cylindrical drift tube of radius 2m and length 10 m [4]. The self consistent solution of this problem has been computed by means of the last version of the COLLGUN code [2], including the above described computational facility for SCMF. A relativistic beam carrying a current of about 170 and having an energy of 212 kV ($\gamma\beta = 1$, $\beta=v/c$, $\gamma = 1/(1-\beta^2)^{1/2}$) was injected at one end of the drift tube. Three unstructured tetrahedral meshes have been employed for this problem, generated by imposing a constraint to the maximum element volume (less than $2^{1/2}h^3/12$, where h assumes the values 0.5m, 0.25m and 0.125m respectively): the rough mesh has about 16k elements, the fined one has about 1M elements. The beam having a radius of 1m was discretized according to mesh size by spacing the particles of about $h/5$ (about 300, 1300 and 5500 particles respectively for the three setup problems). In all the three tests performed 4 iterations were needed to reach the desired accuracy of 0.1 %. The obtained results show a very good agreement with the analytical ones available in literature [5]. Fig. 1 shows the axisymmetric relativistic beam expanding in the cylindrical drift tube (for the intermediate mesh) and the computed magnetic field surrounding the electrons.

Fig.1. The relativistic beam expanding in the drift tube and the compute magnetic field surrounding the electrons

Abstract— This paper deals with an inverse problem methodology devoted to the automated definition and design of electromagnetic structures. Then, using a statistical approach, a discussion on the existence and the uniqueness of the problem solution is led. The last part focuses on the behaviour of the solving algorithm for several case studies.

I. INTRODUCTION

Optimal electromagnetic systems design can nowadays be understood and formulated as an inverse problem, i.e., from characteristic values given by the specifications, obtaining the dimensions and material for a previously chosen structure.

Optimal design procedures are often based on analytical modelling considering an idealized structure. It gives satisfying results thanks various optimization methods [1]. Whatever the character stochastic [2] or deterministic [3] of the employed algorithm, the available solutions field is seriously limited by the preliminary choice of a given structure.

This paper presents an inverse problem methodology devoted to the automated definition and design of electromagnetic structures, in the context of quasi-static fields. The ability to reproduce a prescribed 2D magnetic field pattern with a distribution of out of plane conductors is analysed. Such a problem is ill-posed according to Hadamard's definition [4]. Indeed, existence and uniqueness of the obtained solution, which are not guaranteed, is taken into account in the paper.

II. PROBLEM STATEMENT

A. Assumptions

The aim of the proposed inverse problem methodology consists in finding a current distribution which generates a given magnetic field map in free space of μ_0 permeability. The current distribution will be defined by a set of infinite parallel to the z axis conductors and the field map will be described by tests points on xOy plane. Consequently the resulting system is invariant by translation along the z axis and the analytical calculation can be carried on the xOy plane.

B. Magnetostatic equations

To solve the inverse problem, the field at the test points will be analytically calculated thanks to Biot-Savart's law (1) [3]:

$$\vec{B}(M) = \frac{\mu_0}{4\pi} \int_D \frac{\vec{Idl} \wedge \vec{SM}}{\|SM\|^3} \quad (1)$$

So, considering a set of current elements oriented along z axis, the magnetic flux density $\vec{B}_W(M)$ produced by a single conductor located in W (in the xOy plane), and carrying a current I, at a given point M in the plane perpendicular to z axis is given by (2):

$$\vec{B}_W(M) = \frac{\mu_0 I}{2\pi} \begin{pmatrix} \frac{-(y_M - y_W)}{(x_M - x_W)^2 + (y_M - y_W)^2} \\ \frac{(x_M - x_W)}{(x_M - x_W)^2 + (y_M - y_W)^2} \end{pmatrix} \quad (2)$$

Consequently, the global problem to solve can be formulated as a coupled matrix system (3):

$$\begin{cases} \mathbf{A}_x \mathbf{I} = \mathbf{B}_x \\ \mathbf{A}_y \mathbf{I} = \mathbf{B}_y \end{cases} \quad (3)$$

With

$$\mathbf{A}_x = \left[\frac{-(y_{Mi} - y_{Wj})}{(x_{Mi} - x_{Wj})^2 + (y_{Mi} - y_{Wj})^2} \right]_{[i, j] \in [1, n_{meas}] \times [1, n_{fils}]}$$

$$\mathbf{A}_y = \left[\frac{(x_{Mi} - x_{Wj})}{(x_{Mi} - x_{Wj})^2 + (y_{Mi} - y_{Wj})^2} \right]_{[i, j] \in [1, n_{meas}] \times [1, n_{fils}]}$$

Components of \mathbf{I} vector corresponds to the various current elements.

\mathbf{B}_x and \mathbf{B}_y are the vectors of the expected magnetic flux density values on each test point, projected on x and y axes.

The inverse electromagnetic problem can be linear or not depending on the investigated quantities (conductor position, and current value). So the problem is linear only when the conductor position is fixed.

III. DISCUSSION ON EXISTENCE AND UNIQUENESS OF THE SOLUTION

A. Existence

The linear and non-linear problems are solved by a least-square optimization method. Existence and uniqueness of solution are analysed by statistic approach on test cases depending on number of test points and conductors. Concerning the existence of solution we can observe that:

- In a linear case (position fixed), a configuration in which the test points number is twice conductors number leads to a well-posed problem according to Hadamard's definition.

- In the non-linear case (position and current value are not fixed), the solutions domain is significantly increased (as illustrated in Fig.1).

A more precise sensitive analysis on bounded values of investigated quantities will be described in the final paper.

B. Uniqueness

The magnetostatic inverse problem methodology can be applied on underdetermined or overdetermined systems. In the case of underdetermined systems, it is interesting to determine the initial conditions (i.e. number and bounded values of conductors and test points) which guarantee a set of available solutions. This set must be wide enough to allow an optimization procedure. In this context, from a given field map generated by a known conductors distribution, the convergence of the solving inverse problem is studied. It can be observed for example on Fig.2 that when the number of conductors is sufficient, this method does not only converge on the initial known conductors distribution.

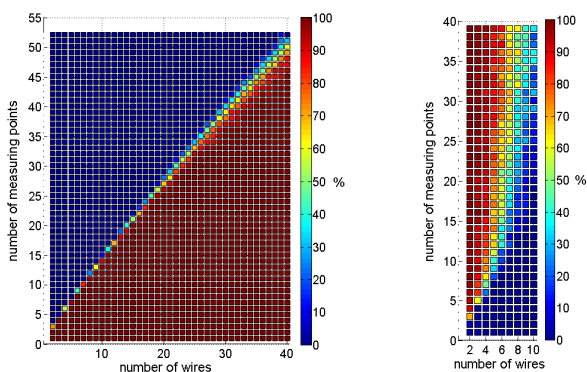

Fig 1. Convergence rate on a solution (100 resolutions per case).
Random B field value on test points.

3 degrees of freedom per conductor (coordinates and current value)
Fig. 2. Convergence rate on the initial solution (100 resolutions per case).

IV. CASE STUDIES

The final paper will present several cases in order to study the behaviour of the resolution algorithm and the resulting solution for a strongly constrained problem (conductors excluded from domain of test points, and/or bounded current value). As example, the Fig.3 shows a linear case with a very high number of conductors. The comparison between the initial magnetic field test point and the magnetic field resulting from inverse problem solving gives satisfying results with a difference lower than 0.7% (cf. Fig.4).

Let us underline that from Fig.3 it is possible to easily characterize patterns in the current distribution. Those patterns could be used in a postprocessing inverse problem solving for the design of a magnetic structure.

Fig. 3. Example of current values distribution obtained after resolution.
12 test points, 840 current values.

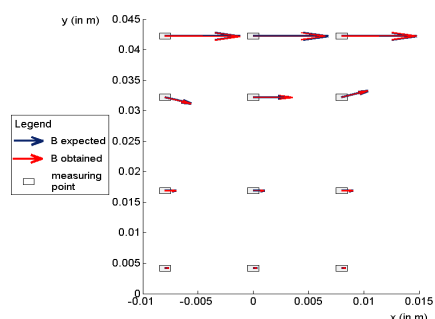

Fig. 4. Comparison of B values on the test points for the same example.

V. CONCLUSION

The authors have presented an inverse problem methodology devoted to the optimal design of electromagnetic structures. This methodology is based on an analytical description of the static fields thanks to Biot and Savart equation. Considering a generic multi-conductor distribution makes it possible to discuss existence and uniqueness of the solution by using a statistical approach. This analysis led to a rational definition of the required conductor number considering the number of test points. Case studies have been done to explore the limits of the solving method. The results presented in this last part open a new field of investigation in the magnetostatic inverse problem methodology.

Abstract — The dual-channel switched reluctance machine (SRM) is driven by two independent sets of power electronic circuits with dual control channels, so a fault tolerated operation mode can be used in this system for high reliability. This paper presents a magnetic analysis of a 12/8 dual channel SRM in order to compute the nonlinear magnetization curves including mutual coupling. The proposed analysis implements the magneto-motive force (mmf) sources and consists of the equivalent magnetic circuit, the analytical saturable airgap permeances and nonlinear yoke permeances. Then the performance of this dual channel SRM including self flux and mutual flux have been determined using the two-dimensional finite-element (2D-FE) method under different rotor positions (fully aligned to fully unaligned) for varying exciting current conditions. The effectiveness of this proposed magnetic circuit analysis is verified by comparing with 2D-FE method in terms of the analytical accuracy.

I. INTRODUCTION

With the development of the power electric and control technology, the switched reluctance machine (SRM) is becoming more and more attractive for many applications. However, it is rather difficult to design the machine and develop the drive performance because of the magnetic nonlinearity of the motor [1]-[2]. The 12/8 novel dual-channel SRM is a dual three phase motor and its configuration is shown in Fig.1. Dual channel SRM control system can work as dual channel mode or single channel mode. When a power circuit is failure, the system is transferred into single channel mode which is called fault-tolerant operation.

Fig.1 Structure of dual-channel SRM

Fig.2 Flux paths ($\theta=0^\circ$)

This paper presents a magnetic circuit model for calculating the self and mutual flux linkage of a 12/8 dual channel SRM including saturation effects. The model determines the flux linkage of one channel in each phase for any geometry, phase count, rotor position, and combination of phase current. The model presented in this paper does not require time consuming data entry and meshing. And the results presented can be obtained in a matter of minutes. Then the results of this modeling method are verified against the Ansoft/Maxwell 2D finite element solver.

II. THE MAGNETIC CIRCUIT MODEL

As the channel one of A-phase is only excited, the equivalent magnetic circuit and flux path diagram are shown in Fig.2. The rotor angular position θ is defined as $\theta = 0^\circ$ at the aligned position and $\theta = 22.5^\circ$ at the unaligned position.

III. AIRGAP PERMEANCES

There are three different permeances which are included in the airgap model: overlap; fringing; and nonoverlapping.

A. Overlap and fringing permeance

Fig.3 shows the case of overlap and fringing flux path in airgap 1. In this paper, the stator and rotor pole arcs are assumed $\pi/12$ respectively.

Fig.3 Partially overlapping poles

Fig.4 Nonoverlapping poles

The overlap and fringing permeance P_a of airgap 1 can be divided into three parts of permeances $P_1 \sim P_3$.

$$P_a = P_1 + P_2 + P_3 \quad (1)$$

$$= \frac{\mu_0 h (\pi/12 - |\theta|) (r_{sp} + r_{rp})}{l_g} + \frac{2\mu_0 h}{\pi} \ln \left(\frac{l_g^2 + 2l_g r_{rp} |\theta| + 2r_{rp}^2 |\theta|^2}{l_g^2} \right)$$

B. Nonoverlapping permeance

Fig.4 shows the situation being considered and outlines the appropriate flux tubes to approximate the path.

The nonoverlapping permeance P_a of airgap can be divided into three parts of permeances $P_{11} \sim P_{22}$.

$$P_a = P_{11} + P_{12} + P_{21} + P_{22} = 2P_{11} + 2P_{21} \quad (2)$$

$$= \frac{2\mu_0 h}{\pi} \left[\ln \frac{l_g + l_g r_{rp} \pi/6 + r_{rp}^2 \pi^2/72}{l_g + 2l_g r_{rp} (|\theta| - \pi/12) + 2r_{rp}^2 (|\theta| - \pi/12)^2} + \ln \frac{l_g + l_g r_{rp} \pi/6 + r_{rp}^2 \pi^2/72}{l_g + 2l_g r_{rp} (\pi/6 - |\theta|) + 2r_{rp}^2 (\pi/6 - |\theta|)^2} \right]$$

IV. YOKE PERMEANCES

Fig.5 shows the flux path in the stator yoke, the permeance of stator yoke between adjacent poles

$$P_{sy} = \frac{u_r A}{L_{sy}} = \frac{12u_r L_{syd} h}{(r_s + r_{sy})\pi} \quad (3)$$

where u_r is steel permeability.

Fig.5 Flux paths at stator yoke

Fig.6 Flux paths at rotor yoke

Fig.6 shows the flux path in the rotor yoke, similarly the permeance of rotor yoke between adjacent poles can be derived as

$$P_{ry} = \frac{8u_r L_{ryd} h}{(r_r + r_{ry})\pi} \quad (4)$$

V. NONLINEAR SOLUTION

To obtain the static characteristics of the SRM, the rotor position should be changed in small decrements to cover half an inductance cycle. With a change in rotor position, the flux pattern in the poles and airgap changes. Once all of the various airgap permeances have been determined for a give rotor position, they must be incorporated into the model. The complete set of closed loops equations is a system which can be represented in matrix form

$$[R][\Phi] = [F] \quad (5)$$

Where Φ is the vector of branch fluxes, F is the vector of magneto motive forces and R is matrix of magneto resistance. Gauss-Siedel method with an accelerating factor for faster convergence has been used to solve the nonlinear problem. Once the fluxes have been calculated form (5), the flux linkage can be calculated.

V. FINITE ELEMENT ANALYSIS

In this section, a finite element analysis using Ansoft/Maxwell 2D is performed to obtain the magnetic characteristics of the machine, considering the saturation and mutual coupling effects.

1) *Flux lines*: One and two channels of A -phase are excited in the aligned and unaligned positions. Flux contours at these two positions are shown in Fig.7, respectively.

Fig.7 Magnetic field distribution of dual-channel SRM: (a) one channel is excited; (b) two channels are excited.

2) *Self flux linkage and inductance*: The self flux linkage and inductance in channel one of A -phase as a function of rotor position and excitation current as obtained by finite

element method analysis are shown in Fig.8 along with the magnetic circuit analysis results.

Fig.8 Comparison of self flux linkage and inductance computed by the analytical and FE methods: (a) flux linkage, (b) inductance

3) *Mutual flux linkage*: In Fig.9-10, the mutual magnetic flux linkage obtained by FE method is compared with the results of the analytical model.

Fig.9 Mutual flux linkage in (a) B1 and (b) B2 when A1 is excited

Fig.10 Mutual flux linkage in (a) C1 and (b) C2 when A1 is excited

VI. CONCLUSION

This paper has described the electromagnetic characteristics including mutual coupling and saturation for a dual-channel 12/8 switched reluctance machine (SRM) from its magnetic circuit model analysis and compares the two-dimensional finite element method (2D-FE) analysis results by using Ansoft/Maxwell. The magnetic circuit model presented airgap permeance including the stator and rotor poles overlap and nonoverlapping and the nonlinear yoke permeance. The magnetic characteristics results show that the self flux linkage and mutual flux linkage in the two channels of the same phase are not the same. The magnitude of mutual coupling in neighboring channels is almost identical but the direction is not the same. The model approach presented here is also suitable for conventional SRM geometries that require consideration of mutual coupling effects. Additional numerical algorithms can translate model flux solutions to motor torque predictions.

Abstract— Magnetic field in an active magnetic bearing has been analyzed with Finite Element Method (FEM). Influence of the magnetization characteristics on the field distribution and values of the device static parameters has been studied. The investigations have been done for the physical model of the magnetic bearing, as well. Selected parameters of the device have also been measured and compared with the calculation results.

I. INTRODUCTION

Rotary magnetic bearing, like other electric motors and generators, is a composite of interacting subsystems: stators and rotors [1], [3]. Each stator is assembled from horse-shoe electromagnets, which form a multipole system (Fig.1). So far, rotor and stator magnetic cores were stacked from silicon-steel sheets. We simulated parameters of the bearing with magnetic core made of amorphous magnetic alloy, as well [1], [2].

Magnetic field, arisen in the stator, is passing to the rotor and generates forces supporting rotating shaft of a drive without any mechanical suspension [3]. They are produced by the bias and control currents which supply the stator coils (Fig.1) in response to the signals from sensors [4]. Disturbing of the balance in the control currents brings that the rotor is attracted (along a radius) towards the stator. It indicatives of the stator and rotor axes are out of alignment [5]. The magnetic forces depend not only on the stator currents, but the magnetic material characteristics, as well.

II. GEOMETRY OF THE BEARING AND THE FIELD PROBLEM

The eight-pole magnetic bearing, pictured in Fig.1, has been considered. The laminated stator and rotor stacks are 10 and 20 mm in thickness, respectively. We supposed thin (0.35mm) sheets, which are made from silicon steel M55 in our prototype. Small air gap between the rotor lamination and the set of stator teeth is amount of 0.2 mm.

The considered bearing has basic and control windings. They are situated so that four, horse-shoe electromagnets are created. The $N_1=40$ turn basic coil and $N_2=100$ turn control one are situated on each pole of the magnets. The I_b and I_s currents are forced in the coils, respectively. Both, bias and control windings are located separately, and generate the flux crossing two stator poles.

The simplified shapes of the coils in Fig.1 slightly differ from the physical object ones [6]. It is due to limiting the number of elements in the field simulation with FEM [7]. One should add that more exact approximation does not change the resulting field significantly.

Fig. 1. Magnetic bearing outline with stator cutting out

Fig. 2. Permeability curves $\mu_r(H)$ of silicon steel and amorphous alloy

Including, in the field analyses, the nonlinearity of the magnetization curves (Fig.2), $T-\Omega$ method has been used for the solutions of the boundary problems [4].

$$\nabla^2 \vec{T} = j\omega\mu\gamma \vec{H}_s \quad (1)$$

$$\nabla \cdot (\mu(H)\nabla\Omega) = 0 \quad (2)$$

The electric vector potential T is used, in Eq. (1) for regions contain currents. The field intensity H_s , excited by currents is governed by Biot-Savart law. In other regions, e.g. occupied by the magnetic material, the equation (2) governs the field distribution. After solution of the nonlinear equations above, magnetic flux density distribution has been calculated for the conducting and other regions, respectively:

$$\vec{B} = \mu_r(H) \mu_0 [\vec{H}_s - \nabla\Omega] \quad (3)$$

$$\vec{B} = -\mu_r(H) \mu_0 \nabla\Omega \quad (4)$$

III. COMPUTATIONAL RESULTS OF THE FIELD ANALYSIS

Fig. 3. Flux density distribution under the bias current excitation of $I_b=0.8A$

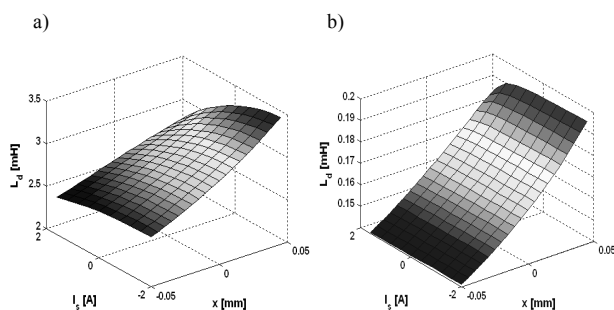

Fig. 4. Dynamic inductances vs. control current I_s , and shaft position x for:
a) M55 steel b) amorphous material

The flux distribution in the prototype of the bearing under bias excitation is shown in Fig. 3.. In this case, the shaft was centrally positioned. Although the prototype magnetic circuit is made of M55 steel [8], we also considered other modern materials. We see from Fig. 2 that at $H < 200$ A/m the permeability curves are strongly nonlinear, for both considered materials. Due to brevity we did not present the distributions of the magnetic flux densities for other materials.

TABLE I. STATIC INDUCTANCE OF THE WINDING FOR TWO MATERIALS OF THE CORE

Material	L_s [mH]
Amorphous	16,4
M55 calculations	3,72
M55 measurements	3,7

The field distribution is used to estimate the electromagnetic force, which acts on the moving bearing shaft, as well as to determine the dynamic L_d (Fig.4) and static L_s (Tab.1) inductances of the stator winding.

In the calculation model the control current has been superposed on the bias excitation. Its magnitude varied from up to 2 A, and the shaft center was moved from the middle position by $x=0.05$ mm. For calculation of the static inductance, the bias current $I_b=0.8A$ has been assumed.

We presented the force values for the shaft extracted from the central position up to $|x|=0.05$ mm. The control current magnitude altered up to 2 A, (Fig. 5).

Fig. 5. Magnetic force vs. the shaft center locus

The variation of the magnetic forces is slightly nonlinear respect to the rotor position x (Fig. 5). However, the force generated by the interaction between rotor and stator, strongly depends on the rotor position and sense of the control current, which is opposite to the bias current direction. Thus, the force value is greater when the bias current I_b is lower (Fig. 5). Differences between calculated and measured parameters are attributed to the simplifications of the field modeling and the measurement errors, as well.

IV. CONCLUSIONS

Bearings with the core laminations which are made up of different materials have been considered in 3D field analyses. Small air-gap between the stator and rotor as well as slight displacement of the shaft was included. Additional benefits of the computer simulations, is that different coils and their dimensions can be tried.

The integral parameters of the magnetic field were calculated and compared with the measured ones. The calculated errors occur also due to eddy currents and anisotropy neglecting. Estimation with their including is very difficult. However, they are not as profitable as expected. Despite the simplifications in the mathematical modeling, the measured results confirm acceptability of the computer simulations.

Abstract—This paper applies optimization techniques to design electromagnetically feasible optimal micromotors, considering torque characteristics and electrical breakdown. Furthermore, it tries to bring the non-linear interior point method to the optimization of electromagnetic devices.

I. INTRODUCTION

Microtechnology and nanotechnology have become new important fields of research with wide range of applications, including medicine and electronics. In very small scales, simple geometries are highly desirable due to fabrication constraints. Under this conditions, electrostatic motors are truly competitive.

Unfortunately, the torque ripple of an electrostatic micromotor is typically large [1]. Another important issue about micromotors is the electrical breakdown due to high electric field magnitudes. Much effort has been devoted to improve feasibility of micromotors, since the very beginning [2], which is closely related to materials science and development of new technologies. Some micromotors have also been optimized, specially with the objective of minimizing the torque ripple [1]. This paper investigates the optimization of electromagnetically feasible micromotors, considering torque and electrical breakdown.

The optimization algorithm in focus at this paper is the interior point method in its non-linear version. Despite it has been largely applied to many real-world problems [3], [4], there are few works on optimization of electromagnetic devices. The most constraining feature seems to be the need of second order derivatives from the objective and constraint functions. This paper proposes to take this information from iterative techniques.

II. ELECTROSTATIC MICROMOTOR

The electrostatic micromotor is formed by electric conducting rotor and stator, as shown in its geometry in Fig. 1. The rotor is a contiguous piece tied to ground. The stator teeth are mutually electrically isolated, so that each one can be tied to arbitrary electric potentials. The electrostatic micromotor is typically build on a dielectric board and surrounded by air.

In this work, the electrostatic micromotor is analyzed with a finite element method (FEM) derived from a bi-dimensional

This work was supported by FAPEMIG under grants 13180 and 13348, Brazil.

Fig. 1. Geometry of the micromotor and its parameters.

electrostatic formulation. The rotor and stator are modeled as perfect electric conductors, so that only their boundaries are considered. The FEM is then applied to the meshed air region between rotor and stator, where the electric potential is known in some nodes, from where the torque is calculated using Maxwell stress tensor.

The torque is calculated for each rotor position. In order to reduce the computational cost, it is considered the electrical symmetry of the problem, leaving natural boundary conditions at split interfaces. For instance, only a quarter of a motor with 8 rotor teeth and 12 stator teeth, as shown in Fig. 1, can answer for the whole motor. Furthermore, a uniform segmentation at the middle gap region is guaranteed by the mesh generator, so that the mesh can be split into two and doubled nodes are reconnected by boundary conditions. Hence, every rotor position can be simulated using the same mesh.

III. INTERIOR POINT METHOD

The primal-dual interior point method used in this work [3], [4], [5] considers optimization problems in the form

$$\begin{aligned} \min_x \quad & f(x) \\ \text{s.t.} \quad & g(x) \leq 0 \\ & Ax = b \end{aligned} \quad (1)$$

where $x \in \mathbb{R}^n$ is the vector of parameters, $f(x) : \mathbb{R}^n \mapsto \mathbb{R}$ is a twice continuously differentiable objective function, $g(x) : \mathbb{R}^n \mapsto \mathbb{R}^m$ is the vectorial twice continuously differentiable constraint function, $A \in \mathbb{R}^{p \times n}$ is a full row rank equality constraint matrix, and $b \in \mathbb{R}^p$ is the equality constraint vector. The interior point method then approximate, in the neighborhood of point x_k at iteration k , the non-linear objective and constraint functions by quadratic functions in the form

$$\tilde{f}(x) = f(x_k) + \nabla^T f(x_k)x + \frac{1}{2}x^T \mathcal{H}f(x_k)x \quad (2)$$

where $\nabla f(x_k) \in \mathbb{R}^n$ denotes the gradient vector of f at x_k , and $\mathcal{H}f(x_k) \in \mathbb{R}^{n \times n}$ denotes the Hessian matrix of f at x_k . To avoid calculating second order derivatives of a numerical evaluated problem, the Hessian of objective and constraint functions are iteratively approximated by the Broyden-Fletcher-Goldfarb-Shanno (BFGS) method.

The primal-dual search direction d_k is given by

$$d_k = -H_k^{-1}r_k \quad (3)$$

where

$$r_k = \begin{bmatrix} \nabla f(x_k) + \nabla g(x_k)\lambda_k + A^T \nu_k \\ -\text{diag}(\lambda_k)g(x_k) - 1/t_k \\ Ax_k - b \end{bmatrix} \quad (4)$$

is the residual, $\eta_k = -\lambda_k^T g(x_k)$ is the dual gap, $t_k = (\mu m)/\eta_k$ is the barrier parameter, μ is an algorithm parameter (typically 10), λ_k and ν_k are Lagrange multipliers, and

$$H_k = \begin{bmatrix} L_k & \nabla g(x_k) & A^T \\ -\text{diag}(\lambda_k)\nabla^T g(x_k) & -\text{diag}(g(x_k)) & 0 \\ A & 0 & 0 \end{bmatrix} \quad (5)$$

where

$$L_k = \mathcal{H}f(x_k) + \sum_{j=1}^m \lambda_{kj} \mathcal{H}g_j(x_k) \quad (6)$$

A backtracking line search algorithm is then applied to find a step $\alpha_k \in (0, 1)$ towards d_k such that $\lambda > 0$ and $g(x) < 0$. The iterative update is then given by

$$\begin{bmatrix} x_{k+1} \\ \lambda_{k+1} \\ \nu_{k+1} \end{bmatrix} = \begin{bmatrix} x_k \\ \lambda_k \\ \nu_k \end{bmatrix} + \alpha_k d_k \quad (7)$$

IV. OPTIMIZATION

The optimization problem is to minimize the torque ripple constrained to a maximum electric field to prevent breakdown. It can be written as

$$\begin{aligned} \min_x & \frac{\max_{\theta}(\tau(\theta, x)) - \min_{\theta}(\tau(\theta, x))}{\text{mean}_{\theta}(\tau(\theta, x))} \\ \text{s.t.} & \max_{\theta}(E_{\max}(\theta, x)) \leq 75\text{V}/\mu\text{m} \\ & x_{\min} \leq x \leq x_{\max} \end{aligned} \quad (8)$$

where $x \in \mathbb{R}^n$ is the vector of variables, θ is the rotor position, $\tau(\theta, x)$ is the torque, $E_{\max}(\theta, x)$ is maximum electric field in the air. The stator teeth potentials switch between 0 and 100V.

Two parameters of the electrostatic micromotor (see Fig. 1) are variables of the optimization problem: the rotor w_r and stator w_s teeth width. The remaining parameters are set

constant: gap radius $r_{gap} = 50.75\mu\text{m}$, rotor to stator gap $gap = 1.5\mu\text{m}$, stator teeth height $h_s = 40\mu\text{m}$, rotor teeth height $h_r = 20\mu\text{m}$, and rounding radius $r_c = 1\mu\text{m}$. As a preliminary result, the optimal parameters for problem (8), with constraints not yet considered, are shown in Table I. The respective optimal torque is shown in Fig. 2, with optimal ripple of about 20%.

TABLE I
LOWER BOUND, UPPER BOUND AND OPTIMAL PARAMETERS.

parameter	min	max	optimal
w_r ($^{\circ}$)	4.50	40.50	21.23
w_s ($^{\circ}$)	3.00	27.00	19.79

Fig. 2. Optimal torque.

Results considering more parameters of the electrostatic micromotor as variables, as well as more optimal solutions of variations of problem (8), will be shown in the final paper. Further details about the primal-dual interior point method used in this work will also be given.

Abstract — This paper presents a modified version of the hybrid FEM-DBCI method to solve static and quasi-static electromagnetic field problems in open boundary domains. The modification consists of overlapping the fictitious truncation boundary with the integration one, as in the FEM-BEM method. The global algebraic system obtained is solved iteratively by means of the GMRES solver, applied virtually to a reduced system in which the unknowns are those relative to the potential on the truncation boundary only. Some validation examples are provided.

Index Terms— Finite element method, boundary element method, integral equations, electrostatic field.

I. INTRODUCTION

The well-known hybrid FEM/BEM (Finite Element Method - Boundary Element Method) method [1], [2] is probably the most widely used numerical method to solve static and quasi-static electromagnetic field problems in open-boundary domains. Recently the authors have devised another hybrid method, called FEM-DBCI (Dirichlet Boundary Condition Iteration), to solve electrostatic [3], [4], time-harmonic skin effect [5], [6] and eddy current [7] problems.

Both FEM-BEM and FEM-DBCI couple a differential equation, which governs the interior problem, with an integral one which makes use of the free-space Green function and expresses the unknown boundary condition on the fictitious truncation boundary.

The differences between the two methods are the following.

In FEM-BEM the integration surface coincides with the truncation one, whereas in FEM-DBCI the integration surface is another surface strictly enclosed by the truncation boundary; note that this characteristic allows us to avoid singularities in the integral equation and to obtain it in explicit form with respect to the potential values in the nodes of the truncation boundary. Nevertheless FEM-BEM requires less mesh than FEM-DBCI (typically one or two layers of elements are inserted between the integration surface and the truncation one);

In FEM-BEM the normal derivative of the potential on the truncation boundary is introduced and treated as an independent unknown, so that the interior problem is very often a pure Neumann one. In FEM-DBCI the normal derivative is not explicitly defined, but a numerical derivative is performed in the integral equation, so that the interior problem is a Dirichlet one;

Both the resulting global algebraic systems are partly sparse and partly dense. The FEM-DBCI system can be efficiently solved in an iterative way: assuming an initial guess for the Dirichlet condition on the truncation boundary, the sparse FEM equation is solved by means of the

conjugate gradient (CG) solver; the explicit dense equation is then used to improve the Dirichlet condition; the procedure is iterated until convergence is reached; this solution strategy is efficient because the CG is applied to the sparse equation only, and the dense equation is used only a few times. An improvement on this solving method is obtained by means of the Generalized Minimal Residual (GMRES) method, as described in [4]. Recently the authors have shown that a similar GMRES-based solving strategy can also be used for the solution of FEM-BEM algebraic systems [8].

A comparison was made in [9] between the two methods, concluding that FEM-BEM is more accurate than FEM-DBCI, but requires more computing time: FEM-DBCI appears more appropriate for applications which require a shorter computing time, for example in the stochastic optimization of electrical devices, where some thousands of analyses must be performed to obtain satisfactory results. Conversely, FEM-BEM is more appropriate in cases in which a high level of precision is required in a single computation.

This paper presents a modified version of the FEM-DBCI method in order to alleviate its major drawback, that is, the insertion of some meshes between the integration and truncation surfaces. The paper is organized as follows: in Sect. II the modified FEM-DBCI formulation is described for a simple- electrostatic problem; in Sect. III the iterative solution of the resulting global system is outlined; in Sect. IV a numerical example is given which validates the method.

II. THE MODIFIED FEM-DBCI FOR ELECTROSTATICS

Consider a system of voltaged conductors, dielectric bodies and charges embedded in an unbounded vacuum. A fictitious truncation boundary Γ_F is introduced, enclosing all the conductors and dielectric bodies, but possibly leaving out some (lumped or distributed) charges. In the bounded domain D thus obtained, the Poisson equation holds:

$$-\epsilon_0 \nabla \cdot (\epsilon_r \nabla v) = \rho \quad (1)$$

where ϵ_0 is the vacuum electric permittivity, ϵ_r the relative permittivity and ρ the charge density. Equation (1) is subject to Dirichlet conditions on the conductors, whereas an unknown Dirichlet condition is assumed on Γ_F .

Discretizing the domain D by means of simplex finite elements, (1) is rewritten in matrix form as:

$$\mathbf{A}\mathbf{v} + \mathbf{A}_F \mathbf{v}_F = \mathbf{b}_0 \quad (2)$$

where: \mathbf{v} and \mathbf{v}_F are the vectors of the unknown values of the potential v in the nodes inside the domain and on the boundary Γ_F , respectively, \mathbf{A} and \mathbf{A}_F are sparse matrices of geometrical coefficients, \mathbf{b}_0 is due to the conductor potentials and internal (distributed) charges.

The integral equation at node P_i on Γ_F is:

$$c_i v(P_i) + \iint_{\Gamma_F} v(P) \frac{\partial G(P, P_i)}{\partial n} dS =$$

$$= v_{\text{ext}}(P_i) + \iint_{\Gamma_F} \epsilon_r \frac{\partial v}{\partial n} G(P, P_i) dS \quad (3)$$

where $G=1/4\pi r$ is the free-space Green function, v_{ext} is due to the external (lumped or distributed) charges, and the normal derivative is evaluated internally to D . In numerical form, equation (3) reads

$$c_i v_i + \sum_k \sum_n v_n \iint_{T_k} \alpha_n(P) \frac{\partial G(P, P_i)}{\partial n} dS =$$

$$= v_{\text{ext}}(P_i) + \sum_k \epsilon_k \sum_n v_n \iint_{T_k} \frac{\partial \alpha_n(P)}{\partial n} G(P, P_i) dS \quad (4)$$

where T_k is the triangular face of tetrahedron E_k lying on Γ_F ; index n refers to the nodes of the tetrahedron E_k , α_n are the nodal shape functions, ϵ_k is the relative permittivity of E_k , c_i is the normalized solid angle of the domain at P_i . In matrix form we obtain:

$$\mathbf{H} \mathbf{v}_F = \mathbf{G} \mathbf{v} + \mathbf{v}_{\text{ext}} \quad (5)$$

where \mathbf{H} and \mathbf{G} are dense matrices of geometrical coefficients. Note that \mathbf{H} is square by construction, whereas \mathbf{G} may be rectangular. Note also that null columns appear in \mathbf{G} for the nodes of the tetrahedra not lying on Γ_F .

III. SOLUTION OF THE GLOBAL SYSTEM

In order to solve the global system (2)-(5):

$$\begin{bmatrix} \mathbf{A} & \mathbf{A}_F \\ -\mathbf{G} & \mathbf{H} \end{bmatrix} \begin{bmatrix} \mathbf{v} \\ \mathbf{v}_F \end{bmatrix} = \begin{bmatrix} \mathbf{b}_0 \\ \mathbf{v}_{\text{ext}} \end{bmatrix} \quad (6)$$

a simple approach is the direct use of an iterative CG-like solver for non-symmetric systems of linear algebraic equations. This approach suffers from the fact that in each step of the solver the matrix-by-vector multiplication is very costly, due to the presence of dense parts in the global matrix, and the number of steps is high (typically several hundreds).

Now consider the reduced system:

$$\mathbf{M} \mathbf{v}_F = \mathbf{k} \quad (7)$$

where formally:

$$\mathbf{M} = \mathbf{H} + \mathbf{G} \mathbf{A}^{-1} \mathbf{A}_F \quad \mathbf{k} = \mathbf{G} \mathbf{A}^{-1} \mathbf{b}_0 + \mathbf{v}_{\text{ext}} \quad (8)$$

The matrix \mathbf{M} and vector \mathbf{k} are not directly available. However, the vector \mathbf{k} is simply built as follows: 1) assume a zero initial guess $\mathbf{v}_F=0$; 2) solve (2) by means of the CG solver to obtain \mathbf{v} ; 3) compute $\mathbf{k}=\mathbf{G}\mathbf{v}+\mathbf{v}_{\text{ext}}$. Similarly, matrix \mathbf{M} can be used to perform matrix-vector multiplications $\mathbf{M}\mathbf{v}_F$, as follows: 1) given the vector \mathbf{v}_F ; 2) solve (2) with $\mathbf{b}_0=0$ by means of the CG solver to obtain \mathbf{v} ; 3) compute $\mathbf{M}\mathbf{v}_F=\mathbf{H}\mathbf{v}_F-\mathbf{G}\mathbf{v}$.

Then several non-stationary CG-like solvers for non-symmetric matrices, such as BiCG (BiConjugate Gradient), QMR (Quasi Minimal Residual), CGS (Conjugate Gradient Squared), BiCGstab (BiCG stabilized) and GMRES could be used to solve (7). However, GMRES should be preferred because it performs a true minimization of the residual and thus minimizes the number of matrix-vector multiplications.

IV. A VALIDATION EXAMPLE

In order to validate the modified FEM-DBCI method a

simple two-wire transmission line is considered. The line is constituted by two parallel conducting circular cylinders of radius R whose centers are separated by a distance of $D=2.4R$, voltaged with opposite potentials $V_0/2$ and $-V_0/2$. This problem exhibits a well-known analytical solution v_a [10]. A FEM-DBCI solution is pursued in this paper by selecting the truncation boundary as constituted by two circumferences of radius $1.1R$ centered at the cylinder centers. For symmetry reasons the analysis is restricted to the first quadrant only. The domain is filled with 2 layers of elements (a total of 360 triangles). An accuracy indicator is defined as:

$$\zeta = 100 \sqrt{\iint_D (v - v_a)^2 dx dy} / \iint_D v_a^2 dx dy \quad (9)$$

where D is the domain of the FEM analysis. The end-iteration tolerances are set to 10^{-2} per cent for the GMRES and 10^{-4} per cent for the CG. Three analyses are performed using triangular elements of orders 1, 2 and 3. Curved elements are used at the conductor surface for orders 2 and 3. The accuracy indicators are $5.05 \cdot 10^{-1}$, $3.17 \cdot 10^{-1}$ and $2.85 \cdot 10^{-1}$, for the three analyses, respectively.

More details will be provided in the full paper.

Abstract— A method to simulate the surge corona of power transmission line is introduced. The charge simulation method (CSM) and the finite element method (FEM) are applied to calculate the electric field, while a time-dependent upwind difference (TDUD) algorithm is applied to calculate the migration of space charges. The Q-V (charge-voltage) curves of impulses applying on bundle conductors in a cage having a square cross-sectional shape are calculated. The simulation results are supported by the published experiments.

I. INTRODUCTION

Corona on overhead transmission lines is one of the key factors for the propagation characteristics of overvoltage occurring in electric power systems. When the applied voltage exceeds a certain value, corona discharge occurs and space charges are formed in the vicinity of transmission lines. Then, the space charges migrate with the electric field force and in turn affect the electric field. In the case of surge overvoltage, the corona discharge process appears as a dynamic capacitance of the transmission lines and is usually investigated by the Q-V (charge-voltage) diagrams which indicate the derivative of the charge towards the voltage.

Several computer simulation models have been proposed to reproduce the dynamic process of surge corona. Most of the models are constructed in 1-D. Menegozzi and Feldman [1] simulated a single ionizing burst in the wire-cylinder geometry. Sekar [2] used the idea of charge shells to simulate the pulsed corona discharges in the wire-cylinder geometry. Jesus [3] introduced dynamic radius of the ionization layer to explain the delay effect. In sum, the applicability of 1-D models is restricted in coaxial geometries. 2-D models are needed to deal with the practical complex geometries.

Rajanikanth [4] and Buccella [5] reported 2-D methods with uniform meshing. However, the uniform meshing leads to a huge amount of calculation with large scale geometry as line-to-ground geometry. Zhang and Adamiak [6] presented a new numerical algorithm for the simulation of the dynamic corona discharge in the 2-D point-to-plane geometry. The space charge distribution was considered as a steady state in each time step. However, the steady state is hardly reached in the transient process of surge corona.

In this work, the process of surge corona of transmission line is simulated in 2-D. The charge simulation method (CSM) and the finite element method (FEM) are applied to calculate the electric field, while a time-dependent upwind difference (TDUD) algorithm is applied to calculate the migration of space charges. The space charge distribution is calculated in a dynamic process rather than a steady state.

II. CALCULATION METHOD

A. Overview of the method

The computational process of surge corona is separated in several parts. Firstly, the corona onset field E_c is calculated with Peek's formula. Secondly, the time lag t_0 of the surge corona is calculated with the critical volume theory proposed in [7]. Then, corona inception time t_c is decided with E_c and t_0 for the given surge waveform. Thirdly, mesh of triangular elements is generated. After that, at each time step, the Laplacian field is solved with CSM; the space charge density is calculated with TDUD; the field caused by space charges is calculated with FEM; the space charge density boundary condition in the vicinity of conductor surfaces is calculated as Clade [8] suggested. These processes are executed iteratively until the last time step has been solved.

B. The governing equations

The equations that constitute the mathematical description of the surge corona are as follows. Overvoltage of positive polar is presented as example here.

Poisson's equation:

$$\nabla^2 \Phi(t) = -\rho^+(t)/\epsilon_0 \quad (1)$$

The positive and negative current density vectors:

$$\mathbf{J}(t) = -k^+ \cdot \rho^+(t) \cdot \nabla \Phi(t) \quad (2)$$

The current continuity condition:

$$\frac{\partial \rho^+(t)}{\partial t} = -\nabla \cdot \mathbf{J}(t) \quad (3)$$

where, $\Phi(t)$ is the total electric potential (V); $\rho^+(t)$ is the positive charge density (C/m^2); ϵ_0 is the permittivity of air; k^+ is the positive ion motility (m^2/Vs); $\mathbf{J}(t)$ is the ion current density vector (A/m^2).

CSM and FEM are applied to solve the Laplacian field and the field caused by the space charges. The space charge density $\rho^+(t)$ is calculated with TDUD method described as follows.

C. Time-dependent upwind difference method

By combining the equations (1) to (3), equation for solving the space charge density is obtained

$$\frac{\partial \rho^+(t)}{\partial t} = -k^+ \nabla \Phi(t) \cdot \nabla \rho^+(t) - \frac{k^+}{\epsilon_0} (\rho^+(t))^2 \quad (4)$$

In (4), the migration of space charge is solved dynamically, which is different from the stationary solution proposed in [6].

Triangular meshes are applied to discrete the calculating region. Fig. 1 illustrates the node i and the triangular mesh elements around it.

Fig. 1. Triangular mesh elements around node i .

In Fig. 1, $V_i^+(t) = -k^+ \nabla \Phi_i(t)$. $V_i^+(t)$ serves as the kinematic velocity of the positive charges. The field caused migration dominates the motion of the charges. So, the charge density of node i is mainly decided in the element opposite to the velocity direction of the positive charge. This element is called upwind element. The upwind element of node i is Δijk in Fig. 1. Then, the first-order discretized form of (4) based on upwind scheme is derived as (5).

$$\frac{\rho_i^+(t_{n+1}) - \rho_i^+(t_n)}{\Delta t} = k^+ \cdot \nabla \rho_{\Delta ijk}^+(t_n) \cdot \nabla \Phi_{\Delta ijk}(t_n) - \frac{k^+}{\epsilon_0} (\rho_i^+(t_n))^2 \quad (5)$$

Where, t_n and t_{n+1} are two adjacent points in time, Δt is the time interval between them; $\Phi_{\Delta ijk}(t_n)$ is the electric potential in Δijk on time t_n ; $\rho_{\Delta ijk}^+(t_n)$ is the charge density in Δijk on time t_n .

III. APPLICATION ON CONDUCTOR BUNDLES

The simplification of equivalent sectional radius is usually employed to deal with the conductor bundles. This may produce errors because of the change of the actual geometric boundary. Subconductors can be considered in the simulation with the method in this work. Q-V curves for positive surge corona of 4×15.25 mm radius conductor bundle in a 5.5 m square cage were presented in [9]. Impulses of 260/2300 μ s with peak voltage of 520, 610, and 700 kV were applied. The experimental and calculating results are illustrated in Fig. 2. The time step is 1 μ s. The total calculation time is 10 ms.

Fig. 2 shows that the simulation reproduces the experimental results well for voltage of 700 kV and 610 kV. However, the simulated charge quantity is lower than the experiment for voltage of 520 kV because of the overvalued inception voltage.

The meshes and the charge density distribution on the moment of 10 ms under voltage of 610 kV are illustrated in Fig. 3. It can be seen that the space charges are forced to migrate in the direction departs from the bundle center. And the migration distance of the space charges is very limited.

Fig. 2. Q-V curves of surge corona on conductor bundle.

Fig. 3. Meshes and charge density distribution on the moment of 10 ms under voltage of 610 kV.

Using Neumann Series for Reduction of Computational Effort of Quasistatic EM-Simulations

Carsten Potratz, Daniel Kluess, Robert Souffrant, Hartmut Ewald, Ursula van Rienen

Abstract—In this paper we present an approach using magnetostatic simulations and a generalized geometric series to solve a low-frequency quasistatic problem. This is applicable for systems of inductively coupled coils within the simulation domain. With this approach the discretization may be coarsened significantly thus reducing the simulation time significantly. Consequently, setups which might be beyond computational equipment at hand get computable. This proposal describes the basic theory. The final paper will furthermore include a comparison of results obtained by this approach and conventional simulations. We will also give an analysis of possible deviations.

Index Terms—Inductive coupling, simulation, reduction, numerical effort

I. INTRODUCTION

THE simulation of systems of coils in time-harmonic low frequency magnetic fields is accompanied by an increased computational effort. Especially for coils with many turns and small volumes compared to the computation domain's volume, the discretization effort and the simulation time increase significantly. In 2008 we proposed [1] the usage of an intracorporeal system of electrodes embedded in a total hip revision endoprosthesis to stimulate the growth of new bone after a failed total hip endoprosthesis has been replaced. Different studies suggested that this treatment with a low frequency electric field increases the bone proliferation rate. Aaron et al. [2] analyzed different preclinical and clinical electrostimulation studies. Most of these attest the improvement of bone healing during an electrostimulation therapy. This is applicable for different bone healing dysfunctions, especially for large bone defects caused by osteolysis around a loose, failed implant. The proposed revision cup system is equipped with numerous stimulation electrodes with embedded coils. By applying an extracorporeal oscillating magnetic field an electric field is generated in the vicinity of the endoprosthesis. However, the inherent complexity of both the acetabular region and the endoprosthesis require numerical simulations to compute the generated electric field distribution for a subsequent optimization process. Due to the low stimulation frequency (Kraus [3], 20 Hz) and small volumes of the stimulation electrodes, several hundred turns are needed for the secondary coils to induce a suitable voltage. For numerical reasons the total volume of the computational domain inhibits appropriately fine discretization of the coils unless a very powerful computer system is at hand. Therefore we developed an approach to circumvent the discretization problems and reduce the complexity by replacing the secondary coils by current sources. The amplitudes have to be modeled according to the induced voltage under consideration of the self and mutual induction effects. By applying a generalized geometric series

known as Neumann's series a reaction matrix, incorporating the induction effects, can be created. This matrix maps flux vectors from static simulations to their quasistatic counterparts. Based on these mapped fluxes, suitable current sources and short circuited induction rings are calculated. This results in the reduction of discretization effort by several magnitudes and allows for the quasistatic simulation of a problem that otherwise would be hardly computable. We present the theory as well as practical modeling examples and conclude with a comparison of results of conventional modeling and our approach under aspects of accuracy and necessary simulation/preparation time.

A. Methods

The coils within the stimulation electrodes are comprised of several hundred turns wrapped upon a ferromagnetic core. Therefore, the scattering flux of the secondary coils is minimal. The flux in the i^{th} coil generated by the primary coil is:

$$\Psi_i(t) = \hat{\Psi}_i \cos(\omega t) = \iint_{A_i} \mathbf{B}(t) \cdot d\mathbf{a}, \quad (1)$$

with \mathbf{B} denoting the primary magnetic flux density. By neglecting the reaction field of the induced current, the amplitude of the induced voltage is given by the induction law:

$$\hat{u}_i = \hat{\Psi}_i \omega n. \quad (2)$$

Here n denotes the number of coils turns and ω denotes the circular frequency. The induced current \hat{i}_i generates a reaction flux in the coil proportional to n and \hat{i}_i :

$$\hat{\Psi}_{re,i} = \alpha \hat{i}_i n, \quad (3)$$

with a scaling factor α representing the coils geometry. For identical secondary coils α has the same value for all coils. The ratio of the induced voltage and current is given by Ohm's law:

$$|Z_i + R_w n + j\omega L| = \frac{\hat{u}_i}{\hat{i}_i} \quad (4)$$

with Z_i denoting the outer impedance created by the conductive tissue. R_w and $j\omega L$ denote the coils ohmic resistance and self inductance respectively. The self inductance is proportional to n^2 with the proportionality factor l depending on the geometry of the coil:

$$L = l n^2. \quad (5)$$

A ratio expressing the reaction of the coil to a primary flux can be derived from (2) and (3):

$$c_{ii} := \frac{\hat{\Psi}_{re,i}}{\hat{\Psi}_i} = \frac{\alpha \omega n^2}{|Z_i + R_w n + j\omega l n^2|}. \quad (6)$$

Fig. 1. Simulation model for the optimization process

Similarly a mutual reaction factor can be defined using the i^{th} coil for magnetic excitation:

$$c_{ji} := \frac{\Psi_{re,j}}{\Psi_i}. \quad (7)$$

This ratio describes the reaction of the j^{th} coil to the current flowing through the i^{th} coil. All reaction factors defined above form a matrix:

$$\mathbf{C} = \begin{pmatrix} c_{11} & \dots & c_{1N} \\ \vdots & \ddots & \vdots \\ c_{N1} & \dots & c_{NN} \end{pmatrix}. \quad (8)$$

With this matrix the self and mutual induction effects can be expressed as infinite series:

$$\Psi_{\mathbf{S}} := \begin{pmatrix} \Psi_{S1} \\ \vdots \\ \Psi_{Sn} \end{pmatrix} \quad \Psi_{\mathbf{Q}} := \begin{pmatrix} \Psi_{Q1} \\ \vdots \\ \Psi_{Qn} \end{pmatrix} \quad (9)$$

$$\Psi_{\mathbf{Q}} = \Psi - \mathbf{C}\Psi_{\mathbf{S}} + \mathbf{C}^2\Psi_{\mathbf{S}} - \dots + = \sum_{i=0}^{\infty} (-1)^i \mathbf{C}^i \Psi_{\mathbf{S}}$$

with $\Psi_{\mathbf{S}}$ and $\Psi_{\mathbf{Q}}$ denoting the fluxes through the secondary coils extracted from a magnetostatic simulation and the expected fluxes of a quasistatic simulation respectively.

Due to conservation of energy the norm of \mathbf{C} has to be less than one. Therefore partial sum of eq. (9) is given as:

$$\sum_{i=0}^{\infty} (-1)^i \mathbf{C}^i = (\mathbf{I} - \mathbf{C})^{-1} \text{ while } \|\mathbf{C}\| < 1 \quad (10)$$

The resulting fluxes $\Psi_{\mathbf{Q}}$ are given by:

$$\Psi_{\mathbf{Q}} = (\mathbf{I} - \mathbf{C})^{-1} \Psi_{\mathbf{S}} \quad (11)$$

Based on the flux vector $\Psi_{\mathbf{Q}}$ and eq. (2), the secondary coils in the simulation model are replaced by current sources. They generate the same current density in the electrode's vicinity while the discretization effort is highly reduced.

The secondary coils cannot be omitted entirely. The distortion of the primary magnetic field due to the secondary

coils and the generated eddy current distribution has also to be accounted for. Equation (3) states that the reaction flux is proportional to the current flow and the number of turns. Therefore, the turns wrapped around the ferromagnetic core were replaced by a conductive hollow cylinder. The conductivity of the used material has to be adapted, such that the induced eddy currents equals n times the current of the equivalent current sources. This guarantees that the distortion of the primary magnetic field is similar to that of the original problem.

II. CONCLUSION

The presented approach requires a series of simulations to extract the necessary geometric parameters and reaction ratios. Yet, the discretization of the simulation model may be rather coarse and the overall numerical effort is acceptable. Main advantage of this procedure is that the whole setup of the endoprosthesis within the acetabular bone and the surrounding tissue may be simulated without the need for a high-performance supercomputer.

Exposure of working population to pulsed magnetic fields

Aldo Canova, Fabio Freschi, Luca Giaccone, Maurizio Repetto

 Email: name.surname@polito.it

Abstract—Reference values of exposure for working population at extremely low frequency electromagnetic fields have been stated in ICNIRP Guidelines of 1998, and accepted by European Parliament in 2004. Nevertheless, quantification of coupling mechanism under pulsed field conditions is still an open question. The effect of complex non-sinusoidal or non-periodic waveforms is not univocally defined and several ways of estimating it have been proposed. This paper compares different ways of assessing effects of pulsed electromagnetic fields with frequency spectrum below 100 kHz and compare them to the eddy currents induced in one realistic model of human body by a resistance spot welding system supplied by in pulsed medium frequency direct current mode.

I. INTRODUCTION

Protection of working population against the possible effects of extremely low frequency (ELF) electromagnetic fields is a concern of European Community which has published in 2004 Directive 2004/40/EC [1]. The Directive refers to the risk to the health and safety of workers due to known short-term adverse effects in the human body caused by the circulation of induced currents and by energy absorption as well as by contact currents. One of the most important points stated in the Directive is the rationale of exposure at low frequency which is defined in accordance with ICNIRP 1998 guidelines [2]. These Guidelines report that in the ELF frequency range, the risk to the health and safety of workers is due to known short-term adverse effects caused by the circulation of induced currents in the human body. The evaluation of eddy currents is not an easy task, involving the electromagnetic study of a complex system like the human body.

While continuous wave mode of exposure is strictly defined in ICNIRP guidelines, the evaluation of eddy currents induced in human body by pulsed or non-sinusoidal magnetic field waveforms is still an open question. In 1998 ICNIRP guidelines, the problem of non-sinusoidal waveforms was tackled by means of superposition of harmonic values. This approach, even if possible, has been highly criticized afterwards because of an excessive conservative estimates of exposure levels. Due to the increasing importance of non-sinusoidal sources of magnetic fields, in 2003 ICNIRP has published a new guideline for pulsed and complex non-sinusoidal waveforms [5]. This document addresses the exposure evaluation in non-sinusoidal conditions by means of proper weighting factors to be applied to different harmonic components of the waveform

spectrum and by focusing more precisely the time derivative of magnetic flux density as the most important cause of biological interaction. Notwithstanding this correction to the previous 1998 Guidelines, also this approach has been considered not particularly effective for the representation of the real interaction mechanism with nervous stimulation caused by induced eddy currents. In 2007 Heinrich [3], in fact proposes a new set of weighting coefficients more strictly related to the process of electrostimulation of nervous tissues. By resorting to a biomedical equation which states the inverse relation between duration of eddy currents and cell membrane excitation, very short pulses, even with relatively high amplitudes, are considered less effective in causing dangerous nervous excitations.

Even if all these techniques address in depth the interaction between source magnetic flux density and tissues, they consider only very rough models of the human body. All considerations are in fact related to simple circular loops representing the path of eddy currents inside the body, considered as homogeneous in electrical conductivity.

The use of electromagnetic analysis tools for assessing the exposure levels is possible and this fact opens an opportunity of application to this topic of numerical tools. Several difficulties are present at this stage: modelling of external magnetic fields and of the human body are not an easy task. In the following the main simplification hypotheses that can be adopted in the computation of eddy currents are described and then the application of numerical evaluation tools to an industrial case of resistance spot welding, which is working in a pulsed way, is presented and discussed.

II. EVALUATION OF INDUCED EDDY CURRENTS IN HUMAN BODY

The Scalar-Potential Finite-Differences (SPFD) method for the calculation of induced current densities inside the human body has been introduced in [6]. This approximated approach is valid when the magnetic field created by induced currents is small with respect to the one created by source currents. Under this hypothesis, the magnetic field distribution is not perturbed by eddy currents and so it can be computed independently on the conducting body. By making reference to the standard notation for discrete operators introduced in [7] the problem can be formulated in algebraic form as follows.

Solenoidality of eddy currents (since displacement currents are neglected) imposes that:

$$\tilde{\mathbf{D}}\mathbf{i} = \mathbf{0} \quad (1)$$

where $\tilde{\mathbf{D}}$ is the discrete expression of divergence operator and \mathbf{i} is the vector of induced eddy currents. Electromagnetic induction law can be expressed in terms of magnetic vector potential:

$$\mathbf{u} = -\mathbf{G}\varphi - \frac{d\mathbf{a}}{dt} \quad (2)$$

where \mathbf{G} is the discrete expression of gradient operator, \mathbf{u} are induced electro-motive forces, φ is the vector of electric scalar potential and \mathbf{a} is the array of magnetic vector potential. Electrical constitutive equation can be written as:

$$\mathbf{i} = \mathbf{M}_\sigma \mathbf{u} \quad (3)$$

where \mathbf{M}_σ is the discrete expression of Ohm's law. By inserting (3) in (1) and using (2) together with duality relations $\tilde{\mathbf{D}} = -\mathbf{G}^T$ [7]:

$$\mathbf{G}^T \mathbf{M}_\sigma \mathbf{G} \varphi - \mathbf{G}^T \mathbf{M}_\sigma \frac{d\mathbf{a}}{dt} = \mathbf{0} \quad (4)$$

Finally, by exploiting the hypothesis that magnetic flux would not be modified by eddy currents, magnetic part of (4) is a known term so that previous equation can be rewritten as:

$$\mathbf{G}^T \mathbf{M}_\sigma \mathbf{G} \varphi = -\mathbf{G}^T \mathbf{M}_\sigma \frac{d\mathbf{a}_s}{dt} \quad (5)$$

where \mathbf{a}_s is the magnetic vector potential due to imposed current sources.

Under sinusoidal steady-state (with angular frequency ω), previously defined variables become phasors and (5) becomes:

$$\mathbf{G}^T \mathbf{M}_\sigma \mathbf{G} \hat{\varphi} = -j\omega \mathbf{G}^T \mathbf{M}_\sigma \hat{\mathbf{a}}_s \quad (6)$$

III. HUMAN BODY MODEL

The choice of a suitable human model is not a standardized task. In fact, possible 3D models may have different spatial resolutions and tissue properties are not well assessed. A realistic model is the "Hugo" 3D anatomical data set which is a discretization of the body of a 38 year old man of about 180 cm height [8]. Many resolutions are available from $8 \times 8 \times 8$ mm down to $1 \times 1 \times 1$ mm voxels and 31 tissues with their electrical properties are defined.

IV. RESISTANCE SPOT WELDING SYSTEM

Welding systems are characterised by high values of currents and by non-sinusoidal waveforms, thus their effects of exposure must be evaluated by means of particular techniques [4]. Resistance spot welding system supply system is often based on medium frequency direct current (MFDC). In MFDC technique, the primary current is regulated by a three phase inverter and the secondary current is rectified by a diode bridge.

The welding gun was placed at a distance of 1.5 m from the body. Supply current value was set to a maximum value of 20 kA rms with the waveform shown in Fig. 1. Evaluation

Fig. 1. Behavior of the secondary transformer current with MFDC supply: abscissas in seconds and normalized.

Fig. 2. Detail of induced eddy currents in Hugo model using the 4 mm voxel model.

of eddy currents has been performed by means of harmonic summation, as proposed in [2], using its frequency spectrum and by means of time-stepping technique as previously proposed in (5). In Fig. 2, the color map of induced eddy currents at the highest value of eddy current is shown. An accurate comparison of results will be presented in the full paper.

Abstract - Electrochemical Therapy (in short EChT) is a technique used to treat cancer by applying a small constant electric current or low level constant voltage. The EChT treatment effectiveness depend on Dose (charge) imparted into the cancer region [Dose (Coulomb) = Current (Ampère) x time (second)], beyond the accuracy of electrodes insertion (vertical or parallel electrodes direction into the cancer region), the number and the distribution of electrodes into cancer area. Our researches indicate that Doses greater than 20 C/cm³ are desirable to treat cancer using EChT. The principal aim of this paper is to show the studies done applying Constant Current Source (CCS) and Constant Voltage Source (CVS) in *ex-vivo* experiments of canine mammary cancer. We performed *ex-vivo* experiments using CCS and CVS for EChT 'standard', monopolar and cerclage electrodes disposition. This study was basically designed to evaluate what scheme (CCS or CVS) increase the delivered charge to the cancer region during EChT, enhancing the treatment efficacy. CCS has been used by our group since 2001, applying EChT *in vivo*. There have been no investigations comparing CCS and CVS to treat cancer using EChT. We investigate the amount of dose deposited at each electrode disposition using CCS and CVS. In the cerclage electrode disposition connected to a CVS; there is a highest amount of dose imparted into cancer area compared with other electrodes disposition and electrical sources schemes.

I. INTRODUCTION

EChT procedures involve placing electrodes into cancer region and connecting the electrodes to CCS or CVS. Current flowing through electrodes into the cancer starts an electrolytic process[1], [2]. Electrochemical products of electrolysis are formed destroying cancer cells by creating toxic products in the vicinity of the electrodes. The important advantage of this treatment is that the electric current is applied locally, with no systemic side effects.

Our research group in October of 2001 started the EChT studies. The EChT experiments were conducted *in vivo* (animals that acquired the malignant tumor during their life, that means, spontaneous cancer). Indeed, we use CCS for *in vivo* experiments. We perform a statistical analysis of our EChT experiments. So, the software SPSS – version 11.5 was used. The total number of animals

statistically evaluated (animals submitted to the EChT) was 79 (147 tumors), having different types of neoplastic disease. It's important to point out that in the number of animals statistically evaluated the spontaneous head and neck tumors of cats and dogs are not included. Statistical analysis of head and neck tumors was done in previous paper [3]. Sensitivity and Specificity are statistical measures well known in scientific area. The sensitivity is the proportion of actual "positives" which are correctly identified as such, and the specificity is the proportion of "negatives" which are correctly identified. Having these concepts in mind, the sensitivity for the Dose k was defined as the proportion of cases with dose $\geq k$ among patients cured and the specificity was the proportion of cases with dose $< k$ among patients not cured. Graph showing the sensitivity and specificity is called Receiver Operating Characteristic curve or simply ROC curve. The ROC curve allows to identify the doses (or other parameter of interest) cut points that maximize the estimated probability of cure. For the *in-vivo* experiments conducted by our research group since 2001, Fig. 1a and 1b shows the obtained ROC curves for EChT Response x Applied Dose and for EChT Response x Cancer Volume, respectively.

Fig.1b – EChT x Volume.

Fig. 1. EChT Statistical Analysis.

According ROC Curve the "ideal/optimum" dose is situated among 20.8 and 23.9 C/ cm³ (Fig. 1a). Indeed, volumes smaller than 6.35 cm³ the Sensibility is

approximately 73% (Fig. 1b). That means, among all cured tumors 73% shown volume smaller or equal than 6.35 cm³. About Specificity, our evaluation indicates that among all non-cured tumors, 70% had volume greater than 6.35 cm³. Results shown in Fig. 1 were obtained using CCS scheme. However, doubts arise: what is the difference in EChT treatment effectiveness using CCS or CVS schemes? Reminding, EChT treatment effectiveness depend of the Dose (charge) imparted into the cancer region [Dose (Coulomb) = Current (Ampère) x time (second)], beyond the accuracy of electrodes insertion (vertical or parallel electrodes direction into the cancer region), the number and the distribution of electrodes into cancer area.

II. EChT EX-VIVO EXPERIMENTS

EChT *ex-vivo* experiments were performed using equipment which constant electric current and constant voltage modes are possible. So, current (CCS) and voltage (CVS) operations modes can be adjusted in the equipment. With this equipment, the range of electric current and voltage are 0-100.0 mA and 0-30V, respectively. In this study, *ex vivo* fresh mass of different types of dog's mammary cancer were used. The cancer mass was obtained by surgical resection of dog's mammary glands. Each mammary cancer mass was divided in six small pieces. The volume of each piece is approximately 4.2 cm³. So, fresh cancer mass was divided in six samples. It's important to say that samples with necrosis were discarded. Samples 1, 3 and 5 (odd samples) forms the *group 1*, which electrodes dispositions are connected to a CCS. Samples 2, 4 and 6 (even samples) forms the *group 2*, connected to a CVS. The electrodes dispositions used in these experiments were: (a) 'Standard' EChT electrode disposition: Anodic and Cathodic electrodes into the tumor, 1.0cm apart (samples 1 and 2); (b) EChT monopolar: Anodic electrode into the tumor and Cathodic electrode outside the tumor (samples 3 and 4) and (c) EChT Cerclage: Anodic electrode connected to the wire and Cathodic electrode outside the tumor (samples 5 and 6). In the 'Standard' and monopolar EChT electrodes schemes Platinum (90%) and Rhodium (10%) electrodes were used. Steel wire was used in EChT cerclage scheme. Fig. 2 shows the electrodes dispositions. In this figure, the number after the letter N indicates the fresh masse under test following the sample number. For example, N2.6 represents the second fresh mass under test, EChT cerclage electrode disposition is been evaluated and we are using the CVS scheme.

Fig. 2a – 'Standard' EChT electrode disposition: Anode and Cathode into the tumor (Samples 1 & 2).
 Fig. 2b – Monopolar electrode disposition: anode into the tumor and Cathode outside (Samples 3 & 4).
 Fig. 2c – Cerclage disposition: anode connected to the wire and cathode outside the tumor (Samples 5 & 6).

Fig. 2. Electrodes dispositions for groups 1 and 2.

Applying CCS scheme to samples of group 1, the equipment was adjusted to produce an initial voltage of 5 Volts. The electric current obtained with 5Volts is the Constant Current (DC current) flowing into the cancer samples during the experiment. The voltage was recorded every 1 min for 10 min during electrochemical therapy. On the other hand, applying CVS scheme to samples of group 2, the equipment was adjusted to produce a constant voltage of 5Volts during the experiment. The electric current was recorded every 1 min for 10 min during EChT. The charges (doses) delivered to the samples were calculated by integration of the electric current versus treatment time (10 min). After the experiment, the sample was sent for pathological examination.

III. RESULTS

Distinct behavior was verified applying CCS and CVS schemes to the samples. In all fresh mass of group 1 (CCS), the voltage between electrodes decreased gradually during the experiment. On the other hand, using the CVS scheme (group 2) the current flowing by the all cancer samples increased during the experiment. The EChT efficacy is enhanced maximizing the charge delivered to the cancer region. Table 1 shows for the second fresh mass under test some obtained results. Similar results were obtained for all fresh cancer mass evaluated.

TABLE I
DOSE COMPARATIVE RESULTS.

SOURCE TYPE/ SAMPLE (*)	CCS/ 1	CVS/ 2	CCS/ 3	CVS/ 4	CCS/ 5	CVS/ 6
TUMOR RESISTANCE VARIATION (Ω)	25.0	116.4	27.9	147.0	121.7	129.4
DOSE (C)	4.8	3.1	4.7	4.9	5.5	17.75

(*) **Samples 1 & 2:** Anode and Cathode Electrodes into the tumor; **Samples 3 & 4:** Monopolar Electrodes disposition, **Samples 5 & 6:** Cerclage electrode disposition.

IV. CONCLUSION

We agree that up to now there have been no investigations comparing CCS and CVS schemes to treat cancer using EChT. Important conclusion is that the EChT cerclage electrode configuration applying CVS scheme increase the treatment efficacy, because the charge delivered (dose) is greater than the others tested electrodes dispositions and sources of electrical energy.

Abstract—A novel method to analyze the energy transfer efficiency of the HV transmission lines is presented in the paper based on the Poynting Vector (PV) distribution around the transmission lines, which can avoid the calculation of the circuit parameters of the transmission lines. The charge simulation method and current simulation method were used to compute the distribution of the PV distribution around the transmission lines, and the influence on the PV distribution caused by the distance of the phase conductors was investigated.

I. INTRODUCTION

With the installed capacity of electric power system around the world, many new techniques have been investigated for the transmission lines [1], such as compact transmission lines, FACTS, and UHV DC transmission lines. In the investigation of new type transmission lines, analysis on the energy transfer efficiency is necessary, and all the analysis on the energy transfer efficiency were carried out from the view of circuit at present, which need to compute the circuit characteristics parameters, and the load of the transmission lines should be given.

The Poynting Theory indicates that the energy is transferred by the electromagnetic field around the transmission lines, and the transmission lines only determine the direction of the energy transfer [2]. In addition thermal loss rises up inside the transmission lines.

In the paper a novel method to analyze the energy transfer efficiency of the transmission lines is presented based on the PV distribution around the transmission lines, and the charge simulation method and current simulation method were used to compute the distribution of the PV around the transmission lines. In addition, the influence on the PV distribution caused by the distance of the phase conductors was investigated.

The numerical calculation on the PV distribution around a 500 kV double-circuits was carried out firstly, and results indicate that the PV distribution changes with the distance between the phase conductors. When the distance between the phase conductors reduces to a certain degree, the average longitudinal component of the PV reduced from 2.347×10^3 to 2.196×10^3 W/m², even the maximum value change from 2.59×10^5 W/m² to 3.23×10^5 W/m². Therefore for the design of HV transmission lines, the PV distribution around the transmission lines can be computed to analyze the energy transfer efficiency, based on which measures to increase the energy transfer efficiency can be obtained.

II. COMPUTATIONAL METHOD

According to the definition of PV, $\mathbf{S}=\mathbf{E} \times \mathbf{H}$, the PV \mathbf{S} can be computed in the following way: Firstly in the Cartesian coordinate system, the three components E_x , E_y , E_z of the electric field strength \mathbf{E} and the three components H_x , H_y , H_z of the magnetic field strength \mathbf{H} around the transmission lines can be computed, then with the calculated E_x , E_y , E_z and H_x , H_y , H_z , \mathbf{S} can be calculated.

For the calculation of E_x , E_y , E_z and H_x , H_y , H_z , the charge simulation method can current simulation method were adopted respectively.

According to the charge simulation method and the geometry characteristics of transmission lines, the electric field strength in the vicinity of them can be calculated according to equation (1).

$$\begin{aligned} [P][Q] &= [U] \\ [E_x] &= [f_x][Q] \\ [E_y] &= [f_y][Q] \\ [E_z] &= [f_z][Q] \end{aligned} \quad (1)$$

Where $[P]$ is potential coefficient of matching points; $[Q]$ is size of the simulation charges; $[U]$ is potential at matching points; $[f_x]$, $[f_y]$ and $[f_z]$ are electric field strength coefficient along x , y , z axis. $[E_x]$, $[E_y]$ and $[E_z]$ are the corresponding electric field strength.

According to the current simulation method, the magnetic field strength around the transmission lines can be computed according to equation (2).

$$\begin{aligned} [\beta][I] &= [A_m] \\ [A] &= [\beta][I] \\ \mathbf{H} &= \frac{1}{\mu}(\nabla \times \mathbf{A}) \end{aligned} \quad (2)$$

Where $[\beta]$ is the magnetic coefficient, $[A_m]$ is the magnetic vector at the matching points, and $[A]$ is the magnetic vector at measuring points.

III. RESULT AND ANALYSIS

A 500kV double-circuits transmission lines as shown in Fig.1 was taken as an example for the calculation of the PV distribution firstly, then the influence on the PV distribution around the transmission lines caused by the distance between the phase conductors was investigated.

Fig.1 Cross section of a 500kV double-circuits transmission lines

The parameters of the model in Fig.1 are as follows: D_1 , D_2 , D_3 are the distance between the phase conductors and y -axis, and $D_1=4.5\text{m}$, $D_2=5.5\text{m}$, $D_3=11.5\text{m}$. H_1 and H_2 are the height of the phase conductor, and $H_1=20\text{m}$, $H_2=25\text{m}$. For each phase conductor, 4 bundle conductors were used, and the radius of the sub-conductor $r=0.0148\text{m}$, the split radius $R'=0.323\text{m}$, and the radius of the lightning conductor $R'_L=0.0054\text{m}$. To simply the calculation, the influence caused by the arc sag was ignored, hence the electric field and magnetic field produced by the transmission lines can be solved as two dimensional field.

Firstly the PV distribution around the transmission lines when the y -coordinate of each phase conductor are 20m, 25m, 20m, 20m, 25m, 20 m, 30m, 30m respectively. As mentioned above, the E_x , E_y , E_z and H_x , H_y , H_z were calculated firstly, then PV S was computed, and Fig.2 shows the longitudinal component of PV S_z around the transmission lines, it can be seen that the main power energy is transferred near the transmission lines. The maximum value of the S_z is $2.59 \times 10^5 \text{ W/m}^2$, and with the increase of the distance of the measuring points between the transmission lines, the value of S_z decreases.

Fig.2 Distribution of S_z when the y -coordinate of each phase conductor are 20m, 25m, 20m, 20m, 25m, 20 m, 30m, 30m

To investigate the influence on the PV distribution and energy transfer efficiency caused by the change of the distance between the phase conductors, the PV distribution around the transmission lines were calculated when the distance between the phase conductors was changed, for which the y -coordinates of each phase conductors are 20m, 22.5m, 20m, 20m, 22.5m, 20m, 30m, 30m, and Fig.3 shows

the distribution of the S_z , and the maximum value of the $3.23 \times 10^5 \text{ W/m}^2$.

Fig.3 Distribution of S_z when the y -coordinate of each phase conductor was changed

To evaluate the energy transfer efficiency of the transmission lines, an average value of the longitudinal component is set as S_{zav} , which is the average value of 10201 points in the vicinity of the transmission lines shown in Fig.1, and the $S_{zav1}=2.347 \times 10^3 \text{ W/m}^2$ for the first case, and $S_{zav2}=2.196 \times 10^3 \text{ W/m}^2$ for the second case, which means that the energy density around the transmission lines decreases, even though the maximum value of longitudinal component of PV S_z increases from $2.59 \times 10^5 \text{ W/m}^2$ to $3.23 \times 10^5 \text{ W/m}^2$. Therefore the energy transfer efficiency of the transmission lines decreases. Therefore for the design of the HV transmission lines, to increase the energy transfer efficiency, the distance between the phase conductors can be analyzed according to the PV distribution around the transmission lines.

IV. CONCLUSION

A novel method to analyze the energy transfer efficiency of the HV transmission lines is presented in this paper based on the PV distribution around the transmission lines, which can avoid the calculation of the circuit parameters of the transmission lines. The PV distribution around a 500 kV double-circuits was computed, and results indicate that the PV distribution changes with the distance between the phase conductors. When the distance between the phase conductors reduces to a certain degree, the average longitudinal component of the PV reduced from 2.347×10^3 to $2.196 \times 10^3 \text{ W/m}^2$, which means that the energy transfer efficiency decreases.

Abstract—A numerical code based on Finite Element Method (FEM) developed to study the focusing properties of electrostatic lenses for non-relativistic electrons trajectories on a two-dimensional electron gun with cylindrical symmetry is presented. In order to apply the FEM, the Galerkin Weak Formulation was used. A Delaunay triangulation of the domain was built, and using FEM, the sparse system was solved for the scalar potential associated to the nodes. To solve the non-linear second order electron path differential equation, a fourth-order Runge-Kutta integrator is used. It's shown that absolute paths errors were below $1.5 \times 10^{-4}\%$, even with a modest discretization of the total space domain.

Index Terms—Finite Element Method, electron path, electron gun.

I. INTRODUCTION

The focusing properties of electron guns to be used in power microwave tubes can be investigated analysing the charge-particle path equation. The particle paths in electron gun are important because they establish the beam edge, the beam waist and beam waist distance from the anode. For this purpose many gun codes, such as [1]-[3], were developed.

In this work it is proposed a methodology to solve the electron steady-state self-consistent space-charge on electron guns from path instead of the equations of motion in axially symmetric field.

The finite element formulation and the derivation of the second order differential equation for non-relativistic charged-particle path are described. The code has been benchmarked and the most relevant results are also presented.

II. THE THEORETICAL PHYSICAL PROBLEM DESCRIPTION

A. Physical Formulation

Starting with the Lorentz force and energy conservation equations, the charged-particle path is obtained by elimination of the time variable. In order to obtain the scalar potential, a code using FEM with first order triangle elements was developed. The axially symmetric electron path steady-state flow can be described by the Poisson equation for the scalar potential $V(r, z)$:

$$\nabla^2 V = \frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial V}{\partial r} \right) + \frac{\partial^2 V}{\partial z^2} = -\frac{q}{\epsilon_0} \sum_i \frac{\delta(r - r_i) \delta(z - z_i)}{2\pi r_i} \quad (1)$$

were the right hand side is due to the space-charge, i.e, q represents the macro particle charge transported by the beam

current of the electron gun located at (r_i, z_i) position, and $\delta(r - r_i)$ and $\delta(z - z_i)$ denote the Dirac delta function.

From the scalar potential, the electric field \vec{E} , is given by:

$$\vec{E} = -\nabla V = -\left(\frac{\partial V}{\partial z} \hat{z} + \frac{\partial V}{\partial r} \hat{r} \right) = -E_z \hat{z} - E_r \hat{r} \quad (2)$$

The charged-particle path is obtained using the Lorentz force, under condition $\frac{v}{c} \ll 1$ and energy conservation law:

$$\frac{d^2 r_i}{dz_i^2} = \left[\frac{1 + \left(\frac{dr_i}{dz_i} \right)^2}{2V_i} \right] \left(E_{r_i} - E_{z_i} \frac{dr_i}{dz_i} \right) \quad (3)$$

where subscript i represents the i -th particle path of the problem.

In order to solve (1)-(3), a FEM code with first-order triangle elements was developed, and for the second-order differential equation for the path a fourth-order Runge-Kutta integrator was used.

B. Finite Element Formulation

Due to accuracy and versatility associated with weighting residual methods, such as Galerkin method, the finite-element method (FEM) [4]-[5], has been adopted as a standard on solving electromagnetic problems. The triangular finite element scalar potential V_e is written as $V_e(z, r) = \sum_{i=1}^3 \phi_i V_i$, where V_1 , V_2 and V_3 be the unknown potential at nodes 1, 2 and 3 and $\phi_i = \phi_i(z, r)$ represents the basis/shape function. This leads to the following system of equations:

$$[S][U] + [g] = 0 \quad (4)$$

where:

$$S_{ij} = \int_{\Omega} \nabla \phi_i \cdot \nabla \phi_j d\Omega \quad (5)$$

$$U_i = V_i \quad (6)$$

and,

$$g_i = \frac{1}{\epsilon_0} \int_{\Omega} \phi_i \rho_i d\Omega \quad (7)$$

where ρ_i is the right-hand side of Eq. (1).

This system can be solved for the N unknown equations and coefficients. To use the Galerkin method the weighting

functions must be set as the same as shape functions. A Gaussian Elimination solver was developed to solve the global system matrix.

C. Self-Consistent Algorithm

All electron gun codes, used to design intense beam guns, are said to be self-consistently if their solvers take into account the space-charge contribution to the static fields and the static fields forces contribution that act on the particles.

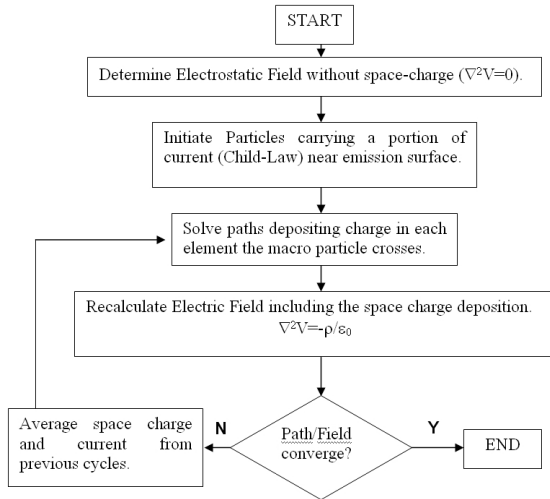

Fig. 1. Flowchart of the method of successive approximation.

The flowchart at Fig. 1 presents the successive approximation method to be implemented. At the first approximation, only the electrostatic field without the space-charge field is used to trace the particle paths. These paths establish a distribution of space charge. The second approximation takes into account that charge contribution to calculate the new electrostatic field which in turn is used to calculate the paths of the second approximation. This procedure is repeated several times until the convergence criterion is reached.

III. RESULTS

In order to validate the code, five axial-symmetric rectangular regions, with length equals five times height, were evaluated. The number of nodes and finite elements vary from 12 up to 3000 and 14 up to 4790, respectively. It was used 20 paths and was observed an absolute error radial position at the final point of integration lower than $1.5 \cdot 10^{-4}\%$.

It was also evaluated the charged-particle trajectory for the ideal Pierce diode structure. This model, Fig. 2, has 2996 nodes and 5731 finite elements. As expected, due to the focusing electrode, the paths curved down to the axis of symmetry according to Fig. 3. Under space-charge limited condition, the paths have to be parallel [6].

IV. CONCLUSION

It was described the FEM formulation to solve Poisson equation for the scalar potential and the non-linear second order differential equation for non-relativistic electrons path, which was integrated using the fourth-order Runge-Kutta integrator

Fig. 2. A Pierce structure domain subdivided into 5731 finite elements.

Fig. 3. Output solution shown for the ideal Pierce diode structure. Equipotentials are represented by the red lines and the trajectories by the light-blue.

method to obtain the electrons paths. Path absolute errors were below $1.5 \times 10^{-4}\%$ on a rectangular model, and on a Pierce diode structure, without space-charge deposition yet, paths presented a consistent behavior which indicates that the code is ready to evolve in order to work under space-charge limited condition. The next objective is solve the paths taking into account the space-charge limited condition and solve complex geometries, such as electron guns with grids and shadow-grids.

A complete set of results will be presented in the final paper.

Hierarchical Block Wavelet Compression for BEM Problems of Arbitrary Dimension

Christian Scheiblich, Remus Banucu, Jan Albert, Veronika Reinauer, and Wolfgang M. Rucker
 Institute for Theory of Electrical Engineering
 Pfaffenwaldring 47, 70569 Stuttgart, Germany
 christian.scheiblich@ite.uni-stuttgart.de

Abstract — Today’s computer hardware developments offer a complete and powerful parallel shared memory system (multi core CPUs) for a price of a home office system. To deliberate these developments on compression techniques for numerical applications using a Boundary Element Method (BEM), techniques are of first choices which are easy to parallelize by offering state of the art compression rates. The latest development of our Wavelet based compression technique fulfills these requirements. Its efficiency should be presented, discussed, and proven by numerical examples investigating the numerical accuracy related to different compression rates.

I. INTRODUCTION

To compute numerical applications using a BEM, one has to establish a compression technique for the fully populated system matrix (SM) of the system of linear equations (SLE). If a compression technique is not used, even nowadays available hardware capacities are rapidly limited, due to the fact of quadratic memory consumption while applying a BEM.

Several widely used compression techniques, like the well-known Fast Multipole Method, the Adaptive Cross Approximation (ACA) and algorithms working with a Singular Value Decomposition, reduce this memory consumption to a nearly linear dependency. All those techniques are established and selected by their advantages relying on the chosen numerical BEM application.

Furthermore, following in aspects of computer hardware developments a compressions technique offering an easy to handle parallelization becomes more and more important. This highlights techniques, like the ACA, that are exclusively dealing with the SM for compression. Whereas, the ACA uses a block structure for splitting the system matrix into several parallel computable blocks.

These blocks represent by their different sizes the importance of the expectant entries for the numerical accuracy of the BEM SLE. So, it is a good idea to pick up such a useful block structure called Hierarchical Matrices (HM) and bases a new development called Hierarchical Block Wavelet Compression (HWC) on it.

II. FAST WAVELET TRANSFORM AND COMPRESSION

Another well-know compression technique for BEM SMs of different formulations is based on the Fast Wavelet Transform (FWT). This technique applies a 2-D FWT to the SM for a selected wavelet, e. g. the Haar wavelet or one of the Daubechie wavelet family.

If only one dimension is considered, a 1-D FWT can be represented as a recursively applied filter bank:

Fig. 1. 1-D FWT displayed as a recursively applied filter bank

By Fig. 1 all data are split into half parts by every filter level; low pass (energy) coefficients and band pass (detail) coefficients. To receive the requested 2-D FWT, two 1-D FWTs can be applied horizontal and vertical over all entries.

For a compression of the BEM SM one has to thin out smaller detail coefficients by artless setting those to zero, e. g. using the average magnitude of all detail coefficients. Finally, not storing those zeros, normally around 60% percent, by a Compressed Row Storage fulfills the physical compression in memory. An advantage for orthogonal wavelets is that the right hand side (RHS) of the BEM SLE can also be transformed by a 1-D FWT and the matrix vector operation (MVO) can be directly applied at compressed state. The found solution vector (SV) has to be reverse transformed by a 1-D FWT and discloses the requested solution of the BEM SLE.

But an enormous disadvantage is the applicability of the described compression technique. It claims that data are always of length to the power of two while splitting it into halves by each transform level. Assigning this fact to a BEM SM, the dimension N subjects to $N = 2^p \mid p \in \mathbb{N}_0$. Whereas, the FWT is not applicable for other dimensions without extending the BEM SM by empty entries to the next possible dimension $N + 1 \Rightarrow 2^{p+1}$. For common numerical applications this is a knock-out criterion due to the fact of a growing to $2^{p+1} \times 2^{p+1}$.

III. BLOCK WAVELET COMPRESSION

The basis technique to overcome this knock-out criterion was introduced by setting up a Block Wavelet Transform [1].

A. Block structure for selected dimensions

Therefore, the BEM SM is split into blocks of the same size allowing for still the same procedure of compression as described above, but now applied block by block.

The dimension N extends to $N = k \cdot 2^p \mid (k, p) \in \mathbb{N}_0$ for the number of k^2 blocks picturing the BEM SM. Reapplying the example from above, the overhead reduces to

$N+1 \Rightarrow (k+1)2^p$ and results in $2 \cdot k - 1$ nearly zero filled blocks as a necessary extension of the BEM SM [1].

B. Block structure for arbitrary dimensions

To finally tackle an arbitrary dimension N by absolutely no overhead, our achievement was to apply an adaptive block structure [2] combined with a modification of the used wavelet coefficients (Haar, Daubechie, Coiflet coefficients) [3].

Fig. 2. SM at compressed state for an adaptive block structure

Fig. 2 displays these modifications; a calculated, transformed and compressed BEM SM of worst case dimension $N = 511$ split by an adaptive block structure.

C. Modification of the 2-D FWT for arbitrary dimension

To handle stretched or squeezed blocks, each dimension of the 2-D FWT has to be matched to each dimension of a treated block. For example, a block of size $2^p \times 2^q$ ($p, q \in \mathbb{N}_0$) claims a 2-D FWT of p recursive steps in vertical and q recursive steps in horizontal dimension (see Fig. 2).

Another indispensable modification regards the coefficients of the mandatory orthogonal wavelet. Those have to be normalized concerning the energy to allow for a block by block MVO at compressed state. Therefore, the MVO can be fulfilled by the matching and transformed parts of the RHS and the SV for each block multiplied by a selectable solver. In our case a GMRES or a BICG solver [2][3] is used.

The given example of $N+1$ is tackled in mathematical manner by absolutely no overhead and results in a dimension of $N+1 \Rightarrow k \cdot 2^p + 2^0$ for the BEM SM.

IV. HIERARCHICAL BLOCK WAVELET COMPRESSION

Within this work, our aim is to present an innovation of the already established [2] and parallelized BWC [3] towards Hierarchical Matrices.

A. Renumbering Degree of Freedom

For using HM in an efficient way, it is necessary to renumber the Degree of Freedom (DoF) to achieve a bandwidth minimization of the BEM SM. This is done by a kd-tree using a bounding box based algorithm in 3-D [2].

B. Hierarchical Matrices

Afterwards, an estimator function, derived from the kernel function of the BEM problem, splits the base structure of k^2 blocks into smaller hierarchical blocks. Fig. 3 was directly

generated from data output of our software ELFE++ and displays HM by a comprehensible example:

Fig. 3. HM of an applied HWC for an example of dimension $N = k \cdot 2^p$

C. Modified Wavelet Packet Transform for tackling HM

To attain the same advantages as described within the BWC, a MVO at compressed state, a modified 2-D Wavelet Packet Transform (WPT) [3] instead of a 2-D FWT has to be applied. A normal 1-D WPT displays an extension of the filtering scheme of the FWT (Fig. 1) by also recursively filtering details of each level. Our modification of the WPT interchanges the filtering scheme completely and, therefore, matches to the zoning of hierarchical blocks as shown (Fig. 3).

D. Push and pull functions for MVO

For a MVO at compressed state with no overhead, so called push and pull functions were particular developed for the HWC. Those functions change the hierarchical representation of the matching parts of the RHS and the SV for a hierarchical block. Both functions can be seen as a single matching transform step to lower (push) or higher (pull) hierarchy. For example, two smaller parts of the RHS of length 2^{p-1} are combined to match a block vertical length 2^p by only one call to the pull function with negligible linear effort of 2^p multiplications and 2^{p-1} additions.

V. NUMERICAL APPLICATIONS

In general, the HWC is applicable to any compressible SLE. Therefore, typical numerical applications demanding an electrostatic BEM problem in 3-D will be investigated for an arbitrary number of DoFs. The applications will be presented in detail and proven by numerical accuracy for different compression rates.

Abstract — The paper describes a quick method to calculate the radial flux density in the air gap of a superconducting inductor. This original topology uses superconducting bulks to shield the magnetic field created by two solenoids. Hence, the obtained airgap field is multipolar as in conventional AC machines. We propose a simple method based on the determination of the modulating function associated with the radial flux density distribution resulting from the introduction of the superconducting bulks. In a first step, a 2D magnetostatic finite element (FE) analysis allows the calculation of the modulating function. The later is used in a second step together with the field produced by the two solenoids to calculate the radial flux density distribution in the airgap of the considered inductor. Comparisons to 3D FE results show the validity of the proposed approach.

I. INTRODUCTION

In some types of electrical machines (claw pole, Lyndell machines...) ferromagnetic materials are used to modulate and concentrate the magnetic field to obtain a multipolar wave in the airgap from a constant excitation. In superconducting (SC) applications, ferromagnetic materials are heavily saturated since they are subjected to high magnetic fields. Hence, they can not be used for modulation purposes.

The use of the shielding properties of superconducting bulks allows flux concentration. An original topology of inductor, Fig.1, has been proposed [1] and a SC synchronous motor has been designed, built and successfully tested [2].

Fundamental to the operation of this inductor is the modulation of the magnetic field produced by two solenoids supplied by dc currents in contra-direction. In so doing, the radial flux density in a circle of the airgap is multipolar as in conventional ac machines. This flux density is minimal above the SC bulk and maximal above the bulks interspace.

Three dimensional finite elements as well as Monte Carlo methods [3, 4] can be used to compute the magnetic field distribution but this leads to high computation time. In this study, we propose a simple and quick method based on the determination of the modulating functions associated with the radial flux density distribution resulting from the introduction of the superconducting bulks.

Fig. 1. Schematic of the flux concentration superconducting inductor

II. PRINCIPLE OF THE METHOD

At a given axial position in the air above the SC bulks, the radial flux density distribution at a radial distance r produced by the two solenoids can be written in the following form:

$$B_r(r, \theta) = B_{r0}(r) \cdot \Lambda_r(r, \theta) \quad (1)$$

where θ is the angular position, B_{r0} is the radial flux density created by the solenoids without the SC bulks and Λ_r is the modulating function. Because of axial symmetry, B_{r0} has no azimuthal component and it can be computed analytically using the Biot-Savart law.

It has to be noticed that the modulating function only depends on the geometry and the magnetic permeability of the system as far as the linearity of the materials is assumed. In the present work, the superconducting materials are considered almost diamagnetic so their relative permeability is much smaller than unity (a value of 10^{-3} is found to be enough for the numerical simulations).

The modulating function can be written as follows:

$$\Lambda_r(r, \theta) = \Lambda_{r0}(r) + \sum_{k=1,2,3,\dots} \Lambda_{rk}(r) \cos(kN_b \theta) \quad (2)$$

where Λ_{rk} are the Fourier coefficients for the modulating function and N_b is the number of the superconducting bulks. From (1) and (2):

$$B_r(r, \theta) = B_{r0}(r) \Lambda_{r0}(r) + \sum_{k=1,2,3,\dots} B_{r0}(r) \Lambda_{rk}(r) \cos(kN_b \theta) \quad (3)$$

1. StaticFields

From (3), it can be seen that the radial flux density exhibits a dc component which doesn't create any emf.

Since the highest space harmonic is obtained for $k=1$, the number of pole pairs of the device is $p = N_b$.

A. Determination of the modulating function

To calculate the A_{rk} coefficients, we consider a 2D domain corresponding to the median cross section of Fig.1 where the radial flux density distribution is maximal.

We proceed in two steps:

Firstly, at a radius R_0 , Fig. 2.a, we impose a radial flux density by imposing a magnetic vector potential (mvp) of the form:

$$a(R_0, \theta) = A_0 \cos(p\theta) \quad (4)$$

The mvp A_0 can take any value and the magnetic field distribution can be computed analytically in this configuration where the SC bulks are removed. From this computation, the radial flux density at a radius R has the following form:

$$B_{ra}(R, \theta) = B_0 \sin(p\theta) \quad (5)$$

In a second step, the SC bulks are introduced, Fig.2.b. A 2D magnetostatic FE analysis is carried out with the same condition on R_0 as in (4). The radial flux density resulting from the introduction of the SC bulks is called $B_{rb}(R, \theta)$.

The modulating function can be obtained by simply dividing $B_{rb}(R, \theta)$ by $B_{ra}(R, \theta)$. This straightforward method leads to some indeterminations due to divisions per zero in some points. The preferred method is to proceed to a Fourier series expansion of $B_{rb}(R, \theta)$, then to use (2) and (5) to obtain the A_{rk} coefficients. Indeed, the harmonic analysis allows a better understanding of the modulation process.

III. APPLICATION EXAMPLE

The dimensions of the considered inductor [2] are given in Table I. We have tested the proposed method to determine the radial flux density on a circle of the airgap.

Fig. 2. Studied domains for the determination of the modulating function (a) without SC bulks (b) including SC bulks

TABLE I
PARAMETERS OF THE SUPERCONDUCTING INDUCTOR

Solenoid SC material (wires)	NbTi
Number of solenoids	2
Inner radius of solenoid, mm	75
Outer radius of solenoid, mm	105
Axial length of solenoid, mm	50
Bulk SC material	YBCO
Number of bulks ($N_b = p$)	4
Bulk thickness, mm	5
Bulk axial length, mm	50
Bulk angular opening, deg.	45

Because of the cryostat wall, the magnetic airgap is large in SC machines (typically 15 to 20 mm). Hence, for a radius $r=124$ mm and a current density in the solenoids of about 70 A/mm², we have compared, Fig.3, the results obtained by the presented method and these issued from a 3D FE analysis. The results are in good accordance. Furthermore, the computation time is about 5 minutes when using the FE method whereas it is only 5 seconds for the proposed approach.

Fig. 3. Comparison of radial flux densities at $r = 124$ mm

IV. CONCLUSION

A simple and quick method to compute the radial flux density created by an original topology of a superconducting inductor has been presented. Comparisons to 3D finite element calculations show the validity of the proposed approach with the benefit of huge savings in computation time.

Abstract— The solution of stochastic PDEs using the Stochastic Finite Element Method (SSFEM) can lead to a very large linear system. If the random input data are independent, it can be shown that the initial linear system can be split into smaller independent linear systems by using double orthogonal polynomials. In this paper, we propose to apply this approach in the case of the dual potential formulations in electrokinetics and to compare the two.

I. INTRODUCTION

The Spectral Stochastic Finite Element Method can be used to solve the stochastic static electromagnetics problem. This method has been proposed originally in mechanics by Ghanem [1] in the early 90's and has recently been applied to solve stochastic static electromagnetics problems [2][3]. This method is very accurate but requires the solution of a large linear system. The number of unknowns in the system is equal to the product of the number of Degrees of Freedom (DoFs), N required to discretise the spatial dimension (spatial mesh) and the number of DoFs, P_{out} required to discretise the random dimension. Even though the system to solve has special properties, its solution can be tricky when the number of random input variables is greater than about a dozen. If the randomness is in the behaviour laws and the input random variables are independent it has been shown by Babuska et al. [4], that using special polynomials (so called double orthogonal polynomials) as basis to discretise the random dimension, the SSFEM yields P_{out} independent equation systems of size N . The double orthogonal polynomials have been previously used to solve the scalar potential formulation in static electromagnetics [5]. Here, we propose to solve the two dual potential formulations using double orthogonal polynomials and to compare them on an example.

II. DESCRIPTION OF THE STOCHASTIC PROBLEM

On a contractible domain D with a boundary S , the electrokinetic problem can be written as:

$$\text{div } \mathbf{J} = 0 \quad (1)$$

$$\text{curl } \mathbf{E} = 0 \quad (2)$$

Boundary conditions are imposed on S . To simplify the problem, we will assume that we have only two disjoint surfaces S_{E1} and S_{E2} ($S_E = S_{E1} \cup S_{E2}$) on which:

$$\mathbf{E} \times \mathbf{n} = \mathbf{0} \quad (3)$$

with \mathbf{n} the outward unit vector on S . On the complement of S_E , denoted S_J , we have:

$$\mathbf{J} \cdot \mathbf{n} = 0 \quad (4)$$

The behaviour law can be written on D as:

$$\mathbf{J} = \sigma(\mathbf{x}, \theta) \mathbf{E} \quad (5)$$

$\sigma(\mathbf{x}, \theta)$ is the random field conductivity. We will assume that the conductivity is equal to a random variable $\sigma_q(\theta)$ on M disjoint subdomains D_q of D :

$$\sigma(\mathbf{x}, \theta) = \sum_{q=1}^M \sigma_q(\theta) I_q(\mathbf{x}) \quad (6)$$

With $I_q(\mathbf{x})$ is the function that is equal to 1 on the subdomain D_q and 0 elsewhere. Since the conductivity is random, \mathbf{E} and \mathbf{J} are random fields. To solve the previous problem, two potential formulations can be used. Since, $\mathbf{E}(\mathbf{x}, \theta)$ is curl free, it can be written as the gradient of a scalar function $\varphi(\mathbf{x}, \theta)$. The equation to solve is then:

$$\text{div}[\sigma(\mathbf{x}, \theta) \mathbf{grad} \varphi(\mathbf{x}, \theta)] = 0 \quad (7)$$

We have Neumann boundary conditions on S_J and Dirichlet type on S_E with:

$$\varphi(\mathbf{x}, \theta) = 0 \text{ on } S_{E1} \quad \varphi(\mathbf{x}, \theta) = V \text{ on } S_{E2} \quad (8)$$

To obtain an unknown with homogeneous boundary conditions, we consider a function $\boldsymbol{\beta}(\mathbf{x})$ on D such that $\boldsymbol{\beta}(\mathbf{x})$ satisfies (2), (3) and such that the circulation of $\boldsymbol{\beta}(\mathbf{x})$ from S_{E1} to S_{E2} is equal to 1. We now consider the new problem with the scalar potential $\varphi'(\mathbf{x}, \theta)$ and with homogenous boundary conditions on S_E :

$$\text{div}[\sigma(\mathbf{x}, \theta) \mathbf{grad} \varphi'(\mathbf{x}, \theta)] = -V \text{div} \sigma \boldsymbol{\beta}(\mathbf{x}) \quad (9)$$

If we denote I the current flowing through S_{E1} and S_{E2} , this current can be calculated as:

$$I(\theta) = - \int_D \mathbf{J}(\mathbf{x}, \theta) \cdot \boldsymbol{\beta}(\mathbf{x}) dD \quad (10)$$

Since $\mathbf{J}(\mathbf{x}, \theta)$ is divergence free, $\mathbf{J}(\mathbf{x}, \theta)$ can be written as the curl of the vector potential $\mathbf{T}(\mathbf{x}, \theta)$. The equation to solve is then:

$$\text{curl}[\sigma^{-1}(\mathbf{x}, \theta) \text{curl } \mathbf{T}(\mathbf{x}, \theta)] = \tilde{0} \quad (11)$$

$\mathbf{T}(\mathbf{x}, \theta)$ has nonhomogenous boundary conditions on S_J . We therefore introduce a field $\mathbf{N}(\mathbf{x})$ satisfying (1) and (4) such that the flux of $\mathbf{N}(\mathbf{x})$ through the surface S_{E2} is equal to 1. It can be shown that the problem to solve is then:

$$\text{curl}[\sigma^{-1}(\mathbf{x}, \theta) \text{curl } \mathbf{T}'(\mathbf{x}, \theta)] = -I \text{curl}[\sigma(\mathbf{x}, \theta) \mathbf{N}(\mathbf{x})] \quad (12)$$

With \mathbf{T}' the unknown with homogeneous boundary conditions. The voltage $V(\theta)$ can be calculated using the following equation:

This work is supported by the IAP IPOLFE (Belgium government) and also by the French American Commission (Fulbright Program)

$$\mathbf{V}(\theta) = - \int_D \mathbf{E}(x, \theta) \cdot \mathbf{N}(x) dD \quad (13)$$

III. APPROXIMATION OF THE POTENTIALS USING DOUBLE ORTHOGONAL POLYNOMIALS

In the following, we detail the solution of the vector potential formulation. In the deterministic case, the vector potential \mathbf{T}^* is approximated using edge shape functions. Let us denote N_1 the set of edges, N_1^0 the sets of edges not located on S_j , $\mathbf{w}_a(x)$ the function associated with the edge a . The cardinal of the set N_1^0 will also be denoted N_1^0 . We will denote $W_1^0(D)$ the space generated by the functions associated with the edges belonging to N_1^0 . Functions in $W_1^0(D)$ have naturally homogeneous boundary conditions (3) on S_E .

Let us denote Ω the space of outcomes θ , consider the space of functions X depending on the random variables $\sigma_1(\theta), \dots, \sigma_M(\theta)$ such that the variance exists. To approximate this space, we will consider a set of P_{out} orthogonal polynomials $(H_i(\sigma_1(\theta), \dots, \sigma_M(\theta)))_{1 \leq i \leq P_{\text{out}}}$ (these polynomials will be denoted $H_i(\theta)$ to simplify the notations in the following):

$$E[H_i(\theta)H_j(\theta)] = 0 \text{ if } i \neq j \quad (14)$$

With $E[\cdot]$ the expectation. We will denote $W_{\text{Pout}}(\Omega)$ the space generated by this set of polynomials. Various methods have been proposed to define these polynomials. The most common polynomials used are the multivariate polynomial based on the Askey Scheme. We are looking for an approximation of the vector potential \mathbf{T}^* in the space $W_0^0(D) \otimes W_{\text{Pout}}(\Omega)$, so that \mathbf{T}^* can be written as:

$$\mathbf{T}^*(x, \theta) = \sum_{a=1}^{N_1^0} \sum_{j=1}^{P_{\text{out}}} T'_{ij} \mathbf{w}_a(x) H_j(\theta) \quad (15)$$

where T'_{ij} are the degrees of freedom we need to determine. Applying the Galerkin method to a weak form of (11) leads to $N_n^0 \times P_{\text{out}}$ linear equations:

$$\mathbf{S} \mathbf{T}^* = \mathbf{F} \quad (16)$$

where \mathbf{S} is a $(N_1^0 \times P_{\text{out}}) \times (N_1^0 \times P_{\text{out}})$ square matrix and \mathbf{F} a $(N_1^0 \times P_{\text{out}})$ vector. The vector \mathbf{T}^* is the vector of DoFs T'_{ij} . Using the expression **Erreur! Source du renvoi introuvable.** for the conductivity allows us to rewrite the equation system in a different way [3]. We denote the matrices \mathbf{S}_q and \mathbf{D}_q , the vectors \mathbf{F}_q and the Σ_q with the coefficients:

$$\begin{aligned} s_{ni}^q &= \left(\mathbf{I}_q(x) \mathbf{curl} \mathbf{w}_i(x), \mathbf{curl} \mathbf{w}_n(x) \right)_D \quad q \in [1, M] \quad (i, n) \in [1, N_1^0]^2 \\ d_{mj}^q &= E \left[\sigma^{-1}_q(\theta) H_j(\theta) H_m(\theta) \right] \quad q \in [1, M] \quad (j, m) \in [1, P_{\text{out}}]^2 \\ f_n^q &= \mathbf{I} \left(\mathbf{I}_q(x) \mathbf{N}(x), \mathbf{curl} \mathbf{w}_n(x) \right)_D \quad q \in [1, M] \quad n \in [1, N_1^0] \\ \Sigma_m^q &= E \left[\sigma^{-1}_q(\theta) H_m(\theta) \right] \quad q \in [1, M] \quad m \in [1, P_{\text{out}}] \end{aligned}$$

Then, using the Kronecker product \otimes , the system (16) can be written in the form [3]:

$$\mathbf{S} = \sum_{q=1}^M \mathbf{D}_q \otimes \mathbf{S}_q \quad \mathbf{F} = \sum_{q=1}^M \Sigma_q \otimes \mathbf{F}_q \quad (17)$$

The size of the linear system (17) can become very large even with a coarse mesh. If the random variables $\sigma_q(\theta)$ are independent, we can take advantage of this property by using double orthogonal polynomials $H_i(\theta)$ which enables us to get a

diagonal matrix \mathbf{D}_q . In that case, we have to solve P_{out} linear systems of size $N_1^0 \times N_1^0$ instead of the whole system (16). The multivariate double orthogonal polynomial $H_i(\theta)$ are constructed from $(p_{\text{out}}+1)$ univariate polynomials $h_q^n(\theta)$ of order p_{out} that satisfy the following relations:

$$E[h_q^n(\sigma_q[\theta]) h_q^m(\sigma_q[\theta])] = \delta_{nm} \quad (6.a)$$

$$E[\sigma_q[\theta] h_q^n(\sigma_q[\theta]) h_q^m(\sigma_q[\theta])] = 0 \text{ if } m \neq n \quad (6.b)$$

The polynomials are orthogonal to each other according to the first relation and the second relation is related to their double orthogonality property.

IV. APPLICATION

We consider a device with three subdomains where the conductivity is assumed to be random. We calculate the expectation of energy for both formulations and for 4 meshes (M1, M2, M3, M3). We consider an approximation of the first, second, third and fourth order ($p_{\text{out}}=1, 2, 3$ and 4) for the multivariate polynomials $H_i(\theta)$ which lead to the calculation of $P_{\text{out}}=8, 27, 64, 225$ "deterministic" problems. The evolution of the energy expectation as a function of the number of elements is given figure 1. The difference between the energy expectation given by both formulations is an image of the numerical error. Therefore, the closer the energies are, the more accurate the model. According to that statement, we can see that whatever the order of interpolation the error decreases with the number of elements. But we can see also that up to an order two the accuracy does not improve much.

Figure 1: Evolution of the energy expectation for both formulations and for different order of approximation and different meshes.

Abstract — Nonlinear eddy currents induced in a steel plate are formulated with the help of the boundary integral equations of minimum order for the calculation of three-dimensional eddy current problems. The integral equations for the nonlinear analysis are derived by considering nonlinear terms as fictitious sources. Since the periodic electromagnetic fields in the steel are distorted, these fields are expressed with the help of Fourier series, whose fundamental and harmonic fields are determined by solving the corresponding integral equations with the surface magnetic fields given as the boundary values. The internal and surface electromagnetic fields are obtained numerically one after the other until convergence by a simple iterative method.

I. INTRODUCTION

Nonlinear eddy current is formulated by considering nonlinear terms as fictitious sources in BEM. Recently an efficient nonlinear analysis by BEM has been proposed [1]. With the help of the rapid attenuation of the electromagnetic field in the conductor, the nonlinear eddy current is analyzed with negligible few additional computer-memory. Mayergoyz has proposed minimum order eddy current formulation [2]. Since the minimum order formulation gives the magnetic field in the conductor with only the surface electric current, the nonlinear eddy current may be formulated easily. Hence, employing the minimum order formulation and utilizing the procedure given in [1], we derive boundary integral equations to solve the nonlinear problems and check effectiveness.

II. FORMULATION OF EDDY CURRENT

A. Electromagnetic fields in steel

The electromagnetic fields in the steel with the conductivity σ satisfy Maxwell's equations as:

$$\nabla \times \mathbf{E}_i + \partial \mathbf{B}_i / \partial t = 0, \quad (1)$$

$$\nabla \times \mathbf{H}_i - \sigma \mathbf{E}_i = 0, \quad (2)$$

$$\nabla \cdot \mathbf{B}_i = 0, \quad (3)$$

$$\nabla \cdot \sigma \mathbf{E}_i = 0, \quad (4)$$

where \mathbf{E}_i is the electric field, \mathbf{H}_i is the magnetic field and \mathbf{B}_i is the magnetic flux density. The permeability is affected by the magnetic field. Thus, in order to apply Green's theorem, we introduce a fictitious permeability μ_f , and with the help of Fourier series we rewrite (1)-(4) for the k -th harmonic electromagnetic fields as:

$$\nabla \times \mathbf{E}_k + j\omega_k \mu_f \mathbf{H}_k = -j\omega_k (\mathbf{B}_k - \mu_f \mathbf{H}_k), \quad (5)$$

$$\nabla \times \mathbf{H}_k - \sigma \mathbf{E}_k = 0, \quad (6)$$

$$\nabla \cdot \mu_f \mathbf{H}_k = -\nabla \cdot (\mathbf{B}_k - \mu_f \mathbf{H}_k), \quad (7)$$

$$\nabla \cdot \sigma \mathbf{E}_k = 0. \quad (8)$$

where ω_k is the k -th angular frequency of the fundamental one ω , and the subscript k denotes the k -th harmonic. Hence, (5)-(8) are regarded as linear equations by considering the right sides of (5) and (7) to be fictitious magnetic current \mathbf{K}_k and charge m_k sources, which are defined as:

$$\mathbf{K}_k = j\omega_k (\mathbf{B}_k - \mu_f \mathbf{H}_k), \quad m_k = \nabla \cdot \mathbf{K}_k / (j\omega_k). \quad (9)$$

B. Magnetic field given by minimum order formulation

Following the minimum order formulation [2], we derive the integral equation for the nonlinear magnetic field inside the steel. From (5) and (6), we get

$$\nabla \times \nabla \times \mathbf{H}_k - j\omega_k \mu_f \sigma \mathbf{H}_k = \sigma \mathbf{K}_k. \quad (10)$$

Green's theorem gives the integral representation of \mathbf{H}_k with the subscript p denoting an observation point P_o as:

$$\mathbf{H}_{kp} = \mathbf{H}_{kep} - \int_S \mathbf{J}_{sf} \times \nabla G_k dS \quad (11)$$

where S is the surface of the steel, \mathbf{J}_{sf} is the fictitious surface electric current, G_k is fundamental solution of (10) defined as $G_k = \exp(-\gamma_k r) / (4\pi r)$ with $\gamma_k = \sqrt{j\omega_k \mu_f \sigma}$ and the distance r from an integration point on S to P_o , and \mathbf{H}_{kep} is the magnetic field produced by \mathbf{K}_k at P_o defined as:

$$\mathbf{H}_{kep} = -\int_V \left[\sigma \mathbf{K}_k G_k - \frac{\nabla \cdot \mathbf{K}_k}{j\omega_k \mu_f} \nabla G_k \right] dV \quad (12)$$

where V is the volume of the steel.

C. Nonlinear eddy current formulation

The magnetic field \mathbf{H}_o at an observation point P_o in the free space is given from scalar potential Φ produced by the fictitious surface magnetic charge m_{sf} , see [2]:

$$\mathbf{H}_{op} = -\nabla \Phi = \mathbf{H}_{ep} + \int_S \frac{m_{sf}}{\mu_0} \nabla G_o dS \quad (13)$$

where $G_o = 1/(4\pi r)$ and \mathbf{H}_{ep} is the exciting magnetic field at P_o .

The boundary integral equations for nonlinear eddy current analysis are derived as follows. Firstly, we shall obtain the magnetic fields, \mathbf{H}_i and \mathbf{H}_o , at an observation point P_o on the surface of the inside and outside steel by employing (11) and

(13), respectively. Next, we obtain the tangential magnetic fields, H_{it} and H_{ot} , and also the normal magnetic flux densities, B_{in} and B_{on} . Applying the boundary conditions, we get the surface integral equations to analyze the nonlinear eddy current. From the continuity of the tangential magnetic fields, $H_{it}=H_{ot}$, we get

$$-\frac{\mathbf{J}_{sf}}{2} + \mathbf{n}_p \times \int_S \left[\mathbf{J}_{sf} \times \nabla G_k + \frac{m_{sf}}{\mu_0} \nabla G_o \right] dS = -\mathbf{n}_p \times [\mathbf{H}_{oep} + \mathbf{H}_{kep}] \quad (14)$$

and from the continuity of the normal magnetic flux densities, $B_{in}=B_{on}$, we get

$$\frac{m_{sfp}}{2\mu_0} + \mathbf{n}_p \cdot \int_S \left[\frac{\mu_f}{\mu_0} \mathbf{J}_{sf} \times \nabla G_k + \frac{m_{sf}}{\mu_0} \nabla G_o \right] dS = -\mathbf{n}_p \cdot \left[\mathbf{H}_{oep} + \frac{\mu_f}{\mu_0} \mathbf{H}_{kep} \right]. \quad (15)$$

III. NONLINEAR EDDY CURRENT ANALYSIS

We shall solve the eddy current induced in a steel plate when the plate is placed in the uniform magnetic field. The plate dimension is much larger than the skin depth and its thickness is 0.5 cm. The conductivity is $\sigma=64850$ S/cm and the relation between \mathbf{B}_i and \mathbf{H}_i is given as:

$$\mathbf{B}_i = \frac{1000}{0.194 + 0.0734|H_i|} \mu_o \mathbf{H}_i \quad [\text{Wb/cm}^2]. \quad (16)$$

The strength of uniform magnetic field parallel to the plate surface is given as function of time t [s] as:

$$H_{oep} = 20\sqrt{2} \sin(100\pi t) \quad [\text{A/cm}]. \quad (17)$$

As the electromagnetic fields are attenuated rapidly in conductive materials such as steel, (14) is rewritten by taking the same procedure given in [1] as:

$$-\frac{\mathbf{J}_{s1fp}}{2} + \frac{\mathbf{J}_{s2f}}{2} e^{-\gamma_k d} - \frac{\sigma}{2\gamma_k} \int_0^d \mathbf{n}_{1p} \times \mathbf{K}_k e^{-\gamma_k z} dz = -\mathbf{n}_{1p} \times \mathbf{H}_{oe1p} \quad (18)$$

$$-\frac{\mathbf{J}_{s2fp}}{2} + \frac{\mathbf{J}_{s1f}}{2} e^{-\gamma_k d} - \frac{\sigma}{2\gamma_k} \int_0^d \mathbf{n}_{2p} \times \mathbf{K}_k e^{-\gamma_k(d-z)} dz = -\mathbf{n}_{2p} \times \mathbf{H}_{oe2p} \quad (19)$$

where the subscripts 1 and 2 denote the face-to-face plate surfaces shown in Fig.1, z is the distance from S_1 and d is the plate thickness. Substitution of (12) into (11) leads to:

$$\mathbf{H}_{kp} - \frac{\sigma}{2\gamma_k} \int_0^d \mathbf{K}_k e^{-\gamma_k|z-z_p|} dz = \frac{\mathbf{J}_{s1f} \times \mathbf{n}_1}{2} e^{-\gamma_k z_p} + \frac{\mathbf{J}_{s2f} \times \mathbf{n}_2}{2} e^{-\gamma_k(d-z_p)} \quad (20)$$

Since the fictitious surface electric currents \mathbf{J}_{sf1p} , \mathbf{J}_{sf2p} are affected by the fictitious magnetic current \mathbf{K}_k , we can't adopt them as the boundary values. And so, regarding the boundary values as $\mathbf{J}_{s1p}=\mathbf{n}_1 \times \mathbf{H}_{oe1p}$ and $\mathbf{J}_{s2p}=\mathbf{n}_2 \times \mathbf{H}_{oe2p}$, which are defined by the actual surface magnetic fields on the plate-space boundaries, we solve (20) by modifying (18) and (19) as:

Fig. 1. Actual surface electric and magnetic currents defined respectively as $\mathbf{J}_s=\mathbf{n} \times \mathbf{H}_s$ and $\mathbf{K}_s=-\mathbf{n} \times \mathbf{E}_s$ with surface magnetic and electric fields \mathbf{H}_s and \mathbf{E}_s .

Fig.2. Computed results of magnetic flux density in steel plate

$$\frac{\mathbf{J}_{s1fp}}{2} - \frac{\mathbf{J}_{s2f}}{2} e^{-\gamma_k d} + \frac{\sigma}{2\gamma_k} \int_0^d \mathbf{n}_1 \times \mathbf{K}_k e^{-\gamma_k z} dz = \mathbf{J}_{s1p} \quad (21)$$

$$\frac{\mathbf{J}_{s2fp}}{2} - \frac{\mathbf{J}_{s1f}}{2} e^{-\gamma_k d} + \frac{\sigma}{2\gamma_k} \int_0^d \mathbf{n}_2 \times \mathbf{K}_k e^{-\gamma_k(d-z)} dz = \mathbf{J}_{s2p} \quad (22)$$

where \mathbf{J}_s with the subscript 1 or 2 is the actual surface electric current shown in Fig.1 defined with the magnetic field \mathbf{H}_s as:

$$\mathbf{J}_{sp} = \mathbf{n}_p \times \mathbf{H}_{sp} = \mathbf{n}_p \times \left[\mathbf{H}_{oep} + \int_S \frac{m_{sf}}{\mu_0} \nabla G_o dS \right]. \quad (23)$$

In the numerical analysis, the plate thickness is divided into 20 virtual volume elements (layers). Fig.2 shows the computed results of the magnetic flux density inside the steel plate at 0.5 mm (shown by \circ) and 1 mm (shown by Δ) from the surface with the solid lines obtained by the method given in [1]. The magnetic flux density obtained from sinusoidal magnetic filed on the surface is shown also by the solid line.

IV. CONCLUSIONS

Following the minimum order eddy current formulation, we have derived the boundary integral equations and solved the eddy current induced in the thin steel plate to check adequacy of the nonlinear formulation. The computed results are almost the same as those by the formulation given in [1], which have been confirmed to give adequate solutions. The analysis of the full model is given in the full paper.

Abstract—A perturbation method for the $T - \Omega$ geometric formulation to solve eddy-current problems is introduced. The proposed formulation is applied to the feasibility design of a non-destructive evaluation device suitable to detect “long” longitudinal flaws in hot steel bars.

Index Terms—Cell Method (CM), Finite Integration Technique (FIT), Discrete Geometric Approach (DGA), eddy-currents.

I. INTRODUCTION

The so called “Discrete Geometric Approach” (DGA) [1], similarly to the Finite Integration Technique (FIT) [2] or the Cell Method [3], allows to solve Maxwell equations in an alternative way with respect to the classical Galerkin method in Finite Elements.

The domain of interest D of the eddy-current problem, has been partitioned into a source region D_s and in a passive conductive region D_c . The complement of $D_c \cup D_s$ in D represents the air region D_a .

We cover the domain D with a tetrahedral mesh represented by the simplicial complex \mathcal{K} . The barycentric subdivision is used to obtain the interlocked dual complex \mathcal{B} [1]. For the simplicial complex \mathcal{K} , we denote by \mathbf{G} the incidence matrix between edges e and nodes n , by \mathbf{C} between faces f and edges e and by \mathbf{D} between cells v and faces f . The matrices $\mathbf{G}_{\mathcal{B}} = \mathbf{D}^T$, $\mathbf{C}_{\mathcal{B}} = \mathbf{C}^T$ and $\mathbf{D}_{\mathcal{B}} = -\mathbf{G}^T$ describe the mutual interconnections of the dual barycentric complex \mathcal{B} .

Next, we consider the integrals of the field quantities with respect to the oriented geometric elements of the mesh, yielding the Degrees of Freedom (DoF) arrays [3]:

- Φ is the array of magnetic induction fluxes associated with $f_{\mathcal{B}} \in D$; \mathbf{F} is the array of magnetomotive forces (m.m.f.s) associated with $e \in D$; \mathbf{I} is the array of induced electric currents associated with $f \in D_c$; In D_s the array \mathbf{I}_s of known source currents is defined; \mathbf{U} is the array of e.m.f.s on edges $e_{\mathcal{B}} \in D$.
- \mathbf{T} is the array of the circulations of the electric vector potential T along $e \in D_c$. In D_s the array \mathbf{T}_s of impressed electric vector potential is introduced; Ω is the array of magnetic scalar potential Ω associated to the nodes $n \in D$.

Using the incidence matrices, Maxwell’s laws can be written exactly as balance equations between Dofs arrays as

$$\mathbf{G}^T \Phi = 0 \quad (\text{a}), \quad \mathbf{C}^T \mathbf{U} = -i\omega \Phi \quad (\text{b}), \quad (1)$$

where (1a) is the Gauss’ magnetic law at discrete level and (1b) is the Faraday’s Law. The array \mathbf{T} is defined such that the Ampere’s balance law $(\mathbf{C}\mathbf{F})_f = (\mathbf{I})_f$, $\forall f \in D_c$, holds

$$\begin{aligned} (\mathbf{F})_e &= (\mathbf{G}\Omega)_e & \forall e \in D_a, \\ (\mathbf{F})_e &= (\mathbf{G}\Omega)_e + (\mathbf{T}_s)_e & \forall e \in D_s, \\ (\mathbf{F})_e &= (\mathbf{G}\Omega)_e + (\mathbf{T})_e & \forall e \in D_c - \partial D_c. \end{aligned} \quad (2)$$

In fact one has $\mathbf{C}_c \mathbf{T} = \mathbf{I}$ and $\mathbf{C}_s \mathbf{T}_s = \mathbf{I}_s$, where the subscripts c and s refer to the corresponding sub-array or sub-matrix relative to geometric elements in D_c and D_s respectively. This implies that the continuity law $\mathbf{D}_c \mathbf{I} = 0$, where \mathbf{D}_c is the sub-matrix of \mathbf{D} relative to the volumes and faces in D_c , is identically satisfied, since $\mathbf{D}\mathbf{C} = 0$. The interface conditions that avoid the current flow outside the region D_c are taken into account by considering $T = 0$, $\forall e \in \partial D_c$. In this way, in fact, $(\mathbf{I})_f = 0$, $\forall f \in \partial D_c$ holds.

The discrete counterpart of the constitutive laws can be written using the constitutive matrices [3]

$$\Phi = \mu \mathbf{F} \quad \text{in } D \quad (\text{a}), \quad \mathbf{U}_c = \rho \mathbf{I} \quad \text{in } D_c \quad (\text{b}). \quad (3)$$

The square matrices μ and ρ can be efficiently calculated in a pure geometric way for a mesh composed by tetrahedra as described in [6].

For sake of simplicity, D_c is considered as a union of simply-connected conductive regions. In case of multiply-connected regions, the m.m.f.s along cycles contained in D_a cannot be described completely by the magnetic scalar potential alone. In this case the *thick cuts* [5] have to be found and for each thick cut a non-local Faraday’ law [5] has to be written. One additional unknown per thick cut is added and all of them represent a set of linearly independent currents in D_c .

By substituting (3a), (3b) and (2) in (1a), the algebraic equations corresponding to the nodes in D are obtained. By substituting (3a), (3b) and (2) in (1b) the algebraic equations corresponding to edges in D_c are derived. The final algebraic system, having \mathbf{T} and Ω as unknowns Dofs arrays, can be written as

$$\begin{aligned} (\mathbf{G}^T \mu \mathbf{G} \Omega)_n &= 0 & \forall n \in D_a, \\ (\mathbf{G}^T \mu \mathbf{G} \Omega)_n &= -(\mathbf{G}_s^T \mu_s \mathbf{T}_s)_n & \forall n \in D_s, \\ (\mathbf{G}^T \mu \mathbf{G} \Omega)_n + (\mathbf{G}_c^T \mu_c \mathbf{T})_n &= 0 & \forall n \in D_c, \\ (\mathbf{C}_c^T \rho \mathbf{C}_c \mathbf{T})_e + i\omega (\mu_c (\mathbf{T} + \mathbf{G}_c \Omega_c))_e &= 0 & \forall e \in D_c. \end{aligned} \quad (4)$$

The system (4) is singular and, to solve it, a conjugate gradient method without gauge condition is used.

II. DISCRETE PERTURBATION METHOD FOR $T - \Omega$

Let us suppose that the resistivity of a tetrahedron $v_k \in D_c$ is perturbed from ρ to $\rho + \rho^p$, where ρ^p is a perturbation of the resistivity due to for example a defect in the conductive domain D_c ; this configuration is the defected configuration denoted with a superscript d . From (3b), the e.m.f. associated with edge $e \in v_k$ in the unperturbed configuration is $(\mathbf{U}_c)_e = (\rho \mathbf{I})_e$, where \mathbf{I} is the array of eddy currents in D_c in the unperturbed configuration; it can be equivalently written as

$$(\mathbf{U}_c)_e = ((\rho + \rho^p) \mathbf{I} - \rho^p \mathbf{I})_e = ((\rho + \rho^p) \mathbf{I} + \mathbf{U}_g)_e, \quad (5)$$

where the term $\mathbf{U}_g = -\rho^p \mathbf{I} = -\rho^p \mathbf{C}_c \mathbf{T}$ can be interpreted as an array of compensation e.m.f. generators connected in series to each primal edge e of v_k . By applying the superposition of effects, we consider the following configurations, see Fig. 1:

- \mathbf{I}_s is active, \mathbf{U}_g is switched off. This is the defected configuration, where the resistivity is $\rho + \rho^p$ and the eddy currents \mathbf{I}^d account for the presence of the defect; we have that $\mathbf{U}_c^d = (\rho + \rho^p) \mathbf{I}^d$ holds, where \mathbf{U}_c^d is the array of e.m.f.s in this configuration.
- \mathbf{I}_s is switched off, \mathbf{U}_g is active. This is the perturbed configuration, where $\mathbf{U}_c^p = (\rho + \rho^p) \mathbf{I}^p + \mathbf{U}_g$ holds, where \mathbf{U}_c^p , \mathbf{I}^p are the corresponding arrays of e.m.f.s and currents in this configuration.

Fig. 1. Superposition of effects for the tetrahedron v_k .

A. Analysis of the perturbed configuration

From the above described superposition of effects, an eddy-current analysis of the perturbed configuration, yields e.m.f.s or currents arrays which are opposite to the difference of e.m.f.s or currents arrays between the defected and the unperturbed configuration. For edges belonging to tetrahedra v_k where resistivity has been changed, we introduce the e.m.f. generators $\mathbf{U}_g = \rho_p \mathbf{C} \mathbf{T}$ in the equations in (4) associated with those edges, obtaining

$$\mathbf{C}^T (\rho + \rho_p) \mathbf{C} \mathbf{T}_p + i\omega \boldsymbol{\mu} (\mathbf{T}_p + \mathbf{G} \boldsymbol{\Omega}_p) = \mathbf{C}^T \rho_p \mathbf{C} \mathbf{T}. \quad (6)$$

III. APPLICATION TO NON-DESTRUCTIVE TESTING

The application concerns the design of a device for the detection of long longitudinal defects that can be present during the hot mill rolling process of the steel bars with circular cross-section [7].

The geometry of the problem, depicted in Fig. 2 and described in detail in [7], consists of a conducting steel bar,

Fig. 2. Geometry of the problem and the comparison on the perturbation in the induced e.m.f. due to the defect over the receiving coils between the proposed formulation and an integral formulation.

modeled as a conducting cylinder D_c . A longitudinal perfectly insulating defect is assumed, 0.5 mm deep from the surface of the cylinder and 0.2 mm thick.

A mesh consisting of about 1 million of tetrahedra is used for the computations. The value of the perturbation in the induced voltages over the receiving coils due to the defect calculated with the proposed formulation is compared to the ones computed with the CARIDDI code [8], which implement an integral formulation.

IV. CONCLUSIONS

The perturbation method, reducing the cancellation error, produces accurate results also for small variations in the solution. This is especially required when the tool is used as a forward solver for an inverse problem. Moreover the method yields also a considerable speed-up: The mesh used in the perturbed problem can in fact be reduced [9], considering only a limited region surrounding the defect, at a small fraction of the initial mesh.

Abstract — Steel tubes are used in the heat exchanger in the petrochemical plant. Since these steel tubes are grouped in a bundle by the support steel plate (the baffle), it is necessary to inspect the existence of defects from the inside of each tube. In these steel tubes, the corrosion or the defects are generated by the friction with baffle at the outer side of steel tube.

In this paper, problems in applying the ac flux leakage testing method using an inner coil of low exciting frequency (about 60Hz) for the inspection of the outer side defect on steel tube with baffle are examined using 3-D nonlinear FEM. Moreover, the detecting property of the magnetic noise is investigated by 3-D FEM considering the non-uniformity of the permeability and conductivity in the steel tube and the baffle.

I. INTRODUCTION

The steel tubes of heat exchanger in petrochemical plant etc. are stored as a bundle. Moreover, these steel tubes are covered with the steel plates (baffle). In a heat exchanger, a large friction is generated between the baffle and the steel tube by the flow of the fluid inside or outside of the tube. Therefore, the corrossions or the defects are generated on the outer side of the steel tubes. It is necessary to inspect outer side defects on these tubes from the inside of the tube.

In this paper, the ac flux leakage testing method using an inner coil at a low frequency for detecting outer side defects on steel tube with baffle is proposed [1]. Since the permeability and conductivity of the steel tube and the baffle are usually non-uniform, the signal of the electromagnetic inspection may contain a large magnetic noise [2]. Then, the property of the inspection method of the outer side defect on the steel tube with baffle, and the effect of the non-uniformity of the permeability and conductivity on the large magnetic noise are investigated using the 3-D nonlinear FEM. In addition, the experimental verification is also carried out.

II. NON-UNIFORMITY OF PERMEABILITY AND CONDUCTIVITY IN STEEL TUBE AND BAFFLE

The non-uniformity of permeability and conductivity in the steel tube (SUS430) and baffle (SS400) were measured. Fig.1 shows the maximum non-uniformity of permeability in the steels of SUS430 and SS400, respectively. The dispersion rate ε_μ of relative permeability μ_r is defined by

$$\varepsilon_\mu = \frac{\mu_r(\text{each position}) - \mu_r(\text{average})}{\mu_r(\text{average})} \times 100 \quad (\%). \quad (1)$$

The figure denotes that the non-uniformity (ε_μ) of permeability is increased when the magnetic field is small. When the magnetic field is increased, both ε_μ s are decreased, because the direction of each magnetic moment becomes nearly the same. The non-uniformity of conductivity in SUS430 and SS400 is measured using two column specimens (diameter: 9mm, length: 2m) by the double bridge circuit. The conductivity of the column specimen between two points of 10cm distance was measured. The dispersion rate ε_σ of conductivity σ is defined by

$$\varepsilon_\sigma = \frac{\sigma(\text{each position}) - \sigma(\text{average})}{\sigma(\text{average})} \times 100 \quad (\%). \quad (2)$$

Fig.2 shows the non-uniformity of conductivity at each steel position, respectively. The figure denotes that the non-uniformities of conductivity of SUS430 and SS400 are within about 1.5%, respectively.

III. MODELS AND METHOD OF ANALYSIS

Fig.3 shows the inspection model for outer side defect of steel tube with baffle. The proposed inner inspection probe is also shown in the figure. The inspection probe is composed of a yoke, an exciting coil and a search coil for detecting the perpendicular component $|B_x|$ of leakage flux due to the outer side defect. The outer diameter of the inspection steel tube is 25mm, and the thickness is 1.5mm. B-H curves of steel tube (SUS430) and baffle (SS400) are shown in Fig.4. These curves are the average of non-uniform curves of which the non-uniformity of permeability is shown in Fig.1. The outer

Fig.1. Dispersion rate ε_μ of permeability in steels (SUS430 and SS400).

2. Quasi-Static Fields

Fig.2. Dispersion rate ε_σ of conductivity in steels (SUS430 and SS400).

side defect is a circumferential one. The defect width (z-direction, Dw) and the defect depth (x-direction, Dd) of the steel tube are 2mm and 0.5mm, respectively. The distance (Lift-off, Lo) between the search coil and the inner surface of steel tube is 0.2mm. The frequency is chosen as 60Hz. The exciting current is 5A(rms). The magnetization curve and the conductivity of steel tube and baffle are used in the 3-D

Fig.3. Inspection model for outer side defect of steel tube with the baffle (60Hz, 5A(rms)).

Fig.4. B-H curves of baffle (SS400) and steel tube (SUS430).

Fig.5. Dispersion of μ_r -H curves (SUS430).

Fig.6. Detected $|B_x|$ (60Hz, 5A).

nonlinear FEM using the 1st order hexahedral edge element. The example of non-uniformity of magnetic characteristic of steel tube (SUS430) is shown in μ_r -H curve of Fig.5. As for the dispersion ε_μ of the steel tube (within $\pm 21\%$) and the baffle (within $\pm 47\%$), twenty curves with initial permeability are created, respectively. A curve is chosen at random among twenty μ_r -H curves following the normal random number (standard deviation: 5.0), and the selected curve is given to each finite element in the steel tube region. Similarly, the conductivity is generated according to a normal random number (standard deviation : 0.5 ($\times 10^6$)).

Fig.6 shows the distribution of the calculated value of $|B_x|$ in a search coil when there is the steel tube with baffle. Moreover, the experimental investigation is also carried out. $|B_x|$ is obtained by moving the inspection probe in the z-direction inside the steel tube. The calculated result is in agreement with measurement. The figure shows that each peak value is obtained near two edges of an outer side defect. Moreover, the magnetic noise from non-uniformity of permeability and conductivity is generated about 1×10^{-4} T. Since the signal from the outer side defect is larger than the magnetic noise about 10 times, the outer side defect in the steel tube with baffle is detectable using this proposed inspection method. In the full paper, the optimal magnetization condition for the inspection is examined using the 3-D edge-based hexahedral FEM. In addition, the experimental verification is also carried out.

IV. CONCLUSIONS

The results obtained are summarized as follows:

- (1) The ac flux leakage testing method using an inner coil at the low frequency (about 60Hz) is possible for detecting the outer side defect in steel tube with support steel plate (baffle).
- (2) In this inspection method, the magnetic noise due to the non-uniformity of permeability and conductivity in the steel tube and the existence of baffle is negligible.

Discontinuous Galerkin method with \mathbf{T}, Φ - Φ Formulation for 3D eddy current problems

Stefan Außerhofer and Oszkár Bíró

Institute for Fundamentals and Theory in Electrical Engineering
Graz University of Technology, Austria
Email: stefan.ausserhofer@tugraz.at

Abstract—In this paper a method is proposed where discontinuous shape functions are used in eddy current problems to describe the quantities in the conducting region. Using these shape functions, the application of Galerkin’s method leads to a block-diagonal mass-matrix. Hence, if an explicit time stepping method is used, the solution of the first-order differential equation system can be solved with minimal computational effort. In the non-conducting region traditional continuous basis functions are used. The eddy current problem is formulated with the current vector potential \mathbf{T} and the reduced magnetic scalar potential Φ . In the two domains different time steps are used whereas the time steps in the conducting region have to be chosen small enough to ensure stability.

Index Terms—Discontinuous Galerkin method, Explicit time stepping, Time domain analysis, Eddy currents

I. INTRODUCTION

Discontinuous shape functions are used for several applications in technical science. One motivation for using these basis functions is the ease of handling non-matching meshes (e.g. [1]) and another reason is the ease of solving large algebraic equation systems if an explicit time stepping is used (e.g. [2]). Since the mass matrix becomes block-diagonal in the latter case, only small blocks of the mass-matrix have to be inverted which needs less computational effort. In [3] and [4] the Discontinuous Galerkin Method was introduced for two dimensional eddy current problems using the magnetic vector potential \mathbf{A} .

In this paper, the method is applied to the \mathbf{T}, Φ - Φ formulation and similarly to [3] and [4], discontinuous shape functions are used in the conducting region only because this is the region with a diffusion equation. The support of the basis functions belonging to a finite element in the conducting region is limited to this element only. Therefore, the mass-matrix in the eddy current region becomes block-diagonal and, to take advantage of this structure, explicit time stepping is used. This avoids having to solve the notoriously ill-conditioned system resulting from the discretization of the diffusion equation valid in eddy current regions. Due to the explicit time stepping, the time steps have to be chosen small enough to avoid instability.

In the eddy current free domain, where the fields are static, traditional basis functions are used which leads to a well-conditioned equation system. The time step in this region can be chosen higher compared to the time step in the

conducting domain. The combination of the two methods leads to potentially fast solutions for eddy current problems.

II. \mathbf{T}, Φ - Φ FORMULATION AND GALERKIN’S EQUATIONS

The problem is split up into two regions whereas the conducting region is denoted by Ω_c with boundary $\partial\Omega_c$ and the non-conducting region is denoted by Ω_n with boundary $\partial\Omega_n$. The interface between the two regions is Γ_{nc} .

A. Conducting region Ω_c

Multiplying Faraday’s law by \mathbf{N}_i and multiplying the time derivative of $\text{div}\mathbf{B} = 0$ by f_i , integrating over the k^{th} finite element and summing over all k yield:

$$\sum_k \int_{\Omega_k} \text{curl}\mathbf{N}_i \cdot \rho\mathbf{J}d\Omega - \sum_k \int_{\partial\Omega_k} (\mathbf{N}_i \times \rho\mathbf{J}) \cdot \mathbf{n}d\Gamma = - \sum_k \int_{\Omega_k} \frac{\partial\mu\mathbf{H}}{\partial t} d\Omega, \quad (1)$$

$$- \sum_k \int_{\Omega_k} \text{grad}f_i \cdot \frac{\partial\mu\mathbf{H}}{\partial t} d\Omega + \sum_k \int_{\partial\Omega_k} f_i \frac{\partial\mu\mathbf{H}}{\partial t} \cdot \mathbf{n}d\Gamma = 0. \quad (2)$$

In (1) and (2) the material equations $\mathbf{E} = \rho\mathbf{J}$ and $\mathbf{B} = \mu\mathbf{H}$ have been used, where ρ is the resistivity and μ is the permeability of the conductive material. \mathbf{N}_i and f_i in (1) and (2) denote the basis functions to approximate the potentials \mathbf{T} and Φ :

$$\mathbf{T} \approx \mathbf{T}_n = \sum_j t_j \mathbf{N}_j, \quad (3)$$

$$\Phi \approx \Phi_n = \sum_j \phi_j f_j. \quad (4)$$

Since $\text{div}\mathbf{J} = 0$ and $\text{curl}\mathbf{H} = \mathbf{J}$, these two potentials can be introduced as

$$\mathbf{J} = \text{curl}(\mathbf{T} + \mathbf{T}_0) \quad \text{and} \quad (5)$$

$$\mathbf{H} = \mathbf{T} + \mathbf{T}_0 - \text{grad}(\Phi), \quad (6)$$

where $\mathbf{J}_0 = \text{curl}\mathbf{T}_0$ represents the imposed current density and, therefore, \mathbf{T}_0 is known.

From (1) and (2), a first-order differential equation system can be obtained if \mathbf{J} and \mathbf{H} are replaced by (5) and (6) and if the approximations (3) and (4) are used:

$$\mathbf{M} \cdot \begin{Bmatrix} \dot{t}_i \\ \dot{\phi}_i \end{Bmatrix} + \mathbf{S} \cdot \begin{Bmatrix} t_i \\ \phi_i \end{Bmatrix} = \mathbf{f}. \quad (7)$$

In (7), \mathbf{M} is the mass-matrix, \mathbf{S} is the stiffness-matrix and \mathbf{f} includes terms with the known quantity \mathbf{T}_0 . Using appropriate basis functions (see Section III), the mass-matrix can be made block-diagonal.

B. Non-conducting region Ω_n

In the non-conducting region there are no induced currents and, therefore, only the known vector potential \mathbf{T}_0 and the unknown scalar potential Φ need to be introduced:

$$\mathbf{J}_0 = \text{curl}\mathbf{T}_0, \quad (8)$$

$$\mathbf{H} = \mathbf{T}_0 - \text{grad}(\Phi). \quad (9)$$

As a differential equation, the time derivative of $\text{div}\mathbf{B} = 0$ is used. The unknown scalar potential Φ in Ω_n is approximated by traditional continuous basis functions f_j (see Section III).

III. BASIS FUNCTIONS \mathbf{N}_j AND f_j

A. Conducting region Ω_c

The basis functions \mathbf{N}_j and f_j in Ω_c are chosen so that each of the basis functions is non-zero in one finite element only and zero in all other elements:

$$\mathbf{N}_j^k(\mathbf{r}) = \mathbf{0} \text{ if } \mathbf{r} \notin \Omega_k \text{ for } j = 1, \dots, N_k, \quad (10)$$

$$f_j^k(\mathbf{r}) = 0 \text{ if } \mathbf{r} \notin \Omega_k \text{ for } j = 1, \dots, M_k. \quad (11)$$

In (10) N_k is the number of edge basis functions \mathbf{N}_j^k for the k^{th} finite element Ω_k and in (11) M_k is the number of node basis functions f_j^k for the finite element Ω_k . Using these functions, the mass-matrix in (7) becomes block-diagonal with one block for each finite element. The finite elements are coupled by the surface integrals in (1).

B. Non-conducting region Ω_n

In Ω_n traditional continuous basis functions are used, i.e. each basis function f_j belonging to a global node is non-zero in all elements sharing this node and zero in all other elements.

IV. TIME DISCRETIZATION AND COUPLING

For the two regions Ω_c and Ω_n , two different time steps are used. The time step in Ω_c is denoted by Δt_c and in Ω_n the time step is Δt_n . To discretize the differential equation system in Ω_c an explicit time scheme is used:

$$\dot{\mathbf{x}} \approx \frac{\mathbf{x}_{k+1} - \mathbf{x}_k}{\Delta t_c}, \quad (12)$$

$$\mathbf{M} \cdot \frac{\mathbf{x}_{k+1} - \mathbf{x}_k}{\Delta t_c} + \mathbf{S} \cdot \mathbf{x}_k = \mathbf{f}. \quad (13)$$

The index k in (12) and (13) refers to the k^{th} time step and \mathbf{x} stands for the vector of the unknown variables t_i and ϕ_i in (3) and (4). In (13) the solution at step $k+1$ can be obtained from the previous solution at time step k by inverting \mathbf{M} . As a consequence of the block structure of \mathbf{M} , this can be easily done. However, the explicit scheme requires smaller time steps Δt_c in order to ensure stability. The time step in Ω_n can be chosen larger since the fields in the non-conducting region have a static character. The two time steps have been chosen

so, that the condition $\Delta t_n = L \Delta t_c$ holds. This means that the time step Δt_n is subdivided into L smaller time steps Δt_c .

For the coupling of the two domains it is assumed that the boundary conditions on Γ_{nc} for the differential equation in Ω_c are given by the boundary values obtained from the solution in Ω_n . The solution in Ω_n and hence the boundary values on Γ_{nc} are available at the time steps:

$$t = r_n \Delta t_n \quad (r_n = 1, 2, 3, \dots). \quad (14)$$

To calculate the solution in Ω_c for the time instant

$$t = r_n \Delta t_n + r_c \Delta t_c \quad (r_c = 0, \dots, L), \quad (15)$$

the boundary values from the solution in Ω_n at the time step $t = r_n \Delta t_n$ are used.

The conditions on the surface Γ_{nc} are the continuity of the normal component of \mathbf{B} and the continuity of the tangential component of \mathbf{H} :

$$\mathbf{B}_c \cdot \mathbf{n}_c + \mathbf{B}_n \cdot \mathbf{n}_n = 0, \quad (16)$$

$$\mathbf{H}_c \times \mathbf{n}_c + \mathbf{H}_n \times \mathbf{n}_n = 0. \quad (17)$$

In (16) and (17), \mathbf{n}_c and \mathbf{n}_n denote the normal vector out of the region Ω_c and Ω_n .

V. CONCLUSION

The combination of using discontinuous basis functions in the conducting region and continuous ones in the non-conducting region leads to potentially fast solutions for eddy current problems. The advantage of having a block-diagonally structured mass-matrix and using an explicit time stepping permits to solve the equation system very fast because only small blocks of the mass-matrix have to be inverted. The disadvantage of the method is the higher number of degrees of freedom in the eddy current domain and the higher number of time steps.

A possibility to improve the stability of the method is to introduce a term which penalizes the continuity of the potentials on the interface between finite elements in the conducting domain. This approach will be described in the full paper.

A Mesh-Free Model of Eddy-Current Losses for 2D Analysis of Ferromagnetic Laminations

Paavo Rasilo, Antero Arkkio

paavo.rasilo@tkk.fi

Abstract — A numerical model to include the effect of eddy-currents and associated losses into time-discretized 2D finite-element analysis of ferromagnetic laminations is presented. The flux-density distribution in the lamination is approximated by a truncated Fourier cosine series, and the corresponding components for the 2D nodal values of the vector potential are solved at each time step from the resulting system of equations. The eddy-current losses obtained with the model are compared with losses calculated by solving the 1D diffusion equation for the flux density in the lamination.

I. INTRODUCTION

2D finite-element (FE) analysis is commonly used in the design and analysis of electrical machines with laminated iron cores. One of the major simplifying assumptions of the 2D model is that the eddy-currents in the core regions are assumed to be zero and have thus no effect on the magnetic field to be solved. Although this assumption may be reasonable for the axial component of the currents in thin laminations, the currents flowing parallel to the cross-sectional plane of the machine may have a damping effect on the inducing field, especially at higher frequencies. Thus a method to include the eddy-current effects into the field analysis is needed for accurate loss calculation of variable-speed drives in which high-frequency flux-density harmonics commonly occur.

The in-plane eddy-currents in the laminations can be included into the 2D field calculation by coupling the 2D model to a 1D FE model of the lamination [1]. However, this approach may encounter convergence problems, especially if Newton-Raphson iteration is used, since analytical formulation of the equations needed in the iteration is difficult.

Another method to include eddy currents in laminations into the field calculation was presented in [2]. Originally implemented for homogenization of lamination stacks in 3D FE calculation, the method was based on approximating the flux-density distribution in the lamination by orthogonal polynomial basis functions, without actually discretizing the lamination. The coefficients of these functions were solved from a system of equations resulting from the error between the actual and approximated magnetic field strengths. These equations are relatively easy to form analytically and should thus lead to better convergence.

In this paper, a modified version of the latter method is applied to include the effect of eddy-currents in non-hysteretic ferromagnetic laminations into 2D FE calculation. The lamination model and the 2D model are presented, and the results of calculation are compared with a 1D FE lamination model.

II. THE LAMINATION MODEL

The mesh-free model of the flux-density distribution in a lamination with thickness d and conductivity σ is developed in detail in [1]. The time-dependent behavior of the magnetic field is described by the system of N_F equations

$$\begin{bmatrix} h_s(t) \\ 0 \\ \vdots \end{bmatrix} = \mathbf{C}_1(\nu) \begin{bmatrix} b_0(t) \\ b_1(t) \\ \vdots \end{bmatrix} + \sigma d^2 \mathbf{C}_2 \frac{\partial}{\partial t} \begin{bmatrix} b_0(t) \\ b_1(t) \\ \vdots \end{bmatrix}, \quad (1)$$

where $h_s(t)$ is the magnetic field strength on the lamination surface and $b_n(t)$ with $n = 0, \dots, N_F - 1$ are coefficients of selected basis functions $\alpha_n(z)$ used to approximate the flux-density distribution in the lamination depth $z \in [-d/2, d/2]$ as

$$b(z, t) = \sum_{n=0}^{N_F-1} b_n(t) \alpha_n(z). \quad (2)$$

The matrix coefficients are obtained by integration over the lamination thickness as

$$C_{1,lm}(\nu) = \frac{1}{d} \int_{-d/2}^{d/2} \nu(z) \alpha_{l-1}(z) \alpha_{m-1}(z) dz \quad (3)$$

$$C_{2,lm} = \frac{1}{d} \int_{-d/2}^{d/2} \alpha_{l-1}(z) \beta_{m-1}(z) dz, \quad (4)$$

where $\nu = \nu(b)$ is the reluctivity of the material and functions $\beta_n(z)$ are defined so that $\beta_n(\pm d/2) = 0$ and

$$\alpha_n(z) = -d^2 \frac{\partial^2 \beta_n(z)}{\partial z^2}. \quad (5)$$

Here, instead of polynomial basis functions, the flux-density is approximated by a truncated Fourier cosine series with $\alpha_n(z) = \cos(nkz)$, $k = 2\pi/d$. These Fourier terms fulfill the orthogonality requirement of the basis functions by definition, and make it possible to integrate coefficients (3) analytically also in nonlinear cases, if a discrete Fourier transform is first performed for the reluctivity in the lamination. Linear cases and integrations (4) can be fully handled analytically.

The eddy-current loss density in the lamination can be calculated from the time-varying flux-density distribution as

$$p(z, t) = \sigma \left[\int_0^z \frac{\partial b(z, t)}{\partial t} dz \right]^2. \quad (6)$$

III. THE 2D MODEL

The 2D finite-element electrical machine model used in this work solves the Ampere's circuital law

$$\nabla \times \mathbf{H} = \nabla \times (\nu \nabla \times \mathbf{A}) = \mathbf{J} \quad (7)$$

combined with required circuit equations in the cross-sectional xy-plane of the machine using the axial magnetic vector potential $\mathbf{A} = A(x, y, t)\mathbf{u}_z$ as the variable [3]. In the core regions, the axial component of the current density \mathbf{J} is assumed to be zero, and (7) reduces to

$$-\nabla \cdot (\nu \nabla A) = 0. \quad (8)$$

Discretizing the cross-section into elements with N nodes in total and applying the Galerkin weighted residual method results into a system of N equations for the nodal values $\mathbf{a} = (a_1 \dots a_N)$ of the vector potential.

The effect of the in-plane eddy-currents can be accounted for in the model by requiring the magnetic field strength \mathbf{H} in (7) to be equal to the surface field strength $\mathbf{h}_s = h_{sx}\mathbf{u}_x + h_{sy}\mathbf{u}_y$ obtained from the lamination model (1) and (2) for both x and y components of the magnetic field strength and flux density. This is equivalent with expressing the dependency of the vector potential on the axial coordinate z as

$$A(x, y, z, t) = \sum_{n=0}^{N_F-1} A_n(x, y, t)\alpha_n(z). \quad (9)$$

Now, instead of one single equation as in (7) and (8), a system of N_F equations is obtained for the vector potential coefficients A_n . The spatial discretization of each equation is performed as before, and the time derivatives can be discretized using e.g. the Crank-Nicolson approximation. The resulting system consists of $N_F N$ equations for the nodal values of the vector potential coefficients $\mathbf{a}_n = (a_{n,1} \dots a_{n,N})$, with $n = 0, \dots, N_F - 1$. These equations can be solved by using a suitable linear system solver and Newton-Raphson iteration in case of nonlinear materials.

IV. APPLICATION AND RESULTS

The presented model was applied to calculate eddy-current losses in a rectangular homogeneous steel lamination with a thickness of 2 mm, area of 0.06 m² and conductivity of 8 MS/m supplied by an alternating average flux density $\mathbf{B}_0(t) = B_{y0m} \sin(2\pi ft)\mathbf{u}_y$. Using $N_F = 10$ cosine terms to approximate the flux density distribution, the eddy-current losses at each time step were calculated from (6) by integrating over the volume of the lamination.

For comparison, the eddy-current losses and flux-density profiles in the lamination were calculated by a 1D FE lamination model similar to the ones presented in [1] and [4]. The magnetic vector potential in one half of the lamination was approximated by 20 linear shape functions.

Eddy-current losses obtained from the two models for a frequency range of $f = 50 \dots 5000$ Hz and amplitudes of $B_{y0m} = 0.5, 1.0$ and 1.5 T are presented in Fig. 1. Flux-density

profiles in the lamination at 1.5 T, 1000 Hz excitation are presented in Fig. 2. The results show good agreement.

Fig. 1. Comparison of eddy-current losses from the two models

Fig. 2. Comparison of flux-density profiles from the two models with $B_{y0m} = 1.5$ T, $f = 1000$ Hz (period $T = 1$ ms)

V. CONCLUSION

A mesh-free eddy-current loss model of ferromagnetic laminations for 2D field analysis was presented. The model is able to approximate the eddy-current losses equally to a FE model. In the upcoming paper, the power balance of the model is studied and the model is applied to calculate losses in a synchronous machine.

Abstract — This work deals with the efficient computation of per-unit-length impedances of a railway line. Under the quasi-TEM approximation, valid in a frequency range up to some MHz, in this paper a boundary element formulation based on the magnetic vector potential is proposed, which leads to a straightforward calculation of the per-unit-length impedance matrix. The computational burden is dramatically reduced by implementing appropriate impedance boundary conditions on the rails and on the aerial lines and by substituting in the boundary integral equations the fundamental solution with a Green's function satisfying the boundary conditions at the air-earth interface, avoiding the discretization of the lossy ground.

I. INTRODUCTION

In order to increase the level of accuracy of multiconductor transmission line (MTL) models of railway lines, a key issue is the correct computation of per-unit-length (p.u.l.) impedances, taking into account the real geometry of the rail track and the property of the earth. Under the quasi-TEM approximation, which for typical values of the earth conductivity and geometrical dimensions of the railway track system holds in a frequency range up to 1 MHz [1], the computation of p.u.l. parameters of the rail track equivalent MTL can be carried out using different approaches.

The classical analytical method is based on the Carson's formula, that is valid under the assumption of filamentary conductors and homogeneous earth [2]. In order to take into account the real geometry of the rails and the multilayer nature of the earth, in [3] the finite element method (FEM) was applied. The FEM model of the ground must be sufficiently large to enclose all the eddy current distribution, which means that the current density must be reduced to practically zero before reaching the boundaries. Since the earth is characterized by low conductivity, the FEM model of the ground must have a characteristic linear dimension some orders of magnitude higher than the typical dimensions of the conductors, because it must be equal to some skin depths (in the order of 10^2 m at 50 Hz and in the order of 10 m at 100 kHz). Hence, the computational problem has a multiscale nature and the FEM model requires a mesh of a very large number of elements (of the order of 10^4). Furthermore, the presence of contact lines, some meters far from the earth, requires that a large area of the open space must also be meshed.

In this paper a different numerical approach is proposed, based on the boundary element method (BEM). The adopted

BEM formulation uses the magnetic vector potential (MVP). Following [4], a source component is introduced for the MVP which leads to a straightforward calculation of the p.u.l. impedance matrix of the MTL under analysis. The formulation taken from [4] is enriched by the implementation of the surface impedance boundary condition (SIBC) with the Leontovich approximation [5] on the rails and with its exact expression for circular wires [6] on the aerial lines, dramatically reducing the computational burden. The formulation is also further improved substituting in the boundary integral equations the fundamental solution with a Green's function satisfying the boundary conditions at the air-earth interface: in this way discretizing the lossy ground is not needed any more.

II. BOUNDARY ELEMENT FORMULATION

For the sake of simplicity and without loss of generality, the BEM formulation will be presented here referring to the geometry of Fig. 1, consisting of a MTL constituted by the two rails, the contact line, and the earth.

Under the hypothesis of a time-harmonic regime with angular frequency ω , vector fields are represented using phasors: from here on all field quantities are assumed to be complex. We also assume that displacement currents can be neglected.

Introducing the magnetic vector potential (MVP) as in [4] and expressing it as the sum of a "source" and an "eddy" components $\vec{A}(\vec{r}, t) = \vec{A}^s(\vec{r}, t) + \vec{A}^e(\vec{r}, t)$, the electric field in the conductors can be expressed as $\vec{E} = -j\omega\vec{A}^e$.

A Cartesian coordinate system is introduced, with the z -axis parallel to the conductor's axis. Currents flowing in the conductors are z -directed. Under the hypothesis that the problem is two-dimensional in the plane of the conductor's cross sections, the vectors \vec{H} , \vec{E} , \vec{A} , \vec{A}^s , \vec{A}^e can be written as $\vec{H} = H_x\vec{e}_x + H_y\vec{e}_y$, $\vec{E} = E\vec{e}_z$, $\vec{A} = A\vec{e}_z$, $\vec{A}^s = A^s\vec{e}_z$, and $\vec{A}^e = A^e\vec{e}_z$.

Application of the Coulomb's gauge $\nabla \cdot \vec{A} = 0$ to MVP leads to the Laplace equation for the MVP in air

$$\nabla^2 A = 0. \quad (1)$$

Fig. 1. The geometry of the system: conductor 1 and 2 are the rails, conductor 3 is the contact line. The geometrical dimensions are: $c=0.1$ m, $d=6$ m, $e=1.435$ m, and $r_c=6$ mm.

The boundary integral equation method yields the following integral equations

$$\frac{1}{2}A - \int_C \left(A \frac{\partial g}{\partial n} - g \frac{\partial A}{\partial n} \right) dl - \left(\frac{1}{2}A_k^s - A_1^s \int_{C_1} \frac{\partial g}{\partial n} dl - A_2^s \int_{C_2} \frac{\partial g}{\partial n} dl - A_3^s \int_{C_3} \frac{\partial g}{\partial n} dl \right) = 0, \quad (2)$$

where C_1 , C_2 , and C_3 are the conductors contours and $C = \bigcup_{k=1}^3 C_k$.

The function g is the Green's function of an infinite line current over the earth

$$g(x, y; x', y') = -\frac{1}{2\pi} \left[\log \sqrt{\frac{(x-x')^2 + (y-y')^2}{(x-x')^2 + (y+y')^2}} + \int_{-\infty}^{+\infty} \frac{e^{-\lambda(y+y')}}{\lambda + F(\lambda)} \cos \lambda(x - x') d\lambda \right], \quad (3)$$

where the first term represents the presence of a perfectly conductive plane and the second term takes into account the presence of the earth. The complex function $F(\lambda)$ can have different expressions, depending on the chosen model, which can assume the earth as homogeneous or made of two or three layers [7]. Thanks to the adopted Green's function (3), only the surface integral equations on the contours of the conductors have to be solved, without the need of discretizing the ground.

The entries of the impedance matrix can be computed by means of the following formulas

$$Z_{hh} = \frac{j\omega A_h^s}{I_h} + \text{Re}\{Z_{hh}^{an}\}, \quad (4a) \quad Z_{hk} = \frac{j\omega A_k^s}{I_h} + \text{Re}\{Z_{hk}^{an}\}, \quad (4b)$$

where $\text{Re}\{Z_{hh}^{an}\}$ and $\text{Re}\{Z_{hk}^{an}\}$ are the contribution to the self and mutual resistances from the ground return path, that can be calculated using the convenient analytical expressions of a filamentary current over a homogeneous or multilayer earth [7].

III. COMPARISON WITH FEM AND ANALYTICAL RESULTS

Numerical results given by the BEM formulation are compared with analytical solutions and with FEM simulations obtained with the help of a commercial software [8]. The contact line and the ground are considered of unitary relative permeability, while the rails have $\mu_{r1} = \mu_{r2} = 20$. The following values of conductivities are used: $\sigma_1 = \sigma_2 = 4.44 \cdot 10^6$ S/m, $\sigma_3 = 5 \cdot 10^6$ S/m. In preliminary simulations a homogeneous earth has been considered, so that $\sigma_{g1} = \sigma_{g2} = \sigma_{g3} = 0.01$ S/m. The rails are discretized using 40 constant elements per rail, while the contact line is discretized with 30 constant elements. The integral in (3) is calculated as suggested in [7].

Taking as the reference values those provided by Vance's formula [9], that is an approximation of Carson's formula [2], the maximum relative error of BEM simulations of p.u.l. self-resistance is 4% and of p.u.l. self-inductance is 1%, in a frequency range between 10 kHz and 1 MHz. On the other hand, the maximum relative error of FEM simulations of p.u.l. self-resistance is 15% and of p.u.l. self-inductance is 4.5% in the same frequency range. The errors of FEM results are mainly attributed to the finite size of the earth model and the BEM model gives more accurate results.

The analytical computation of p.u.l. self and mutual impedances of the rails is not possible, since Carson's formulae and their approximations are valid only for filamentary conductors. Anyway, BEM results are in good agreement with FEM results.

Integral Formulation and Genetic Algorithms for Defects Geometry Reconstruction using Pulse Eddy Currents

Gabriel Preda, Mihai Rebican and Florea I. Hantila
Electrical Engineering Department, Politehnica University of Bucharest,
Splaiul Independentei 313, Bucharest 060042, Romania
preda@elth.pub.ro

Abstract — A method for reconstruction of defects, buried deep under material surface, using pulse eddy currents, is proposed. Both an integral-FEM method for simulation of transient eddy-currents and genetic algorithms, as a model-free inversion technique are proposed. Numerical results for the inversion of the eddy-currents signals, using genetic algorithms, are shown.

I. INTRODUCTION

Pulse eddy currents technique is proposed as a method to detect cracks in conductive materials with large thickness. For thin structures, Eddy Currents Testing (ECT) using harmonic mode was used extensively in the past for detection of cracks in steam generator (SG) tubing of pressurized water reactors (PWR) of nuclear power plants. Although its advantages, as high speed and reliability for the routine inspections, skin effect limits this method only to thin and nonmagnetic structures. Pulse eddy currents has multiple advantages: its rectangular pulse profile accounts for a multi-frequency analysis, the lower harmonics penetrating deeper in the material, while limiting the heating exposure of the coil-probe system to only the short duration of a signal allows an increase in the power [1], [2]. Multiple industrial applications were reported, such as detection of cracks in multiple layered plates around fasteners for aeronautics industry [3], crack detection and thickness and conductivity evaluation in structural steels [4]. Current study investigates the possibility to reconstruct defects geometry using simulated pulse eddy currents signals. For the inverse problem, we apply genetic algorithms.

II. FORMULATION FOR THE FORWARD PROBLEM

The proposed method is based on application of \mathbf{T} - electric vector potential to the integral equation of eddy currents, like in [5]. Starting from Maxwell equations in quasi-stationary form and the constitutive relationship:

$$\mathbf{E} = \rho \cdot \mathbf{J}, \quad (1)$$

where \mathbf{J} is the current density, \mathbf{E} is the electrical field and ρ is the resistivity in the conductive domain Ω_c . We suppose that the field sources motion relative to the conductive domain is slow and therefore the component of the induced field through motion is very small and negligible. In the laboratory frame, the electrical field is:

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} - \nabla V, \quad (2)$$

where V is the electric scalar potential and \mathbf{A} is magnetic vector potential. The magnetic vector potential can be calculated using Biot-Savart formula:

$$\mathbf{A} = \frac{\mu_0}{4\pi} \int_{\Omega} \frac{\mathbf{J}}{r} d v + \mathbf{A}_0, \quad (3)$$

with \mathbf{A}_0 being the magnetic vector potential due to the impressed current sources:

$$\mathbf{A}_0 = \frac{\mu_0}{4\pi} \int_{\Omega_0} \frac{\mathbf{J}_0}{r} d v \quad (4)$$

and Ω_0 being the air. Only conductive media are meshed. The current density is expressed in terms of shape functions associated to the edges in the inner co-tree [5] [6]:

$$\mathbf{J} = \sum_{k=1}^n \mathbf{N}_k \nabla \times \mathbf{T}_k. \quad (5)$$

Applying Galerkin approach, the following equation system is obtained:

$$[\mathbf{R}]\{I\} + [\mathbf{L}] \frac{d\{I\}}{dt} = \{U\}, \quad (6)$$

where the terms of matrices $[\mathbf{R}]$ and $[\mathbf{L}]$ and the right-hand term $\{U\}$ are detailed in [5], [6].

In order to model 2D, zero-thickness defects, from the set of inner co-tree edges are eliminated those edges placed in the defect surface. The procedure is equivalent to zeroing the circulation of scalar electric potential \mathbf{T} on those co-tree edges [6].

All the coefficients in the system matrix are unchanged through time integration and, therefore, the resulting matrix system is formed and inverted only once. This results in considerable speed-up of overall computational process. The time step is adapted to each particular problem, in order to simulate accurately the fast variable transient regime of pulse eddy currents. Also, the rich harmonic components of a pulse impose adaptation of mesh size to the smallest skin depth, corresponding to the largest harmonic component to be taken into account [4].

III. INVERSION PROCEDURE USING GENETIC ALGORITHMS

A genetic algorithm first presented in [7] is used to solve the inverse problem of inferring the geometry and position of a zero-thickness outer defect. In order to speed-up the numerical solution, the parallel version, using Message Passing Interface (MPI), available at [8] is adopted. The optimization problem consists in finding the extreme of a fitness function, describing how accurate the simulation using the set of the actual estimated parameters approximate the original signal. Each chromosome corresponds to one parameter to be evaluated, like in [9]. The chromosome length is correlated to the parameters variation space. In our implementation, the maximum chromosome dimension is set to 7, to describe a maximum of 128 discrete values, while in a first set of tests its dimension is limited to 4. We set the following options for the genetic algorithm: variable mutation mode, mutation rate varying between 0.001 and 0.25, evolution plan: steady state with replace worst, elitism being allowed.

IV. NUMERICAL RESULTS AND CONCLUSIONS

The simulation setup for the test problem consists in a conductive plate, a pancake coil used to energize the specimen and a Hall sensor to pick-up the signal. The pancake coil – Hall sensor system is less sensitive to frequency variation than the classical auto-induction pancake used in AC testing, which in turn can be optimized for a single frequency; for pulse excitation, such an optimization is not possible [1][2][9]. The plate is 16 cm \times 16 cm, with 10 mm thickness and having conductivity $\sigma = 10^6$ S/m. Coil dimensions are inner radius $R_{min} = 2$ mm, outer radius $R_{max} = 5$ mm, axial length $l_z = 4$ mm, liftoff $z = 0.4$ mm. The pickup sensor measures the magnetic flux density and is placed in the coil axis, at $z = 0.4$ mm. The coil signal used is a 70 μ s, trapezoidal shaped pulse, and with additional rise and fall intervals of 10 μ s each, with amplitude $I_{max} = 2000$ AT, and with a repetition frequency of 50 Hz. 55 time steps are simulated for a single pulse.

In Fig. 1 we show the difference between signal with crack and signal without crack (difference signal) of z -component of magnetic flux density, measured at $x = 0$, $y = 0$, $z = 0.4$ mm (centered over the plate) for a 12 mm length, 40%, 60% and 80% outer, 0-thickness defect. The peak of the difference signal is obtained earlier for larger defects (80%) and at a later moment for the smaller defects (40%). Selecting the sampling moment according to this observation, we can increase the method sensitivity to one specific class of defects [9].

The difference signals are used as input in the inverse problem, for estimation of the defect geometry. In the first set of experiments, we aim to reconstruct the position, length and depth of a rectangular, with zero-thickness, longitudinal outer defect. The sampling moment used is $t = 30$ μ s. The three parameters to reconstruct are set as following: defect length: 0.4 from maximum 10 mm or 4 mm, defect thickness 60% or 6 mm, from maximum of 10 mm and defect position 0.8 or 4 mm from maximum or 5 mm.

Fig. 1. Difference signals plotted against time. Defects are with zero-thickness, 12 mm long, open on outer side, ranged from 40% to 80%. The signal is the z -component of magnetic flux density, at 0.4 mm over the plate.

In this set of tests, each individual in the population is modeled with 3 chromosomes (one for each parameter to reconstruct), with a dimension of 4 bits per chromosome (to model discrete values from 0 to 1 with a 0.1 resolution). A population with 25 individuals evolves over a maximum of 120 generations. The parallel implementation for genetic algorithm described in [8] was used. The final estimation for the three parameters of (0.4, 0.6, 0.8) is approximated as (0.5, 0.6, 0.7). In the full paper we will extend the results for more complex defect geometries reconstructions, using a matrix-like representation of the defect zone, each cell corresponding to one chromosome.

Abstract — The coupling strategy between linear MHD solvers and 3D electromagnetic codes based on the control surface concept, initially developed for the analysis of the non-axisymmetric resistive wall modes in air core fusion devices, is extended to the problem of shape and position control in the JET tokamak. This case is characterized by the presence of a ferromagnetic iron core, and the main objective of the study is the axisymmetric component of the plasma motion.

I. INTRODUCTION

The design and operation of effective control systems requires predictive models of the evolution of the plasma in the presence of complex 3D conducting structures. In [1] a linearized, non-rigid, MHD consistent model of the plasma vertical displacements is presented. It is in practice a perturbed equilibrium model, which is accurate and can be used for open loop analysis, sensor location optimization and controller design. Similar models have been proposed for the analysis of non-axisymmetric resistive wall modes [2]. For the modelling of the complex 3D structures, an integral formulation of the eddy current problem [3] was developed and successfully applied to the analysis of several cases of interest. A challenging problem is still related to a self consistent description of the MHD plasma models coupled to a detailed description of the passive structures. Although in some cases this coupling has been already efficiently modelled [4], this complex interaction still require a deeper analysis not only in future devices but also in the present tokamak experiments like the Joint European Torus (JET) tokamak, for which the effect of the bellows in the vacuum vessel has been already analyzed in a previous paper [5]. This effect is enhanced by the presence of the vacuum vessel ports and should be carefully analyzed since the time constant of the saddle currents, due to the presence of the ports, could be significant. Another important source of 3D field perturbation is represented by the combined influence of the in-

vessel components, the mechanical structure and the iron core.

The method proposed in this paper uses the coupling strategy between linear MHD solvers and 3D electromagnetic codes based on the control surface concept, initially developed for the analysis of the non-axisymmetric resistive wall modes in air core fusion devices [2, 6]. This technique is extended to the problem of shape and position control in the JET tokamak, characterized by the presence of a ferromagnetic iron core, for which the main objective of the study is to provide a linearized response model of the axisymmetric plasma motion in the presence of 3D structures.

II. THE COUPLING PROCEDURE

The coupling procedure used for the derivation of a linearized plasma response model in the presence of 3D magnetic and conducting structures requires the solution of three auxiliary problems. A suitable coupling surface, the virtual ideal wall (VIW), is chosen. This closed surface divides the domain Ω in two parts, namely the internal domain Ω_{mhd} , where the plasma dynamics is described by the ideal MHD model, and the external region Ω_{em} , in which the 3D eddy current model is used for the description of circuits, 3D magnetic media, and 3D conducting structures.

Problem 1

The first problem is defined in Ω_{mhd} , where the ideal MHD equations hold. The terms related to plasma mass are neglected [1-2]. Being interested to magnetic axisymmetric control, we solve:

$$\begin{cases} L_i^* \delta\psi_{i1} = \delta s_i \text{ in } \Omega_{mhd} \\ \text{with } \delta\psi_{i1} = 0 \text{ on VIW} \\ \text{with } \delta\psi_{i1} = 0 \text{ on } \Omega_{em} \end{cases} \quad (1)$$

where L_i^* is the linearized form of the left hand side of the axisymmetric Grad-Shafranov equation:

$$-\frac{\partial}{\partial r} \left(\frac{1}{\mu r} \frac{\partial \psi}{\partial r} \right) - \frac{\partial}{\partial z} \left(\frac{1}{\mu r} \frac{\partial \psi}{\partial z} \right) - J_\phi(\psi, s) = 0 \quad (2)$$

where μ is the magnetic permeability, ψ the poloidal flux per radian, J_ϕ the toroidal component of the current density, and s a set of plasma parameters, e.g. total plasma current, poloidal beta and internal inductance. Due to the lack of continuity of the tangential field, an artificial surface current distribution J_{s1} arises on the VIW.

Problem 2

The second problem is defined in the external domain Ω_{em} . In the presence of an iron core the problem is non-linear and a linearization procedure is needed. We use the formulation described in [5], i.e., the standard eddy currents equations in the time domain with the assumption that the magnetization \mathbf{M} is nonlinearly related to the magnetic flux \mathbf{B} :

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}), \quad \mathbf{M} = G(\mathbf{B}) \quad (3)$$

We solve the above stated problem using an integral formulation, well established for the analysis of the complex 3D structures. The solenoidality of the current density is warranted by the introduction of the electric vector potential \mathbf{T} (such that $\mathbf{J} = \nabla \times \mathbf{T}$) with a two-component gauge condition [5] to guarantee its uniqueness. We give a finite element discretization of iron and conductors, using edge elements \mathbf{N}_k to approximate \mathbf{T} , so that:

$$\mathbf{T} = \sum_k I_k \mathbf{N}_k \Rightarrow \mathbf{J} = \sum_k I_k \nabla \times \mathbf{N}_k \quad (4)$$

while the magnetization vector is supposed to be piecewise constant (\mathbf{P}_k 's are unit vector pulse functions):

$$\mathbf{M} = \sum_k M_k \mathbf{P}_k \quad (5)$$

The degrees of freedom in problem 2 are the coefficients I_k . The average axisymmetric component of the poloidal magnetic flux on the VIW is set to zero by adding a magnetostatic field in the whole domain generated by suitable axisymmetric surface currents J_{s2} located on the VIW. Suitable distributions of non axisymmetric surface currents can also be added to cancel other harmonic $n > 0$ components of the field on the VIW [2]. The resulting field inside Ω_{mhd} is then zero.

Problem 3

The last step is needed to restore continuity of the tangential field on the VIW. For each degree of freedom of the linearized problem, i.e., $\delta \underline{x}$ and $\delta \underline{l}$, we superpose the contribution due to a surface current density opposite to the previous ones computed in steps 1 and 2:

$$\left\{ \begin{array}{l} \text{linearized GS equation for } \delta \psi_{i3} \text{ in } \Omega_{mhd} \\ \text{linearized magnetostatic for } \delta \psi_{e3} = 0 \text{ in } \Omega_{em} \\ \text{with} \\ \text{poloidal flux continuity on VIW} \\ J_{sVIW} = -J_{sVIW1} - J_{sVIW2} \end{array} \right. \quad (6)$$

Dynamic model

The superposition of the three contributions can be used to derive the plasma response model by calculating the flux linked with each voltage driven circuit as well as the magnetic vector potential in the eddy current region, obtaining:

$$\underline{L}^* \frac{d\delta \underline{I}}{dt} + \underline{R} \delta \underline{I} = \delta \underline{V} - \underline{L}_s^* \frac{d\delta \underline{s}}{dt} \quad (7)$$

where \underline{L}^* is the modified inductance matrix taking account of plasma contribution [1-2, 6], \underline{L}_s^* is a similar term related to the plasma parameters, and \underline{V} is the set of applied voltages.

Abstract — A magnetodynamic formulation is developed within the Finite Volume Method to address specific multiphysic issues involved in circuit breaker modeling. The coupling of various methods is described. Attention is paid on the non-linear magnetostatic problem. It is shown that the magnetic saturation effects have to be taken into account to correctly assess the force acting on the electric arc and, henceforth, not to jeopardize the modeling of the breaking process.

I. COUPLED ELECTROMAGNETISM AND FLUID DYNAMICAL MODELING

Various multi-physic modeling, and more particularly the current breaking modeling, requires fluid dynamics and electromagnetic models [1]. Whereas conventional Finite Volume Method (FVM) is usually dedicated to Computational Fluid Dynamics (CFD) and enforces the *local* conservation of mass, momentum and energy [2]; low-frequency electromagnetic resolutions minimize *global* energy functionals from which is derived the Finite Element Method (FEM) [3]. Hence, magneto-hydrodynamics problems are currently resolved using either:

- a FE dedicated-CFD code, which is not competitive for compressible flow with high Mach Number; or
- a hybrid method combining a FVM and a FEM, thereby sacrificing the high level of integration and the accuracy achieved with a single mesh [4].

Thus, the search for a common, effective and integrated model calls for a single numerical method for the two phenomena. In this work, an electromagnetic model based on the FVM is adopted to keep both numerical efficiency and accuracy for the CFD side.

II. ELECTROMAGNETISM WITH THE FINITE VOLUME METHOD

Previous studies established the finite volume method capabilities to (i) model the stationary current flow; (ii) determine the field in the vacuum; and (iii) characterize the field deformation around ferromagnetic pieces [5]. In order to progress towards a fully electromagnetic FVM package, a specific formulation should be developed to take into account non-linear magnetostatic properties.

A. Formulation

For 3D magnetostatics using a \mathbf{T} - ϕ formulation, the magnetic field reads $\mathbf{H}=\mathbf{T}_0-\nabla\phi$, and the magnetic flux density divergence-free is expressed as a diffusion equation with a source term resulting from the field \mathbf{T}_0 obtained in the vacuum case:

$$\underbrace{\operatorname{div}(-\mu_r \nabla \phi)}_{\text{diffusive term}} = \underbrace{\operatorname{div}(-\mu_r \mathbf{T}_0)}_{\text{source term}} \quad (1)$$

where μ_r is the non-linear magnetic permeability.

Among the various choices to describe the non-linearity [6], an “arctang” law with two parameters is used. After the vacuum magnetostatic resolution and the set-up of the relative magnetic permeability μ_r – typically the half-value of the relative magnetic permeability at the origin μ_{r_init} –, the computation is performed with an updating of μ_r at each iteration. To avoid the oscillation around the solution, an over-relaxation on μ_r is used.

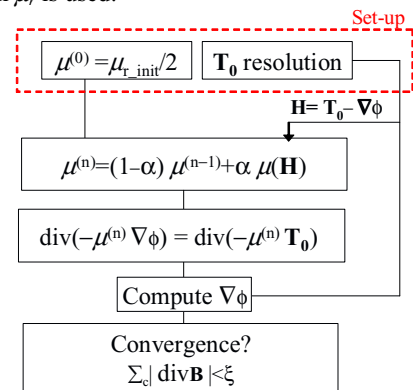

Fig. 1. Algorithm chart for the resolution of a non-linear magnetostatic problem.

The inspection of the flux density conservation provides a criterion to check the convergence.

B. Application to saturation modeling

The previous formulation is used in a 2D case where two circular conductors supplied by steady opposite currents excite a non-linear ferromagnetic plate (Fig. 2).

Fig. 2. Refraction of the \mathbf{H} -lines around a non-linear ferromagnetic plate excited by two conductors supplied in opposition.

The saturation is observed qualitatively and the numerical comparison with finite element computations – achieved with Flux2D[®] software – show that the relative error in energy deviates less than 5% (Fig. 2).

Fig. 3. Energy and co-energy curves reduced by squared current (left) and the maximum relative error computed with FEM (right) vs. supplied current.

Hence, the extension of the $\mathbf{T}\text{-}\phi$ formulation in 3D is quite straightforward [7].

III. CIRCUIT BREAKER MODELING

In the breaking process, the transient effects can be neglected in a first approach [8]. Therefore it is possible to model the whole breaking process within the previous FV electromagnetic developments.

A. The framework of the resolution procedure

The figure 4 describes the resolution procedure for each iteration. The previous formulation was implemented within the plasma physics-dedicated Schneider Electric software [9].

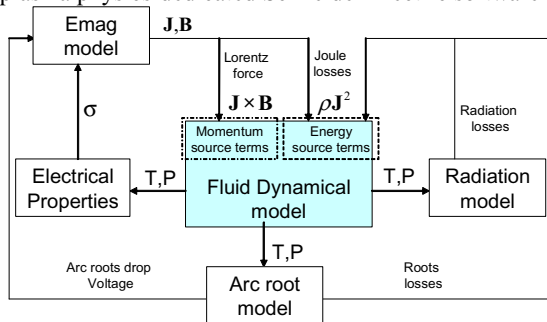

Fig. 4. Chart of the resolution procedure for the breaking process modeling (T temperature, P pressure, σ electrical conductivity)

All the models (real gas, radiation, root model and electromagnetism) are driven by the fluid dynamic based core [10]. These models are the inputs of source terms in energy and momentum. In the case of electromagnetism, the Lorentz forces and the Joule losses are introduced in fluid dynamical solver (Fig. 4).

This resolution with the CFD *Fluent*[®] code is achieved thanks to its explicit solver, which uses a Gauss-Seidel method with a multi-grid resolution.

B. Circuit Breaker Modeling

The figure 5 shows an experimental mock-up, composed of two feeders, three ferromagnetic splitters plates, and a far

pressure outlet. The mesh has 400.000 cells and the unknown solving are $(\rho, \mathbf{v}, H, V, \mathbf{T}_0, \phi)$, respectively density, velocity, Gibbs' energy, electrical potential, field in the vacuum and magnetic scalar potential. The computational time for a breaking process modeling is about 3 weeks on Pentium Xeon 2 GHz -2Go RAM.

The figure 5 also provides three iso-values of the current density when the arc enforces the ferromagnetic splitter plates.

Fig. 5. Modeling of the breaking process: While the electric arc is displayed with three iso-values of the current density ($1.5 \cdot 10^7$; $8.0 \cdot 10^6$; $5 \cdot 10^6$ A·m⁻²), the saturation of the splitter plates is effective and represented with the relative magnetic permeability μ_r .

As a result, the saturation of the splitter plates is effective during the breaking process, showing that a non-linear treatment of the field is required to avoid an over-estimation of the driving force acting on the electric arc [11].

Abstract — A weak coupling technique for an electromagnetic and a structural dynamic model for the finite element method (FEM) is presented. The algorithm fits the needs for acoustic simulations of electrical machines, and additionally offers an interface to any analytical treatment of the electromagnetic part. The algorithm will be applied to simulate vibrations of a skewed induction machine using FEM.

I. INTRODUCTION

For the numerical calculation of audible noise generated by electrical machines, it is necessary to simulate the mechanical vibrations of the stator. Based on the results of an electromagnetic simulation, the periodic reaction forces acting on the stator core stack at the air gap of the machine are estimated first. In a second step, the mechanical displacements caused by these forces on the surface of the stator are calculated by a FEM structural analysis. Displacements obtained in this way present one of the main sources of the audible noise in electrical machines. An example for this procedure can be found in [1].

Normally, the electromagnetic simulation has to be performed in the time domain for taking into account the rotor movement, and therewith the force- and field harmonics, relevant for the acoustic computation. Depending on the machine type, 2D, so called multi slice or if necessary also 3D models are conceivable.

For the mechanical part, the steady state vibrations are of interest, therefore, the structural simulation is usually done in the frequency domain by a linear time harmonic FEM computation. For the consideration of the often complex structural behaviour and boundary conditions, a 3D model is usually needed. In this case, 2D models represent quite a simplification and are therefore seldom used.

So the two models for the electromagnetic and structural simulation take care of quite different aspects and hence, apart from the underlying geometry, they have few common features. Especially the very small element size of the electromagnetic mesh near the air gap is inappropriate for a direct adoption into the structural model. As a result, the meshes of the two models are generally nonconforming with respect to each other and a coupling algorithm accounting for this has to be implemented. Usually, for acoustic concerns, the structural and the electromagnetic part can be handled independently (so called weak coupling), since the very small vibrations compared to the air gap length cause only a negligible fluctuation of the magnetic fields.

The coupling task consists mainly of a transformation of the electromagnetic forces from one mesh to the other. An important special case is the mapping from a 2D electromagnetic model to a 3D structural one. The procedure will be outlined for this case first, and then extended for multi slice and 3D electromagnetic models in the final paper.

II. EXPRESSION OF DISTRIBUTED SURFACE LOADS BY THE MEANS OF EQUIVALENT NODAL FORCES

The force output of the electromagnetic simulation is usually given in form of an electromagnetic surface force density σ (N/m²), acting on the iron core stack. From a mechanical point of view, σ is therefore a distributed force load on the surface of the structure.

The displacement based FEM formulation for a linear undamped structural dynamic problem can be stated as (see e.g. [2])

$$M \frac{d^2 u}{dt^2} + K u = f^N, \quad (1)$$

where M denotes the mass matrix, K the stiffness matrix, and u as well as $d^2 u/dt^2$ represent the unknown displacements respectively their second time derivate. f^N on the right hand side corresponds to the input load vector of equivalent concentrated nodal forces. To apply distributed surface force loads to this formulation, they need to be expressed in form of such equivalent concentrated nodal forces. Using the principle of virtual displacements (see [2]) this can be accomplished by the term

$$f_{m,\Gamma_i}^N = \int_{\Gamma_i} (H_{m,\Gamma_i})^T f_{m,\Gamma_i}^{sf} d\Gamma, \quad (2)$$

stated for a single element m with a distributed force f_{m,Γ_i}^{sf} acting on the surface Γ_i of the element. H_{m,Γ_i} denotes the part of the elemental displacement interpolation matrix contributing to any displacements on the element surface Γ_i . Therewith, f_{m,Γ_i}^N corresponds to the vector of equivalent concentrated nodal forces representing the surface load on the element m .

III. TRANSFORMATION OF THE ELECTROMAGNETIC FORCES

As the electromagnetic computation has to be performed in the time domain, $\sigma(t_n, x)$ is given in dependence of the time instant t_n and the position vector x on the iron surface. On the

other hand, the structural steady state computation is done by a time harmonic simulation and $\sigma(t_n, x)$ has to be expressed therefore by its equivalent (see e.g. [3])

$$\sigma(\omega_k, x_m) = \frac{1}{N} \sum_{n=0}^{N-1} \sigma(t_n, x_m) e^{-j(\frac{2\pi\omega_k n}{\omega_{\max}})} \quad (3)$$

in the continuous frequency domain. With the indices n and k , for the time- respective frequency index, the time period T and the total number of time samples per period N , the discrete angular frequency ω_k in (3) can be expressed as

$$\omega_k = \frac{2\pi}{T} k, \quad k = 0 \dots N-1. \quad (4)$$

Furthermore, ω_{\max} corresponds to

$$\omega_{\max} = \frac{2\pi}{T} N \quad (5)$$

in this case. Equation (3) basically results from the standard discrete Fourier transform (DFT) algorithm which is mapped into the continuous frequency domain used for the time harmonic computation of the structure. The factor $1/N$ therefore accounts for the fact that the DFT algorithm weights the resulting spectral lines with the number of time samples N .

For the transformation of the electromagnetic forces from one mesh to the other, an interpolation of the force density over the position coordinates is helpful, since it delivers a mesh independent description of the force distribution for the integral in (2). Due to the very fine mesh near the air gap, there are usually enough sample points to get a smooth function. Although this would be already sufficient for the force mapping onto the structural mesh, for acoustic computations, an additional step accounting for the periodicity of the angular position coordinate of a rotating machine, is often useful. In consequence of this periodicity, a second transformation of the forces into the spatial frequency domain is possible. Considering a 2D electromagnetic model with, apart from the slotting, constant radius of the iron - air gap interface, the general force density $\sigma(t_n, r_m, \varphi_m, z_m)$, given in a cylindrical coordinate system, reduces to a description of the form $\sigma(t_n, \varphi_m)$, neglecting any forces in the slots. The index m denotes the interpolated equidistant spatial sample points. Given this, a second DFT can be applied, leading to

$$\sigma(\omega_k, p_l) = \frac{1}{M} \sum_{m=0}^{M-1} \sigma(\omega_k, \varphi_m) e^{-j(\frac{2\pi p_l m}{M})}, \quad p_l = 0 \dots M-1, \quad (6)$$

where M denotes the number of spatial samples. Thus $\sigma(\omega_k, p_l)$, besides the angular frequency ω_k , is now given also in dependence of a spatial frequency p_l . For acoustic computations, this form is more intuitive than the form given in (3), as it is very close to the formulation an analytical treatment of the acoustic computation for the electrical machine would deliver (e.g. [4]). Additionally, only a small part of the information present in $\sigma(\omega_k, \varphi)$ respective $\sigma(\omega_k, p_l)$, in particular the parts with small spatial frequencies, produces any noise relevant mechanical vibrations. So, for an acoustic

Fig. 1. Vector plot of the resulting equivalent nodal forces f^N on the cylindrical surface of an iron ring. On the surface, a radial directed, distributed force with a single spatial frequency of $p_l = 3$, constant along the z -axis, was applied. As the surface elements are not equally distributed and are varying in size, the amplitude of the nodal forces is varying too, along the axial direction.

analysis, the force description (6) depicts more clearly the source and cause of any audible noise. Furthermore it offers the possibility to investigate single spatial spectral lines, delivering in this way a better insight into the structural reaction due to specific parts of the entire excitation.

As already indicated, the description with spatial frequencies is really near to the analytical description of the machine, so it offers also a simple interface to any analytical force calculations. On the other hand, due to the totally decoupled meshes, the force distribution can be applied not only to the real structure, but also to more or less arbitrary simplifications of it, like e.g. iron rings used for analytical computations, see [4].

If due to more complex electromagnetic models, the surface forces are not constant along the axial direction, as it is the case for multi slice or 3D models, the axial force behavior has to be interpolated, too.

IV. PRELIMINARY RESULTS

The procedure has been implemented so far for a 2D electromagnetic model of an induction machine. The force transformation onto the structural mesh has been tested on a freely meshed 3D iron ring structure. Fig. 1 shows a vector plot of the estimated nodal forces for a radial surface force density with a single spatial frequency of 3 and constant behavior along the axial z -axis. For the final paper, the coupling mechanism will be implemented in order to compute vibrations of a skewed induction machine for a multi slice electromagnetic and a 3D structural machine model.

Abstract. The aim of this paper is to compare strong and weak coupling of the PEEC and MoM methods applied to the modeling of magnetodynamic problem, and to generalize the weak coupling approach. MoM and PEEC are dedicated to the modeling of specific parts of the overall device. As an example of validation, we chose the modeling of a simple transformer. Resolutions of several weak couplings are compared to the strong coupling approach. Both linear and non-linear problems are treated.

Index terms. PEEC method, MoM method, weak/strong coupling, iterative methods.

I. INTRODUCTION

The PEEC (Partial Elements Equivalent Circuit) approach can model many ranges of cabling and interconnections in electric structures. The MoM method (Method of Moments) is employed to solve ferromagnetic materials interactions. Couplings have been developed [1]-[2] to take into consideration the influence of electric circuits and magnetic regions to the modeling of electric devices. This study compares coupling strategies.

II. PEEC AND MOM METHODS

A. The PEEC method

The principle of the PEEC method is to decompose a closed circuit into several parts, then calculate the mutual between them also the contribution of each of these elementary circuits to the total inductance. Inductance formulas (1) can be solved for different geometries [1]

$$l_{tot} = \frac{1}{I} \oint_C \vec{A} \cdot d\vec{l} \quad (1)$$

\vec{A} is the vector potential obtained with Biot-Savart's law, C is the whole contour of the conductor circuit which can be decomposed in N segments, and I the electric current in the conductor. We can also express the global inductance as follows (2)

$$L_{tot} = \sum_{n=1}^N \sum_{m=1}^N M p_{nm} \quad (2)$$

$M p_{nm}$ is the mutual partial between segment n and segment m calculated taken into account the shape, disposition and distance of the N conductors between them.

B. The MoM method

The MoM is an integral approach. It is well adapted to the modeling of radiating devices with simple geometries [3] The global elements magnetic field is given by (3)

$$H = H_{ext} + H_{red} \quad (3)$$

The discretization of the material gives us the magnetic field in any point P of the material (4)

$$H(P) = H_{ext}(P) + \frac{1}{4\pi} \iiint_{V_{mag}} \left(\frac{3(M \cdot r)}{r^5} \vec{r} - \frac{M}{r^3} \right) dv \quad (4)$$

H_{ext} and H_{red} are respectively the excitation magnetic field and the reaction of the material to the source field, and M is elements magnetizations.

III. PEEC-MOM COUPLING

The coupling of PEEC and MoM method can be carried out strongly by the expression of a unique linear system to solve [2], or weakly by iterations over both the two methods.

A. Strong PEEC-MoM

The strong PEEC-MoM coupling developed in [2] aimed at grouping in one global matrix the overall modeling (5),

$$\begin{bmatrix} A_{11} & A_{12} \\ A_{21} & A_{22} \end{bmatrix} \times \begin{bmatrix} M \\ I \end{bmatrix} = \begin{bmatrix} 0 \\ V \end{bmatrix}^T \quad (5)$$

$[A_{11}]$ is the MoM interaction matrix, $[A_{12}]$ gives the influence of conductors on magnetic region with Biot-Savart's law. The opposite influence is given by $[A_{21}]$ using Maxwell-Faraday's law, and finely $[A_{22}]$ is the impedance matrix obtained from PEEC method.

The resolution of the system (5) gives $[M \ I]^T$ vector composed by magnetizations of the material elements and the electric current in the conductors, according to the sources $[0 \ V]^T$.

B. Weak PEEC-MoM coupling

Each method is available separately; the coupling proposed is then based on iterative methods. The First weak coupling uses a linear system solving method for both PEEC and MoM as presents the algorithm in Fig. 1.

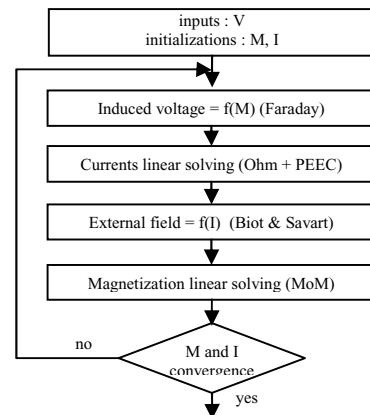

Fig. 1. Algorithm of weak coupling iterative approach

The Second and Third weak couplings use iterative methods (Jacobi or Gauss-Seidel) in order to solve linear systems, taking advantage of the existing loop.

C. Influence of non linear effects

Here we try to introduce the effect on the coupling of a non linear magnetic material. Reader must be aware that only MoM magnetization maximal value is affected by our basic non-linear modeling, PEEC solving has been kept with pure sinusoidal currents. The main idea is to linearize ferromagnetic material to solve iteratively linear systems with an equivalent permeability, taking advantage of the existing loop. Then we will see convergence properties of the coupling, even with temporary approximated currents.

IV. APPLICATION

The application example is the modeling of a simple transformer (Fig. 2). Two square conductors are placed on two parallel planes and a magnetic core is placed through their centers. The first conductor is powered by an alternative source voltage (1V, 1kHz). The second conductor is short-circuited.

Fig. 2. Geometry of the test device

For the same results of currents and magnetizations, the resolution time between the strong and weak couplings are compared.

A. Results

Three comparisons have been made on system solving time, iterations number, computer memory, regarding the number of unknowns; one for a linear modeling, and two with non-linear iterations with and without saturation.

Fig. 3. Linear modeling methods comparison

Fig. 4. Comparison with non-linear treatments without saturation

Fig. 5. Comparison with non-linear treatments with saturation

B. Comments

- linear case (Fig.3): the strong coupling reaches the result without iterations since it is a pure linear solving method, but time for high number of unknown is greater than weak coupling using GS. The case of weak coupling with direct linear solving is particular here since oscillations appear during convergence.

- non-linear material without saturation (Fig. 4): iterations of non linear solving are totally hidden by weak coupling solving. Only strong coupling results change compared to Fig. 3 to reach non linear convergence. It can be noticed that memory limitations have been compared with a limit about two times greater for weak coupling GS comparing to strong coupling.

- non-linear material with saturation (Fig. 5): weak coupling using iterative method shows slow convergence surely due to the interaction between iterative linear solving with approximated permeability. Here weak coupling with direct linear solving is the best (approximated permeability seems to act as a relaxation).

V. CONCLUSION

Different strategies of weak coupling of the PEEC and MoM methods have been compared with the strong coupling. It appears that weak coupling is better in term of time resolution and memory saving but for different method depending cases. An interesting improvement can be realized for both GS method in the case of saturated material, and direct linear solving in non saturated case to respectively speed up and relax convergence.

Adding to the gain on time and memory, the weak coupling presents other advantages like, easy understanding because it repeats faithfully the evolution of physical phenomena in system, more flexible and parallelizable tasks, and also reusability of the codes developed.

Perspectives are the modeling of more realistic non linear MoM-PEEC coupling. And then we try to establish interface specifications on MoM and PEEC methods to be easily coupled.

Abstract — The paper presents the thermal and fluid dynamics prediction of a distribution transformer. The model is based on the solution of the Navier-Stokes equations and the Maxwell equations which are solved sequentially. The thermal-fluid equations are solved using first-order finite elements and the characteristic-based-split scheme was used. The model results are compared against those obtained with commercial CFD software.

I. INTRODUCTION

In the design of electrical equipment, i.e., motors, generators and transformers, one design aim of the engineers is the minimization of the losses to increase efficiency and to avoid high temperatures within it. Thermal prediction is important because it allows assessing the dissipation of losses in the equipment. In addition, the insulation damage is directly linked to the hot-spot winding temperature; most of the transformers are immersed in mineral oil which has the functions of acting as a coolant and as an insulator. The cooling of transformers can be achieved by force-air (dry-type), natural and forced convection (oil-filled) or a combination of them. Conduction, convection and radiation are the forms of heat transfer in the transformer. The Navier-Stokes equations can model the thermal and fluid dynamics of oil-filled transformers [1]. In this paper, two-dimensional (2D) Finite Elements (FE) are used to solve the Maxwell and Navier-Stokes partial differential equations. The loss density in a distribution transformer are computed under no-load and load conditions using two FE models; the loss density is then employed in the Navier-Stokes equations which are solved using the Characteristic-Based-Split (CBS) scheme to compute the transient behavior of temperature and velocity fields within the transformer. The mathematical formulation was coded in C and the thermal results were validated using commercial software. The paper presents initial results of a project to couple the fluid dynamics and electromagnetic phenomenon in order to have a model for the integral analysis of transformers.

II. ELECTROMAGNETIC FIELD MODEL

The electrical losses generated within a transformer are: winding (dc and eddy), core and stray losses; the latter are neglected because its small numerical values. A 1500 kVA, 13200/220 V, delta-wye transformer was used in this paper [2]. The induced eddy current loss was calculated simulating

the load test, and its governing equation for the axi-symmetric model is [3]

$$\frac{\partial}{\partial z} \nu \frac{\partial (rA)}{r \partial z} + \frac{\partial}{\partial r} \nu \frac{\partial (rA)}{r \partial r} + \frac{j\omega\sigma}{r} (rA) = J_s \quad (1)$$

where ν represents the reluctivity, ω is the angular frequency, σ is the electric conductivity, A is the complex magnetic vector potential, J_s is the source complex current and r is radius.

The winding eddy current loss is calculated with

$$P_w = \iiint_{\Omega_w} \left(\frac{J^2}{\sigma} + \frac{\pi^2 \sigma f^2 b^2 B^2}{6} \right) d\Omega_w \quad (2)$$

where P_w stands for the winding losses, f is the rated frequency, b is the dimension of copper strip in the flux density B directions (x and y), J is the current density and Ω_w is the winding region volume.

The no-load core-loss is computed with the 2D Cartesian expression for the non-linear Poisson equation coupled to an external voltage source and after discretizing it using first order finite elements, it can be expressed as

$$\begin{bmatrix} S + j\omega N & -P \\ j\omega Q & R + j\omega L \end{bmatrix} \begin{bmatrix} A \\ I_w \end{bmatrix} = \begin{bmatrix} 0 \\ V_e \end{bmatrix} \quad (3)$$

where S is the FE stiffness matrix, P and Q are weighting winding matrices, R is the external resistance, L external inductance, I_w a vector of winding currents, V_e denotes the external potential sources and A represents a vector of complex potentials.

The core loss is calculated using the computed flux density with (3) and the core-loss information given by the core manufacturer as

$$P_{fe} = \iiint_{\Omega_c} m_c \rho_c f(B) d\Omega_c \quad (4)$$

where $f(B)$ is the specific iron loss, m_c denotes the core weight, ρ_c is the density of core oriented steel and Ω_c is the core volume.

III. THERMAL FIELD MODEL

The fluid and thermal behavior for oil-filled transformers with natural cooling are described by the continuity, momentum and energy equations, they are also known as the Navier-Stokes equations [4]. For incompressible fluids and constant density, the set of equations are:

a) Continuity equation (or mass conservation)

$$\frac{\partial U_i}{\partial x_i} = 0 \quad (5)$$

where $i=1,2$ denotes the components of U_i in 2D, $U_i=\rho u_i$, u denotes the velocity, ρ is the mass density and x_i are space variables.

b) Momentum equation

$$\frac{\partial U_i}{\partial t} = -\frac{\partial(u_j U_i)}{\partial x_j} + \frac{\partial \tau_{ij}}{\partial x_j} - \frac{\partial P}{\partial x_i} - \rho g_i \quad (6)$$

where

$$\tau_{ij} = \mu \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)$$

and $i=1,2$; $j=1,2$, P is the pressure, μ represents the kinematics viscosity, g is the gravity, τ is the viscosity tensor, and t represents time.

c) Energy equation

$$\begin{aligned} \frac{\partial(\rho E)}{\partial t} = & -\frac{\partial(u_j \rho E)}{\partial x_j} + \frac{\partial}{\partial x_i} \left(k \frac{\partial T}{\partial x_i} \right) - \frac{\partial}{\partial x_j} (u_j P) \\ & + \frac{\partial}{\partial x_i} (\tau_{ij} u_j) \end{aligned} \quad (7)$$

where E is the stored energy per unit mass, T denotes the absolute temperature and k is the thermal conductivity.

After applying the characteristic Galerkin procedure to the discretization of (5-7), and applying the Characteristic-Based-Split scheme, where in the first step, the pressure term is dropped and an intermediate velocity is calculated. In the second step, the pressure is calculated and at step 3, the velocities are corrected [4]. The set of discrete equations to solve are,

$$\begin{aligned} [M] \frac{\{\Delta U_1^*\}}{\Delta t} &= [C] \{U_1^n\} + [K_m] \{U_1^n\} + [K_s] \{U_1^n\} \\ [M] \frac{\{\Delta U_2^*\}}{\Delta t} &= [C] \{U_2^n\} + [K_m] \{U_2^n\} + [K_s] \{U_2^n\} + \text{gravity forces} \\ [K_m] \{\Delta P\} &= [M] \{U_1^*\} + [C] \{U_2^*\} + [K_s] \{P^n\} \end{aligned} \quad (8)$$

$$[M] \{U_1^{n+1}\} = [M] \{U_1^*\} + [C] \{P^n\} + [C] \theta_2 \{\Delta P\}$$

$$[M] \{U_2^{n+1}\} = [M] \{U_2^*\} + [C] \{P^n\} + [C] \theta_2 \{\Delta P\}$$

$$[M] \frac{\{\Delta T\}}{\Delta t} = [C] \{T_n\} + [K_i] \{T_n\} + [K_s] \{T_n\} + \frac{qA}{3C_p \rho} [I] + \frac{\mathfrak{I}q}{2} [I^1]$$

where M , C , K_s , K_m and K_i are matrices that contain material properties and domain geometry. U_1^* and U_2^* denote velocity related terms in the first step of the CBS scheme. T is the temperature, C_p is the specific heat, A is area, q is the heat source, \mathfrak{I} represents the distance between nodes at a boundary and \bar{q} denotes power density dissipated in a surface

boundary. The parameter θ_2 are related to the time discretization of the equations. The identity vectors I and I^1 are used for the heat source and boundary regions.

IV. SIMULATION RESULTS

A first order FE mesh was constructed to compute the transformer losses [5]. Using the same mesh, with the proper classification of regions (solid and fluid), the Navier-Stokes equations were solved. The thermal distribution obtained with the formulation presented here and from the commercial software are shown in figs. 1-2 [6]. Good results were also achieved for the velocity field of the transformer oil. Dirichlet boundary condition was used, but the model can handle convective and radiation boundary conditions. More results will be presented in the full paper version.

Fig. 1 Temperature distribution (°K) calculated at 60s using the model.

Fig. 2 Temperature distribution (°K) at 60s using the commercial software.

Abstract—A fully coupled magneto-mechanical model is proposed for simulating the effect of the magnetostrictive and magnetic forces in iron and applied to electrical machines. The model is based on the general balance laws of electromagnetism, mechanics, and continuum thermodynamics and it is implemented in 2D by using a conforming finite element method for the magnetic vector potential and the displacement field. The simulated results are in accordance with measurements on a test device.

I. INTRODUCTION

In non-linear magnetic media, the magnetic permeability depends on the magnetic, mechanical and thermal behavior. The magnetostriction depends on the field and on the stress state of the material. Previous research mainly treats the magneto-mechanical coupling problem as an indirect strongly or weakly coupled problem [1], [2]. In the weak coupled problem, local magnetic forces and local forces due to magnetostriction are calculated and the displacement is evaluated from those. The magnetic flux density updating is realized through measured permeability curves dependent on stress as in [3]. However, the more complex direct coupling requires a formulation of the interaction of different factors on the behavior of the material. This paper reports on a numerical implementation of a model for isochoric magneto-elastic deformation describing the coupled behavior of magnetic and mechanical properties of the material.

II. MODELING MAGNETOELASTIC DEFORMATION

The constitutive equations coupling the magnetic and elastic properties of the material are derived from a suitable form of the Helmholtz free energy presented in [4]. The material is supposed to be isotropic and isochoric. The model is extensively justified in [4] and [5]. The magnetic field strength vector \mathbf{H} is related to the total strain tensor $\boldsymbol{\varepsilon}_{\text{tot}}$ and flux density vector \mathbf{B} by

$$\mathbf{H}(\mathbf{B}, \boldsymbol{\varepsilon}_{\text{tot}}) = \mu_0^{-1} \mathbf{B} + \mathbf{M}(\mathbf{B}, \boldsymbol{\varepsilon}_{\text{tot}}). \quad (1)$$

The total stress tensor, $\boldsymbol{\tau}$ for iron is defined as the contribution of the Cauchy stress tensor $\boldsymbol{\sigma}$ and the electromagnetic stress tensor $\boldsymbol{\tau}_{\text{em}}$

$$\boldsymbol{\tau}(\mathbf{B}, \boldsymbol{\varepsilon}_{\text{tot}}) = \boldsymbol{\sigma}(\mathbf{B}, \boldsymbol{\varepsilon}_{\text{tot}}) + \boldsymbol{\tau}_{\text{em}}(\mathbf{B}, \boldsymbol{\varepsilon}_{\text{tot}}). \quad (2)$$

The necessary 6 parameters of the model are identified from unidirectional magnetostrictive stress measurements from a

modified Epstein frame [5]. Figure 1 shows the measured magnetostrictive strain and corresponding results from the model for both cases of compressive (curves 2-4) and tensile (curves 5-9) mechanical pre-stresses. The best fitted curve (curve 1) corresponds to no mechanical pre-stress.

Fig. 1. Magnetostrictive strain vs. magnetic flux density in the presence of tensile and compressive pre-stresses.

III. PROPOSED FINITE ELEMENT METHOD

The magnetic flux density and the displacements are solved at the element level by a coupled 2-D FEM approach and the Galerkin weighted residual weak form is implemented. The first order linearization of \mathbf{H} and $\boldsymbol{\tau}$ for the Newton's iteration are written as

$$\mathbf{H} = \mathbf{H}_0 + (\partial_{\mathbf{B}} \mathbf{H}) \delta \mathbf{B} + (\partial_{\boldsymbol{\varepsilon}} \mathbf{H}) \delta \boldsymbol{\varepsilon} \quad (3)$$

$$\boldsymbol{\tau} = \boldsymbol{\tau}_0 + (\partial_{\boldsymbol{\varepsilon}} \boldsymbol{\tau}) \delta \boldsymbol{\varepsilon} + (\partial_{\mathbf{B}} \boldsymbol{\tau}) \delta \mathbf{B}. \quad (4)$$

The iterative changes of the magnetic flux density, magnetic vector potential, strain, and displacements are denoted as $\delta \mathbf{B}$, $\delta \mathbf{A}$, $\delta \boldsymbol{\varepsilon}$ and $\delta \mathbf{u}$, and they are related by:

$$\delta \mathbf{B} = \nabla \times \delta \mathbf{A} \quad (5)$$

$$\delta \boldsymbol{\varepsilon} = \frac{1}{2} (\nabla \delta \mathbf{u} + \nabla \delta \mathbf{u}^T). \quad (6)$$

The nodal displacements \mathbf{u}_i and \mathbf{v}_i in x and y directions and the nodal values of the magnetic vector potential \mathbf{a}_i are the quantities solved according to (5) and (6). The Jacobian

matrix for the system of equation is expressed from (3) and (4). Through this formulation, the effect of the magnetic field on the elastic field is accounted for as well as the effect of the elastic field on the magnetic field. The procedure is outlined in Figure 2.

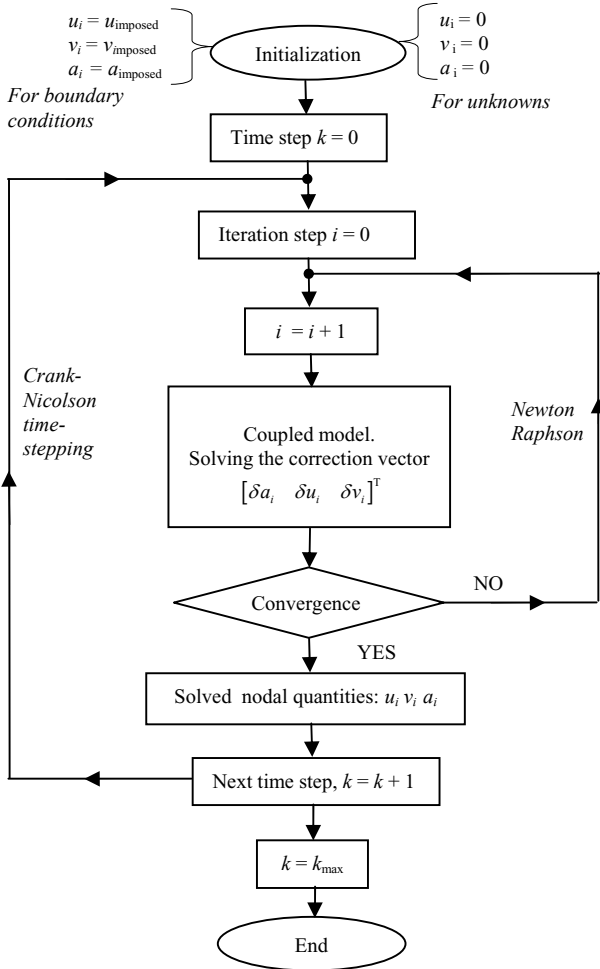

Fig. 2. Simplified flowchart illustrating the magneto-mechanical directly coupled finite element method.

IV. RESULTS AND VERIFICATIONS

The method is applied to a 4-pole 15 kW induction machine and also validated by comparing measurements and simulations from a test device. In the first case, the displacements in the rotor shaft are set to be zero in all directions. The outer surface of the stator can move in the radial direction only and all the other nodes are free. The contribution of magnetostriction and magnetic forces in iron, only, tends to expand the shape of the machine as seen in Figure 3. The simulation was performed under the rated voltage of 380 V and a slip of 3.2%. The amplitude of the maximum magnetic flux density in some parts of the machine (in some of the stator and rotor teeth, for instance) was 2 T. The distribution of the magnetic flux density is presented in Figure 4.

Fig. 3. Deformation of 15 kW induction motor due to magnetostriction and magnetic forces in iron, (Scale x 500 000)

Fig. 4. Geometry of the studied machine for the non-deformed state and distribution of the magnetic flux density, cross section.

V. CONCLUSION

This study focuses on the suitability of a coupled magneto-mechanical technique for vibrations analysis in electrical machines. The 2-D magnetic field and displacement are solved simultaneously without using the common “equivalent forces” approach. It enables an efficient computation as the different single valued stress-dependent magnetization curves do not need to be evaluated one by one as in the previous methods.

Abstract—Thermo-inductive testing is a new technique used for health investigations on different components of automotive and aeronautic industries. In this technique, eddy current deviation around the default creates local heating which can be detected by an infrared camera. The purpose of this work is to develop an original 3D finite element model as a support tool and to study the reliability of the technique. To reduce the number of unknowns, shell elements are introduced to model the defects. Inspected materials are classified into magnetic, non-magnetic and composites. Investigations on various parameters of the technique and crack dimensions are performed in order to optimize the method. Experimental and simulation results show that the method is well suited.

I. INTRODUCTION

Cracks constitute one of the major problems threatening the security of systems subjected to mechanical, thermal or chemical constraints. In order to detect and characterize these defects, many methods of NDT are used and they are in a constant development according to applications and investigation fields. In this context, we propose a new method called thermo-inductive technique which combines the advantages of both eddy current and infrared thermography techniques. The relevance and the feasibility of the technique have been shown in previous papers [1-2].

Numerical modeling of cracks involves difficulties due to their small thickness compared to other dimensions. This is expressed by mesh problems such as high density or deformed elements leading to a prohibitive computing time or ill-conditioned matrix systems. In literature, many researches have been carried out to model thin regions. Among the various proposed methods, the shell elements one which derives from degeneration of Whitney prism elements is well suited for our problem [3].

The ability of thermo-inductive method to detect the defects depends on electromagnetic and thermal properties of the material under investigation. In automotive and aeronautic industry, three principal groups of material are used: ferromagnetic metals, non magnetic metals and carbon fibre composites. The first group has a non linear magnetic permeability and a typical small electromagnetic skin depth compared to the thermal depth. The second group has linear characteristics but the same constraint on electromagnetic and thermal penetration and the third group has non isotropic physical properties but a high skin depth.

To consider all these constraints, we have developed a 3D finite element method based on Whitney's elements under Matlab environment as a support tool to model the different phenomena involved in this technique. This model takes into

account the anisotropy, the non-linearity of materials and cracks modeled by the shell elements.

The new technique is applied to defects detection in typical pieces used in automotive and aeronautic industries. Due to their anisotropic properties and scale factor, composite materials are modeled after a preliminary homogenization stage. Investigations on various parameters such as inductor geometry, defect characteristics and field and thermal frequencies have been carried out for each material in order to optimize the defect detection.

II. PROBLEM DESCRIPTION

A typical measurement installation for the thermo-inductive method is shown in Figure 1. In this technique, the electromagnetic and thermal penetrations have a great influence on the defect detection. These two parameters depend on the field and thermal frequencies as well as the material physical properties. This is why the optimal field and thermal frequencies depend on the material under investigation. The induction frequency may vary from 50 Hz to 2 MHz and the thermal frequency from 0.1 Hz to 20 Hz.

Fig. 1. Schematic of experimental system

A numerical modeling allows a good understanding of the influence of these properties on the current flow and the temperature distribution, and therefore on the defect detection.

III. NUMERICAL MODELING

The electromagnetic problem defined by Maxwell's equations is solved with the 3D finite element method. Using T- Φ formulation, the weak formulation T- Φ used in the harmonic state is [4]:

$$\int_{\Omega_C} \left(\left[\frac{1}{\sigma} \right] \text{curl } \mathbf{W}_{e_i} \cdot \text{curl } \mathbf{T} + j\omega[\mu] \mathbf{W}_{e_i} \cdot (\mathbf{T} - \text{grad}\Phi) \right) d\Omega = - \int_{\Omega_C} \left(\left[\frac{1}{\sigma} \right] \text{curl } \mathbf{W}_{e_i} \cdot \text{curl } \mathbf{T}_0 + j\omega[\mu] \mathbf{W}_{e_i} \cdot \mathbf{T}_0 \right) d\Omega \quad (1)$$

$$- \int_{\Omega_C} j\omega[\mu] \text{grad } \mathbf{W}_{n_i} \cdot \mathbf{T} d\Omega + \int_{\Omega} j\omega[\mu] \text{grad } \mathbf{W}_{n_i} \cdot \text{grad } \Phi d\Omega = \int_{\Omega} j\omega[\mu] \text{grad } \mathbf{W}_{n_i} \cdot \mathbf{T}_0 d\Omega \quad (2)$$

Where \mathbf{T} is the electric vector potential, Φ is magnetic scalar potential, $[\mu]$ represents the tensor of equivalent magnetic permeabilities, and $[\sigma]$ the tensor of electric conductivities and \mathbf{T}_0 is the source field. \mathbf{W}_{e_i} and \mathbf{W}_{n_i} are the edge and nodal shape functions respectively. Ω and Ω_C are respectively the whole and the conducting domains.

In order to take into account of the nonlinearity of magnetic materials, the iterative calculation using the Newton-Raphson method is adopted. Different algorithms to obtain optimal relaxation factor are introduced in our model to get faster and stable convergence [5].

In the thin regions like defects, similar elements to the prismatic elements are introduced. In the discrete formulation of the problem, the volume integrals are replaced by surface integrals using shell elements. The scalar and vector fields are approximated by nodal and edge elements which are developed specifically for thin regions. The formulation will be detailed in the full paper.

The thermal problem is defined by heat transfer equation:

$$\int_{\Omega} \left[\rho C_p \frac{\partial T}{\partial t} - \text{div}([\lambda] \cdot \text{grad } T) \right] \cdot \mathbf{W}_n \cdot d\Omega = \int_{\Omega} \mathbf{P} \cdot \mathbf{W}_n \cdot d\Omega \quad (3)$$

Where ρ , C_p , λ , \mathbf{P} are respectively, the specific mass, the specific heat, the thermal conductivity, and the electromagnetic induced power density. Ω is the studied domain.

Both electric and thermal formulations have been solved using finite element method based on Whitney's elements.

In order to study the defect detection and the influence of various parameters of the system on the characterization of the cracks, thermal and phase contrast are introduced as a discriminating parameter. They provide a good indication of the defect characteristics. The thermal contrast consists to compute the relative surface temperature difference between regions with and without defect. The phase contrast is calculated from the discrete Fourier's transform of the surface temperature $s(t)$ [2, 6]:

$$F(f) = \Delta t \cdot \sum_{n=0}^{N-1} s(t) \cdot \exp(-j2\pi f n \Delta t) = R(f) + jI(f) \quad (4)$$

Where Δt is the sampling time step. $R(f)$ and $I(f)$ are respectively, the real and imaginary components of $F(f)$.

IV. APPLICATIONS AND RESULTS

Numerical models developed for NDT by thermo-inductive technique allow the prediction of the defect detection depending on the parameters of the method and the physical properties of inspected materials. The validation of the finite element model by comparison with experimental data will be detailed in the extended paper.

The investigations show that depending on the nature of material, the induction and thermal frequencies and defect dimensions, the defects are more or less detectable.

Figure 2.b shows the cartography of the thermal contrast of a ferromagnetic material. The calculated temperature is more contrasted around the crack. The defect is appearing as a line with two hot spots in extremities. In the extended paper, the

behavior of the other groups of materials will be detailed and will be explained as function as the physical properties.

Fig. 2. (a) Modeled piece with crack and (b) Image of thermal contrast distribution (fr=100kHz)

Figures 3(a) and 3(b) present the thermal and phase contrasts for ferromagnetic materials calculated from the numerical model. The thermal contrast is inversely proportional to the heating duration. There is also an optimal induction frequency (27 kHz in this case) which corresponds to the maximum of both thermal and phase contrast. The results show that the use of both thermal and phase contrast allow a good and reliable detection of defects.

Fig. 3. (a) Thermal contrast as function of the heating period and (b) Phase contrast versus the thermal frequency for different induction frequencies

V. CONCLUSION

The results have demonstrated the relevance of the thermo-inductive technique and the efficiency of 3D model which takes into account the nonlinearity, the anisotropy of and introduces the shell elements for modeling defects.

In the full paper, the FEM models using shell elements will be detailed. Classification of materials according their properties will be specified. Investigation on various parameters of the method using optimization algorithms will be proposed with a goal function based on the contrast.

Abstract—A three-dimensional numerical method for solving mechanical-electrical-thermal coupled problems and suitable for analyzing electric connectors is presented. The analysis of electric connector performance is a typical multiphysics problem involving mechanical, electrical, and thermal coupled effects. In the proposed approach contact interfaces are analytically modeled in order to account for the surface roughness causing a random distribution of conducting spots. According to the Cell Method mechanical, electrical, and thermal problems in the bulk regions are directly expressed in terms of integral variables allowing for an easily coupling with the analytical contact interface model.

I. INTRODUCTION

Separable connectors are among the most widely used electric components, in a wide range of appliances, starting from signal applications (e.g. micro-connectors and fast-on) up to power applications (e.g. switch-gears). These components ensure the electric continuity between different circuits. The performance of electrical connectors relies on both mechanical and electrical properties of contact materials in order to ensure low and stable contact resistance over the expected service life. Connectors must fulfill tight requirements in terms of maintenance, reliability, and stability of material properties. Other desirable properties are: compact size, rugged construction, durability (capable of many connect/disconnect cycles), rapid assembly, simple tooling, and low cost.

Cost minimization is based on proper numerical design tools which should take care of multiple physics phenomena occurring in connectors. Mechanical, electrical, and thermal effect have to be coupled for a realistic modeling of the electric connector. The contact strength depends either on the applied stress or on the mechanical material response, which is affected by the local temperature distribution. A non-uniform distribution of current density around the contact may lead to hot spot formation, causing a thermal aging of materials. Moreover, the heat generated by Joule's losses determines a local flattening of the contact area and a contact pressure reduction [1].

II. NUMERICAL MODEL

In the following a three-dimensional numerical model accounting for multiple coupled physics phenomena related to electric contacts is discussed.

The analytical contact interface model is used for coupling the discrete models of the bulk connector domains. Bulk

regions are discretized according to the Cell Method (CM), which can be used effectively for coupling different formulations [2] [3]. The electro-thermal model is based on the discrete formulation presented in [4] and coupled to a non-linear elastic discrete formulation for analyzing the effects of the beam deformation on the connector performance.

Fig. 1 shows the reference geometry taken into account in the analysis: a hemisphere (1.2 mm radius, brass) is compressed with a 2 N applied load; the contact beam (0.4 mm thick, 1.4 mm width, iron and brass) is constrained to a hexaedron (1.5 mm edge).

Fig. 1. Three-dimensional model of the electric connector (the brass region is shaded in gray, while the iron region is shaded in orange).

A. Contact interface model

The electric contact is established in correspondence of the mechanical contact surface, which depends on the applied force and the surface roughness. It is assumed that flux lines of the electric current density are concentrated on separated micro contact spots (*a*-spots). The conventional treatment of electrically heated contacts assumes that Joule's losses, concentrated at the *a*-spots, are dissipated only by conduction through bulk conductors [5]. In these conditions, according to Kohlraush's theory, the voltage drop at the contact interface can be expressed as a function of the maximum temperature T_m at the contact interface as:

$$U_c = \left(2 \int_{T_1}^{T_m} \lambda_1 \rho_1 dT \right)^{1/2} + \left(2 \int_{T_2}^{T_m} \lambda_2 \rho_2 dT \right)^{1/2} \quad (1)$$

where λ and ρ are respectively the thermal conductivity and the electrical resistivity of two contact elements, the subscripts

refers to the materials in contact, and T_1 and T_2 are the temperatures in bulk conductors. The coupling interface area can be estimated according to Hertz's theory. The contact surface is approximated locally as a discoidal region, accounting on average for the random distribution of a -spots. In the case of purely elastic deformation and a sphere-plane geometry, the a -spot radius can be approximated as:

$$a_e = \left(\frac{3}{4} F R \left(\frac{1 - \sigma_1^2}{E_1} + \frac{1 - \sigma_2^2}{E_2} \right) \right)^{1/3} \quad (2)$$

where F is the contact force, R is the sphere radius, E_1 and E_2 are the Young's elasticity modulus, and σ_1 and σ_2 are the Poisson's ratios. A similar empirical expression holds for plastic deformation [6].

B. Discrete conduction problem

In CM-based formulations field problem domains are discretized into primal and dual staggered cell complexes, where arrays of degrees of freedom (DoFs) are defined. For a steady state conduction problem the DoFs are voltages \mathbf{u} defined on primal edges and the electric currents \mathbf{j} defined on dual faces. Electric currents include both impressed and ohmic contributions computed by the discrete Ohm's law:

$$\mathbf{j} = \mathbf{j}_s + \mathbf{M}_\sigma \mathbf{u}. \quad (3)$$

where \mathbf{M}_σ is the electric constitutive operator. This operator can be constructed positive definite by a proper choice of shape functions [4]. The array of currents must comply with the div free condition:

$$\tilde{\mathbf{D}}\mathbf{j} = 0. \quad (4)$$

where \mathbf{D} is the discrete div operator and the tilde indicates the dual operator. The source current distribution \mathbf{j}_s is constructed in such a way that $\tilde{\mathbf{D}}\mathbf{j}_s = 0$ is automatically enforced.

In steady state conditions the electric scalar potential \mathbf{v} can be introduced, i.e., $\mathbf{u} = -\mathbf{G}\mathbf{v}$, where \mathbf{G} is the discrete gradient operator. By using the topological relationship $\tilde{\mathbf{D}} = -\mathbf{G}^T$ and by taking into account (3) and (4), the following semi-definite system of linear algebraic equations is obtained:

$$\mathbf{G}^T \mathbf{M}_\sigma \mathbf{G} \mathbf{v} = 0. \quad (5)$$

C. Discrete thermal problem

The transient thermal problem can be modeled by using the discrete Fourier equation [4]:

$$\mathbf{G}^T \mathbf{M}_\lambda \mathbf{G} \mathbf{t} + \mathbf{M}_{\rho c_p} \dot{\mathbf{t}} = \mathbf{w} \quad (6)$$

where \mathbf{t} is the array of temperatures on primal nodes, \mathbf{M}_λ is the discrete thermal conductivity operator, $\mathbf{M}_{\rho c_p}$ is the mass matrix, \mathbf{w} is the array of electric powers generated in dual volumes, and the dot indicates the time derivative. This system of linear differential-algebraic equations describing the propagation of heat in time and space can be integrated by the θ -method, which ensures both accuracy and stability with a proper choice of the parameter θ .

Fig. 2. Stress map σ [N m²] in proximity of the contact region.

D. Discrete non-linear elastic problem

The connector deformation due to thermal and mechanical effects is analyzed in the discrete non-linear elastic problem. By using a small strain approach the total strain array ϵ can be decomposed into elastic ϵ_e and plastic ϵ_p arrays [7]. Discrete Hooke's law accounts for mechanical properties of materials:

$$\boldsymbol{\sigma} = \mathbf{M}_e (\boldsymbol{\epsilon} - \boldsymbol{\epsilon}_p) \quad (7)$$

where \mathbf{M}_e is elastic constitutive operator. By using the Von Mises criterion the yield domain is defined by the plasticity function $f(\boldsymbol{\sigma}, k) = \sqrt{3}\bar{\sigma} - Y(k) \leq 0$ (k is the kinematic hardening parameter, $\bar{\sigma}$ is the Von Mises equivalent stress) and the material behaves elastically when $f < 0$.

Fig. 2 shows the Von Mises equivalent stress distribution around the contact interface.

III. DISCUSSION

The electro-thermo-mechanical coupling of previous equations is realized through constitutive matrices and the right hand sides (e.g., the array \mathbf{w}). For instance constitutive matrices depend on the temperature distribution and the node displacements obtained from the non-linear elastic problem. A more detailed description of the model and simulation results for the main physical quantities will be reported in the paper.

Improvements to convergence of coupled non-linear circuit modelling

S.Taylor, N.Robertson and J.Simkin
Cobham Technical Services, Vector Fields Software

VectorFields.Info@cobham.com

Abstract— The finite element solution of electromagnetic problems often requires coupling into electric circuit equations. These circuits are often coupled to power electronic or control systems, where non-linear components, such as diodes are regularly used. The standard non-linear techniques used within finite element solutions are applicable to the coupled equation system, but tend to struggle to converge to the required accuracy due to the extreme nature of the non-linearity of these components. This paper describes an improvement to the non-linear solution of circuit equations containing diodes, using the Opera-3d finite element analysis software, though the method is equally applicable to other non-linear components.

I. INTRODUCTION

The use of finite element solutions for non-linear problems is common. A formulation for the electromagnetic solution can be found using the magnetic vector potential such that

$$\nabla \times \frac{1}{\mu} \cdot \nabla \times \mathbf{A} = \mathbf{J} \quad (1)$$

The permeability, μ , is a non-linear function of the local magnetic flux density. The standard technique used is an iterative solution process, where the best solution available at the present time is used to update the estimate of the non-linear permeability. For simple cases this technique will converge, but slowly.

Highly nonlinear material characteristics will cause simple update methods to oscillate wildly. The addition of over/under relaxation to the iterative process can be used to control these oscillations and ensure convergence. Typically, the matrix solution requires a significant solution time. By scaling the change in solution vector by a relaxation factor, it is possible to test and select a better estimate of solution. Finding a suitable relaxation factor is still a problem. This can be a particular problem when the current solution lies close to a local minimum. In this case it may be necessary to move away from this area before the convergence can find the true solution.

The use of a Newton-Raphson update is also a common technique for improving solution convergence. By using derivative information representing the change in non-linear property with terms in the solution vector, the equation solution matrix is augmented to give improved convergence properties. Within the capture radius this technique will converge quadratically; however with strong nonlinearities the capture radius is small and the use of Newton-Raphson techniques can slow convergence.

The application of both of these techniques [1,2] within the same system provides a robust solution.

II. COUPLED CIRCUIT EQUATIONS

When solving for the time variation of magnetic fields in a model domain, the use of a time varying current provides the standard input to drive the finite element formulation.

For many applications, the drive is provided by a voltage source rather than a prescribed current. Additionally, such a voltage will operate as part of an electric circuit. The use of a voltage drive requires a close coupling to be modeled as the voltage, current and magnetic fields are all tightly linked.

This can be achieved by including extra equations in the finite element matrix [3] to give a solution for the currents within the electric circuit.

$$\nabla \times \frac{1}{\mu} \cdot \nabla \times \mathbf{A} - \sigma \frac{d\mathbf{A}}{dt} - \mathbf{I} = 0 \quad (2)$$

$$\int n \cdot \frac{d\mathbf{A}}{dt} + \mathbf{I}\mathbf{R} = \mathbf{V} \quad (3)$$

Using Galerkin integration over the finite element mesh, and applying suitable scaling to equations, gives a symmetric matrix of the form

$$\begin{bmatrix} \mathbf{M}_{AA} & \mathbf{M}_{AI} \\ \mathbf{M}_{IA} & \mathbf{M}_{II} \end{bmatrix} \begin{bmatrix} \mathbf{A} \\ \mathbf{I} \end{bmatrix} = \begin{bmatrix} \mathbf{J} \\ \mathbf{V} \end{bmatrix} \quad (4)$$

For most problems $\text{rank}(\mathbf{M}_{AA}) \gg \text{rank}(\mathbf{M}_{II})$.

III. DIODE MODELLING

A typical non-linear characteristic of the diode can be seen in the Shockley description

$$I = I_s \left(e^{V_D / (nV_T)} - 1 \right) \quad (5)$$

where

- I is the diode current,
- I_s is the reverse bias saturation current,
- V_D is the voltage across the diode,
- V_T is the thermal voltage,

The diode can be represented as a non-linear resistor or using equivalent circuits to represent an approximate model at its current operating point. However, the non-linearity is extreme, as can be seen by the exponential variation of current through the diode.

A nonlinear circuit equation must be solved to determine the operating point of the diode. The same techniques used in the non-linear permeability updates can be applied.

IV. IMPROVED DIODE MODELLING

The method proposed uses a sub domain iterative solution of the circuit equations, as part of the relaxation procedure used to improve the convergence of the full solution. Rather than relax the solution to the circuit equations through the use of a single relaxation factor, an approximate solution to the circuit matrix, \mathbf{M}_{II} , can be found, given an updated relaxed magnetic vector potential.

$$\mathbf{I} = (\mathbf{M}_{II})^{-1} \left(\mathbf{V} - \mathbf{M}_{IA} \frac{d\mathbf{A}}{dt} \right) \quad (6)$$

- (1) Solve for full matrix using current estimate.
- (2) Calculate error in solution:
 - If the error is low, convergence has been achieved, exit.
 - If the error is reduced significantly, repeat (1).
- (3) Relax change in magnetic vector solution by new relaxation factor σ .
- (4) Converge the non-linear solution for equation (6).
- (5) Repeat from (2)

The relative rank of the circuit current sub matrix, \mathbf{M}_{II} , means that the independent solution to this sub matrix is very inexpensive compared to the full matrix solution and non-linear updates. By reducing the number of non-linear iterations, (1) in the loop above, we can achieve a reduced overall solution time.

V. RESULTS

The method has been implemented within the Opera-3d finite element module, ELEKTRA.

A model of a transformer and full wave rectifier has been created. Fig. 1 shows a quarter model of the device. Fig. 2 shows the circuit used to drive the model including the full wave rectifier.

Fig. 1. Quarter model of transformer

The total CPU time for analysis using the standard non-linear updates and using the implemented method are detailed in Table I.

Fig. 2. Circuit of transformer and full wave rectifier

The CPU time as a function of simulation time is shown in Fig. 3. It can be seen that using the standard ELEKTRA, the analysis was successful, but as the voltages driving the rectifier switched sign, the analysis struggled to converge the non-linear solution. Using the updated method, the non-linear convergence characteristics are significantly improved as the solution at the switch positions.

TABLE I
CPU Time for analyses

Method	CPU Time (s)
Standard ELEKTRA	1713 s
Updated ELEKTRA	963 s

Fig. 3. CPU time required for analysis time, and resulting rectified current

VI. CONCLUSION

The updated method has been described and implemented within Opera-3d. A significant improvement for the solution of a transformer with full-wave rectifier can be seen. The application of the improved non-linear update algorithm will be tested further on more complex models.

Abstract— Precise permanent magnet generator modeling requires a complex electromagnetic field analysis in order to account for motor eccentricity and end zone leakage field. The paper presents a particular technique enabling to consider such phenomena through convenient 2D and 3D finite element models and incorporate the respective electromotive force distributions including space harmonics in real time control systems. The proposed methodology has been validated by measurements on a permanent magnet generator prototype.

I. INTRODUCTION

In wind generator (WG) systems, the generator holds a key role, both actual, in sense of efficiency as well as insubstantial, in sense of modeling and simulation [1]-[5]. This paper focuses on appropriate modeling of the characteristics of permanent magnet generator (PMG) by employing results of particular FEM analysis and producing harmonic representation of electromotive force and electromagnetic torque with loading and rotor speed. Such a model enables efficient real time generator representation for control purposes. The proposed methodology's accuracy has been verified by measurements on a prototype shown in Fig. 1, under transients as well as under three WG different control techniques which aim at maximizing the WG's output power through load variation.

Fig. 1. Typical permanent magnet variable speed wind turbine system

II. GENERATOR MODELING

A. Permanent Magnet Material Optimization

Due to large cost of permanent magnets, it is necessary to minimize magnet material, given the output effective voltage. A 2D FEM is used to choose the best values for permanent magnet dimensions, in conjunction with sensitivity analysis technique [1] – [3]. In the above analysis it is important to account for rotor eccentricity, simulated through air gap variation as shown in Fig. 2. Eccentricity effects in conjunction with appropriate modeling of the end zone machine parts are then represented by using a convenient hybrid 2D-3D FEM model shown in Figs. 2 and 3.

In order to predict and accurately simulate the voltage waveforms and equivalent circuit components of the generator the 3D representation as well as the eccentricity consideration are necessary. The computed electromotive force waveforms for different eccentricities are shown in Fig. 4.

Fig. 2. 2D FEM model a) Region of reduced air-gap in b) region of increased air-gap

Fig. 3. 3D FEM model

Fig. 4. Induced voltage variation for different air gap eccentricity values Δe

B. Non-linear system behavior

The FEM analysis enables to compute the electromotive force waveforms, varying with the loading and rotor speed as well as the equivalent circuit parameters of the generator. Such an analysis can be easily incorporated in the control algorithm of the system by calculating the electromotive forces e_n shown in Fig. 4 and electromagnetic torque T_{el} . Using these values it is possible to both simulate transient

response and calculate steady-state operation. Since the generator is used with a rectifier, average values sufficiently describe most interesting parameters, such as the rectified current that is charging the DC bus capacitor as well as the electromagnetic torque. In practice look-up tables have been used including a number of points adequate to interpolate the data without significant error, as shown in Fig. 5.

Fig. 5. Generator electromagnetic torque versus electrical frequency and load voltage

III. RESULTS AND DISCUSSION

A. Steady State Operation

When accurate data of voltage and current waveforms are available, it is possible to calculate power, the electromagnetic torque and associated losses with little error, therefore predict and fine tune the system behavior. Figures 6a,b show the computed and experimental phase voltages of the generator, respectively. The waveforms are in very good agreement, in both form and amplitude.

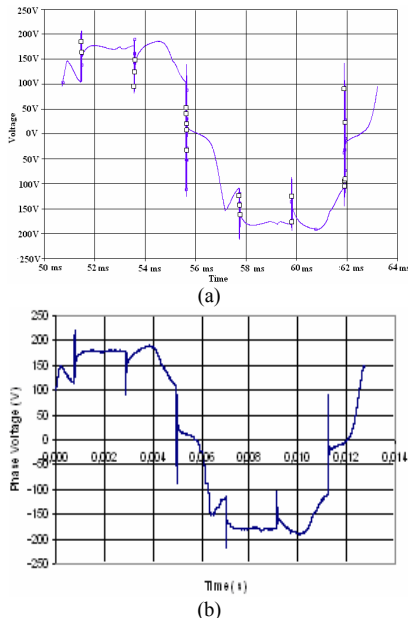

Fig. 6. Generator phase voltage waveform a) Simulation result b) Experimental result.

B. Dynamic Operation

Accurate prediction of operating points allows fine tuning of control parameters, which in turn results in optimal dynamic performance. Fig. 7a shows the simulation result for the rectified generator current for a nearly instant change of input mechanical torque from 4.9 Nt.m to 39.2 Nt.m, while Fig. 7b

shows the measured current for the same input. A good agreement is observed.

Fig. 7. Rectified generator current for input mechanical step torque variation from 4.9Nt.m to 39.2Nt.m a) Simulation results b) Experimental results

C. Operation under Variable Wind Speed

Further validation of the proposed model calls for operation under realistic stresses. The prototype system is tested under a specific measured wind time variation. Simulated and measured WG output power P_g are in conformity as can be seen in Fig. 8.

Fig. 8. Simulated and measured WG output power time variation, P_g .

IV. CONCLUSION

A new methodology has been proposed providing an appropriate model for the PMG representation. The method is based on particular field analysis considering higher harmonics of electromotive forces and taking into account both rotor eccentricity and winding end zone parts. It gives very good accuracy for both steady state and transient system response. Experimental validation on a prototype illustrated the method suitability for wind power applications.

Abstract— The proton exchange membrane is a key component in presently widely studied Proton Exchange Membrane Fuel Cells. In this paper a fully coupled three-dimensional dynamic numerical model of the membrane including ion transport, hydration-dependent conductivity and thermal effects is presented. The highly non-linear model is discretized by means of the Finite Element Method.

I. INTRODUCTION

Fuel Cells (FCs) are considered a very promising energy source for a number of different applications, ranging from small units for portable electronic devices to mid-size generators for the automotive industry and to large stationary power supply systems. The proton exchange membrane (PEM) is a key component in all so-called Proton Exchange Membrane Fuel Cells (PEMFCs). It is the component where most Ohmic losses occur, since ionic conduction is orders of magnitude lower than electron conduction in the anode and cathode current collectors. It also limits the operational temperature of the FC and presents fuel cross-over effects, which reduce fuel efficiency, increase electrochemical kinetics losses and causes cathode catalyst poisoning. An accurate modeling of the membrane is therefore needed for studying its electrical and physical behaviour. In this paper a three-dimensional model which includes all the most relevant physical phenomena (ion transport, hydration-dependent conductivity and thermal dependency) is developed and discretized with the help of the Finite Element Method.

II. COUPLED MODEL

A thorough description of the derivation of all equations is beyond the scope of this paper, further details can be found in [1]. All units are S.I. unless otherwise stated.

A. Polymeric conductivity model

The polymeric conductivity σ can reach values as high as 20 S/m at 100 °C, but strongly depends on the temperature T and on the membrane hydration λ , which varies from point to point being the ratio between the water concentration c_w and the sulfonic acid concentration $c_{sa}=1970$ mol/m³, according to the following semi-empirical expression:

$$\sigma(\lambda, T) = (51.93\lambda)e^{\frac{W_a}{k}\left(\frac{1}{303}-\frac{1}{T}\right)} \quad (1)$$

with W_a the activation energy and k the Boltzmann's constant. In our case $W_a/k = 1268$ K. Measurements show that λ is in the range [0,0.22]. Unfortunately, λ cannot be measured directly at the membrane's surface and therefore must be

expressed as a function of more readily measurable quantities. This can be achieved by following empirical relationship:

$$\lambda = \begin{cases} 4 \cdot 10^{-5} + 0.18a_w - 0.4a_w^2 + 0.4a_w^3 & a_w \in [0,1] \\ 0.14 + 1.4(a_w - 1) & a_w \in [1,3] \end{cases} \quad (2)$$

where a_w is the relative humidity, i.e. is the ratio between the partial water steam pressure p_w and the saturation value p_{ws} [bar] which depends on the temperature T according to:

$$a_w = \frac{p_w}{10^{(-20+0.11T-2.1 \cdot 10^{-4}T^2+1.4 \cdot 10^{-7}T^3)}} \quad (3)$$

The partial water steam pressure p_w , which can be measured at the membrane interface, is determined at the catalyst layers according to the electrochemical semi-reactions (fuel oxidation at the anode and oxygen reduction at the cathode) and the mass transport in the diffusion layers. The distribution of λ inside the membrane thickness depends on two effects, namely electro-osmotic drag and back-diffusion. The water molar flow due to the former effect can be expressed as:

$$N_{we} = \nu_w J_{prot} = \frac{\nu_w J}{F} \quad (4)$$

where $\nu_w = r_w = 2.5$ is the electro-osmotic drag coefficient and F is Farady's constant. Based on Fick's first law, water molar flow due to the back-diffusion effect is:

$$N_{wd} = -D_w c_{sa} \nabla \lambda \quad (5)$$

where D_w is the water diffusivity in the membrane which can be expressed by following semi-empirical expression:

$$D_w(\lambda, T) = (2.6 - 33\lambda + 264\lambda^2 - 671\lambda^3)e^{2416\left(\frac{1}{303}-\frac{1}{T}\right)-23} \quad (6)$$

The total water molar flow N_w across the membrane is therefore:

$$N_w = N_{we} + N_{wd} = \frac{\nu_w J}{F} - D_w c_{sa} \nabla \lambda \quad (7)$$

Its dynamic behavior conforms Fick's second law, expressed in terms of λ :

$$\nabla \cdot N_w + c_{sa} \partial_t \lambda = 0 \quad (8)$$

that, together with (7), gives the following diffusion equation:

$$\nabla \cdot D_w \nabla \lambda - \partial_t \lambda - \nabla \cdot \frac{\nu_w}{F c_{sa}} J = 0 \quad (9)$$

The current density \mathbf{J} of (9) is the same one appearing in Maxwell's equations so that, introducing the electric scalar potential V , (9) can be rewritten as:

$$\nabla \cdot D_w(\lambda, T)\nabla\lambda - \partial_t\lambda + \nabla \cdot \frac{\nu_w}{Fc_{sa}}\sigma(\lambda, T)\nabla V = 0 \quad (10)$$

B. Current flow model

The electric scalar potential of (10) must obey the charge conservation equation:

$$\nabla \cdot \sigma(\lambda, T)\nabla V = 0 \quad (11)$$

where the conductivity σ depends upon the temperature and the hydration according to (1). This equation allows to eliminate the last term in (10).

C. Thermal model

Since most quantities appearing in the polymeric conductivity model and the current flow model depend on the temperature it is also necessary to solve the transient heat equation

$$\rho c_p \partial_t T - \nabla \cdot k(\lambda)\nabla T - \sigma(\lambda, T)(\nabla V)^2 = 0 \quad (12)$$

where the last term on the left hand side represents the Joule losses. It has been shown in [3] that the thermal conductivity in (12) can be represented by $k = 0.12 + 0.81\lambda$.

D. Coupled multi-physics model

The complete model to be solved is assembled from (10), (11) and (12) together with nonlinearities (1) and (6) and with appropriate boundary (time-dependent Dirichlet and homogeneous Neumann) and initial conditions. The peculiarities of the set of equations and the very small thickness of the membrane with respect to its planar extension result in a very badly conditioned system of equations which is one side too large to be handled with a direct solver and on the other hand very difficult to precondition. Furthermore, the kind of nonlinearities in the model are such that the Newton-Raphson algorithm does not converge without strong underrelaxation. All these difficulties make it unadvisable to try and solve the full problem with naïve tools and call for the use of extremely robust nonlinear and linear solvers. Therefore the coupled model has been implemented with the help of the COMSOL Multiphysics environment [4].

III. RESULTS

The coupled model has been used to study a typical laboratory 2cm x 2cm x 200 μ m membrane. Fig. 1 shows the relative magnitude of the electro-osmotic and back-diffusion flows, while Fig.2 shows the behavior of the electrical conductivity across the membrane during a 10 minute transient (one line per minute).

Fig. 1: Electro-osmotic drag (red cones) and back-diffusion (blue cones)

Fig. 2: σ across the membrane during transient

IV. CONCLUSIONS

The presented fully coupled three-dimensional dynamic model of polymeric membranes for fuel cells has been used to simulate the transient behavior of a PEMFC membrane under realistic operating conditions. In ongoing work the model will be coupled with other fuel cell components and will be used to study the influence of localized defects on the membrane's performance and. In the full paper more details regarding the model and its numerical implementation will be presented.

Abstract—Thermal performance in oil-immersed power transformers is governed by the flow of oil, acting both as an electrical insulator as well as a medium for the transport of heat generated in the core and windings towards the tank and the surrounding air. In our previous work, a two-dimensional hybrid analytical-numerical technique for ONAN transformer thermal analysis was presented, able to predict thermal performance at a low computational cost for optimization purposes. The present work expands thermal analysis in three dimensions, taking into account detailed transformer geometrical parameters and coupling with fluid flow dynamics. The proposed methodology provides an integrated tool for thermal simulation, able to predict detailed thermal distribution in a specific transformer, without requiring prior knowledge of nodal temperature or temperature gradient values.

I. PROPOSED METHODOLOGY

Thermal finite element method (FEM), as well as other numerical methods, has been extensively applied in thermal analysis of electric machines and transformers, providing enhanced representation of the geometrical configuration of the considered devices, in an effort to replace semi-empirical methods involving analytical formulas and constants deriving through experimental results. However, such an analysis requires correct definition of heat convection coefficient constants and boundary conditions [1], which are influenced by the oil flow in the transformer tank. For the accurate calculation of these parameters, the coolant flow distribution must be modeled, therefore necessitating the incorporation of computational fluid dynamics (CFD) tools to the analysis [2] [3]. The proposed methodology combines three-dimensional (3D) thermal and fluid flow FEM analysis, for the derivation of the transformer temperature distribution under different loading conditions. The coupling of fluid flow equations with heat equations is necessary in order to model the oil flow within the transformer tank. Therefore, the thermal conditions at the boundaries between the transformer active part and tank components and the cooling medium are calculated by the proposed method and there is no need to externally predefine them in the thermal finite element model.

Apart the aforementioned methodology, accurate prediction of transformer thermal performance is enhanced by:

- Detailed geometry representation of transformer active

part and tank: special consideration is given to the representation of design details of particular importance to thermal analysis, such as the existence of cooling ducts in the coils and the tank corrugated panels geometry.

- Accurate estimation of the transformer heat sources, i.e. the core and coils loss density, which are determined through an appropriate design methodology [4].

A. Thermal FEM Equations

The 3D thermal transformer analysis is governed by the equation:

$$K_x \cdot \frac{\partial^2 T}{\partial x^2} + K_y \cdot \frac{\partial^2 T}{\partial y^2} + K_z \cdot \frac{\partial^2 T}{\partial z^2} = q \quad (1)$$

where T is the temperature at each point of the considered domain ($^{\circ}\text{C}$), K_x , K_y and K_z are the materials thermal conductivity in the x -, y - and z - direction ($\text{W}/(\text{m}^{\circ}\text{C})$) and q is the heat source in the transformer conductors and cores (W/m^3), corresponding to the respective loss density. The proper solution of (1) involves correct definition of the boundary conditions between the transformer active part and tank components and oil (heat convection conditions).

B. CFD FEM Equations

In solid and liquid materials, heat transfer and viscous fluid flow are governed by Navier-Stokes equations, deriving from the basic principles of conservation of mass, momentum and energy:

$$\rho \left(\frac{\partial \vec{u}}{\partial t} + (\vec{u} \cdot \nabla) \cdot \vec{u} \right) - \nabla \cdot (2 \cdot \mu \cdot \bar{\varepsilon}) + \nabla p = \rho \cdot \vec{g} \quad (2)$$

$$\nabla \cdot \vec{u} = 0$$

where ρ stands for the fluid mass density (kg/m^3), \vec{u} is the fluid velocity (m/s), $\bar{\varepsilon}$ is the strain rate tensor, p denotes the pressure (N/m^2) and \vec{g} is the gravitational acceleration (m/s^2).

The thermal flow of incompressible fluids is governed by the Boussinesq approximation, i.e. that the density of the fluid depends linearly on temperature, through the equation:

$$\rho = \rho_o \cdot (1 - \beta \cdot (T - T_o)) \quad (3)$$

where β is the thermal expansion coefficient ($1/^{\circ}\text{C}$), while ρ_o and T_o represent reference values of mass density (kg/m^3)

and temperature ($^{\circ}\text{C}$), respectively.

C. Coupled 3D Fluid Flow-Thermal FEM model

Fig. 1 illustrates the transformer 3D FEM model, consisting of the one fourth of its real geometry, i.e. half of the transformer width and length, due to symmetry, which is taken into account by the imposition of appropriate Dirichlet as well as Neumann conditions. For the derivation of the transformer thermal distribution, the thermal and fluid flow equations (1) and (2) are solved iteratively, for a prescribed loss density in the transformer core and windings, derived by the loss values of the considered design. Fig. 2 illustrates the flowchart of the proposed method, describing the coupling of the thermal and fluid flow equations. Only an initial guess for the transformer temperature and oil velocity has to be defined, providing the initial condition for the coupled FEM solver.

Fig. 1. Perspective view of 3D transformer FEM model: (a) active part, (b) oil tank.

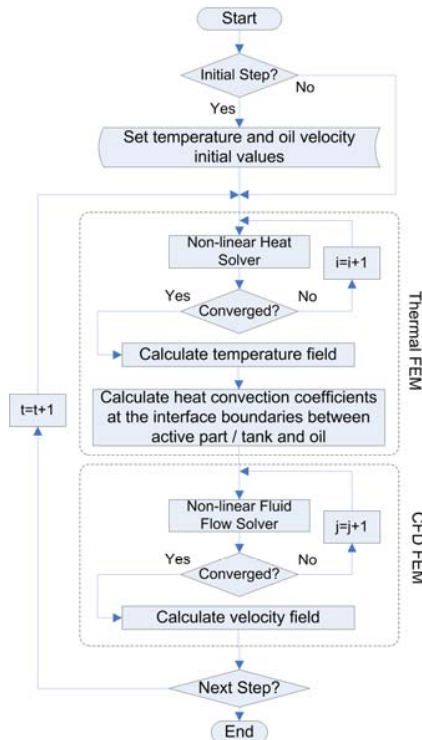

Fig. 2. Flowchart of the proposed coupled method.

II. RESULTS AND DISCUSSION

Figs. 3 and 4 illustrate the results of the method in a 400 kVA, 20-0.4 kV transformer, operating under nominal load, at an ambient temperature equal to 30°C . Fig. 3 comprises the thermal distribution results inside the active part and the tank walls in half of the FEM model (the rest of the wireframe model edges are kept in the figure for better representation purposes) Fig. 4 shows the arrow plot of the transformer oil velocity around the transformer active part, providing an aspect of the oil flow around the winding cooling ducts. These results are in good agreement with the measured ones and show the proposed methodology suitability for hot spots investigation in power transformers.

Abstract – A novel computer model of inductively heated incompressible flow of electrically conductive liquid in a pipe is presented. The numerical solution of this multiply coupled problem is realized by a higher-order finite element method using the code Hermes2d developed and written by the authors that contains a number of original features (i.e., hanging nodes of any order or dynamically changing mutually independent meshes for the evaluation of particular time-dependent field quantities). The methodology is illustrated by an example whose results are discussed.

I. INTRODUCTION

Numerous industrial technologies working with electrically conductive liquids (e.g., molten metals, acids, or solutions of salts) are based on the force and thermal effects of electromagnetic field. We can mention pumping, dosing, stirring, heating, and other similar processes.

The computer modeling of such processes is still a challenge. These tasks represent multiply coupled nonstationary and often nonlinear problems, characterized by interaction of several physical fields. Even when a considerable attention is paid to the topic (the books and papers in the domain abound, see, e.g., [1], [2]), a lot of tasks still remain unresolved.

The paper deals with the problem of heating a conductive liquid flowing slowly in a ceramic pipe. Its numerical solution is carried out (unlike former classical FEM and FVM-based algorithms) by our own code Hermes [3], [4] based on the *hp*-FEM.

II. FORMULATION OF THE PROBLEM

Consider the arrangement depicted in Fig. 1. It shows a ceramic pipe with electrically conductive liquid that flows from the left to the right and is warmed up by a time-variable magnetic field generated by a harmonic current carrying inductor. The arrangement is considered axisymmetric.

Fig. 1. The investigated arrangement

The task is to map the time evolution of all relevant physical fields in the system, namely magnetic field, temperature field, field of the radial and axial velocities of flow, and field of pressure. The physical parameters of the liquid, pipe and inductor are known as well as the initial and boundary conditions of the problem, and also the parameters of the field current (its amplitude I and frequency f).

III. MATHEMATICAL MODEL AND ITS SOLUTION

The mathematical model of the problem is given by three partial differential equations describing the distribution of the magnetic field, the temperature field and the field of flow.

The magnetic field is expressed in terms of the magnetic vector potential \underline{A} . Since the system contains no nonlinearities, its distribution may be described in terms of its phasor \underline{A} that is governed by the Helmholtz equation

$$\text{curlcurl}\underline{A} + \mathbf{j} \cdot \omega \gamma \mu \underline{A} = \mu \underline{\mathbf{J}}_{\text{ext}}, \quad (1)$$

where μ denotes the magnetic permeability, γ is the electric conductivity, ω is the angular frequency, and $\underline{\mathbf{J}}_{\text{ext}}$ stands for the phasor of the external harmonic current density in the inductor. The axis of the arrangement and sufficiently distant artificial boundary are characterized by the Dirichlet condition $\underline{A} = \mathbf{0}$

The heat transfer equation in the liquid continuum reads:

$$\text{div}(\lambda \cdot \text{grad}T) = \rho c \cdot \left(\frac{\partial T}{\partial t} + \mathbf{v} \cdot \text{grad}T \right) - p_J, \quad (2)$$

where λ is the thermal conductivity, ρ is the specific mass, c denotes the specific heat, and \mathbf{v} stands for the velocity. Finally, the symbol p_J denotes the time average internal sources of heat (the specific Joule losses) determined from the formula $p_J = \omega^2 \gamma |\underline{A}|^2$. The temperature field is calculated only in the liquid and also in the pipe, where the term $\mathbf{v} \cdot \text{grad}T$ vanishes. The boundary condition along the external surface of the pipe only respects the convection (basalt is a poor thermal conductor, thus the temperature of this surface is low and radiation from it can be neglected). The temperature of the liquid at the inlet of the pipe is supposed to be known.

The field of incompressible flow obeys the Navier-Stokes equation

$$\rho \cdot \left[\frac{\partial \mathbf{v}}{\partial t} + (\mathbf{v} \cdot \text{grad}) \mathbf{v} \right] = -\text{grad } p + \eta \cdot \Delta \mathbf{v} + \rho \mathbf{g} + \mathbf{f} \quad (3)$$

together with the equation of continuity
 $\text{div } \mathbf{v} = 0.$

Here \mathbf{v} denotes the velocity, p is the pressure, η is the dynamic viscosity, and \mathbf{f} stands for the internal volume Lorentz forces (produced by the time variable magnetic field). For practical computations, we neglected term $\rho \mathbf{g}$ in (4) in order to preserve the axial symmetry of the flow. The boundary conditions are classical—the velocity along the internal wall of the pipe vanishes, due to symmetry its radial component vanishes along the z -axis and the derivative of its axial component with respect to the radius r vanishes here, too.

After transforming (1)–(4) into cylindrical coordinates (respecting the axisymmetry), the numerical solution of the model was realized by a higher-order finite element method. Computation of the electromagnetic field was carried out once at the beginning and independently of the temperature and flow fields. Magnetic vector potential was solved on an automatically adapted higher-order finite element mesh. The obtained solution was subsequently used in a time-dependent computation of fluid-temperature interaction, where the Lorentz forces acted on the fluid flow and average Joule losses caused heating. In the fluid flow, the underlying meshes can generally be different from the hp -mesh used for the electromagnetic field, since they can differ both in polynomial orders and in geometry. Computation of the time-dependent fluid flow was carried out on dynamically changing meshes, where meshes for time level t_n are obtained automatically by our adaptive algorithm and, moreover, the mesh for temperature T can be different from the meshes for the flow fields—radial and axial velocities (v_r, v_z) and the pressure p . This approach leads to a significant reduction of the size of the discrete problem; therefore it speeds up the whole computation. Our own numerical software Hermes2d was used for the computation. It is capable of all the features mentioned above, such as the higher-order finite element method, automatic adaptivity on hp -meshes or assembling of the stiffness matrix on geometrically different meshes.

IV. ILLUSTRATIVE EXAMPLE

For an illustration, the following figures present a few interesting results obtained for molten sodium (for geometry of the pipe see Fig. 1). The inlet velocity of sodium is $v_i = 0.02 \text{ ms}^{-1}$ and the temperature $T_i = 150 \text{ }^\circ\text{C}$. The parameters of the field current are $J_{\text{ext}} = 8 \times 10^6 \text{ Am}^{-2}$ and $f = 50 \text{ Hz}$. Fig. 2 shows the convergence for the magnetic vector potential A (our hp -adaptivity versus the classical h -adaptivity) and Fig. 3 depicts the corresponding hp -mesh. Fig. 4 shows the distribution of the module of magnetic flux density B , particularly in melt. Finally, Fig. 5 shows the distribution of temperature T in melt after $t = 0.4 \text{ s}$ and Fig. 6 depicts the distribution of the module of velocity \mathbf{v} (and the visible vortices at the places where the pipe is getting narrow) for the same time.

Fig. 2. Comparison of the convergence for magnetic vector potential A

Fig. 3. Adaptive hp -mesh for computation of magnetic vector potential A (white—elements of the 1st order, black—elements of the 7th order)

Fig. 4. Distribution of the module of magnetic flux density B in the arrangement (white color – 0 T, black color – 0.3 T)

Fig. 5. Distribution of temperature T (in $^\circ\text{C}$) in melt for $t = 0.4 \text{ s}$ (grey color – 150 $^\circ\text{C}$, black color – 200 $^\circ\text{C}$)

Fig. 6. Distribution of the module of velocity \mathbf{v} in melt for $t = 0.4 \text{ s}$ (white color – 0 ms^{-1} , black color – 2 ms^{-1})

Abstract—A main limitation of most models describing the effect of stress on the magnetic behavior is that they are restricted to uniaxial, tensile or compressive, stress. An idea to overcome this strong limitation is to define a fictive uniaxial stress, the equivalent stress that would change the magnetic behavior in a similar manner than a multiaxial one. Several authors have tried to define such a criterion. We propose in this paper to compare several equivalent stress definitions, and to apply them in the case of uniaxial and biaxial mechanical loadings for which experimental results are available.

Index Terms—Magneto-elasticity, effect of stress, equivalent stress, multiaxiality

I. INTRODUCTION

In most of practical electromagnetic applications, magnetic materials are submitted to multiaxial stress inherited from forming process or appearing in use. These stress states can change significantly the magnetic behavior of materials [1]. However, the few available models describing the effect of stress on the magnetic behavior are usually restricted to uniaxial (tensile or compressive) stress. A solution to introduce the multiaxiality of stress into modeling tools is the definition of an equivalent stress criterion. An equivalent stress for the magnetic behavior is a (fictive) uniaxial stress that would change the magnetic behavior in a similar manner than the multiaxial one. Some authors proposed such an approach in the past years [2]–[6]. We propose in this paper to compare these proposals. Experimental results carried out under biaxial mechanical loading will help to validate these criteria.

II. SEVERAL EQUIVALENT STRESS DEFINITIONS

Several authors tried to define an equivalent stress for magneto-elastic behavior, usually thanks to energetic considerations and experimental observations of magnetic behavior of materials submitted to biaxial mechanical loadings.

Kashiwaya (K) [2] proposed the following definition for the equivalent stress $\sigma_{\text{eq}}^{\text{K}}$:

$$\sigma_{\text{eq}}^{\text{K}} = K(\sigma_1 - \sigma_{\text{max}}) \quad (1)$$

with K a constant, σ_1 the eigenstress aligned with the magnetic field direction and σ_{max} the maximal value of the

stress tensor eigenvalues. This equivalent stress is always negative or null. Iso-values are parallel lines in the (σ_1, σ_2) plane. If the magnetic field is applied along the direction of the maximum eigenstress, the equivalent stress is zero, so that a tensile stress or an equi-biaxial tension or compression are supposed to have no effect on the magnetic behavior.

Schneider and Richardson (SR) [3] proposed the following definition for the equivalent stress $\sigma_{\text{eq}}^{\text{SR}}$:

$$\sigma_{\text{eq}}^{\text{SR}} = \sigma_1 - \sigma_2 \quad (2)$$

σ_1 and σ_2 are the eigenstresses in the sheet plane, the magnetic loading being aligned in the direction of σ_1 . The main difference with K definition is that the area of the stress plane where $\sigma_1 > 0$ and $\sigma_2 < 0$ defines a positive equivalent stress. But an equibiaxial stress is still supposed to have no effect on the magnetic behavior.

Sablik and co-workers (S) [4] proposed the following definition for the equivalent stress $\sigma_{\text{eq}}^{\text{S}}$, based on previous magneto-mechanical measurements by Langman [7]:

$$\begin{cases} \sigma_{\text{eq}}^{\text{S}} = \frac{1}{3}(2\sigma_1 - \sigma_2) & \text{for } \sigma_1 < 0 \\ \sigma_{\text{eq}}^{\text{S}} = \frac{1}{3}(\sigma_1 - 2\sigma_2) & \text{for } \sigma_1 \geq 0 \end{cases} \quad (3)$$

σ_1 is still the stress aligned with the magnetic field. Equi-bitraction and equi-bicompression do not lead to the same result, that is a significant difference with K and SR approaches. But S model is discontinuous for $\sigma_1 = 0$.

Pearson and co-workers [5] also proposed an equivalent stress for a biaxial mechanical loading. In its simplest form this equivalent stress corresponds to SR proposal. The more refined form is a polynomial interpolation that reveals complicated to use because the parameter identification is sample dependent.

Daniel and Hubert (DH) [6] proposed the following definition $\sigma_{\text{eq}}^{\text{DH}}$, based on an equivalence in magneto-elastic energy:

$$\sigma_{\text{eq}}^{\text{DH}} = \frac{3}{2} {}^t \vec{h} \mathbf{s} \vec{h} \quad (4)$$

\vec{h} is the direction parallel to the applied magnetic field and s is the deviatoric part of the stress tensor σ ($s = \sigma - \frac{1}{3}\text{tr}(\sigma)\mathbf{I}$). It can be noticed that the equivalent stress is zero when the stress is hydrostatic, meaning that a hydrostatic pressure has no effect on the magnetic behavior. A main advantage of this criterion is that it can be applied to a fully multiaxial mechanical loading, whereas the previous proposals only refer to biaxial stress state.

As a first analysis, these equivalent stress criteria can be compared in the case of a uniaxial mechanical loading (intensity σ_o). The result is presented in figure 1.

Fig. 1. Equivalent stress σ_{eq}/σ_o in the case of a uniaxial stress σ_o applied in a direction $\theta \in [0, \pi]$ with respect to the magnetic field (direction 0°).

K, SR and S criteria can only be applied in the case when the direction of the magnetic field is a principal direction for the stress. DH criterion can be applied whatever the relative orientation between stress and magnetic field. In the uniaxial case, σ_{eq}^{DH} can be written :

$$\sigma_{eq}^{DH}(\theta) = \frac{3}{2}\sigma_o \left(\cos^2\theta - \frac{1}{3} \right) \quad (5)$$

It can be noticed that in the case of an uniaxial stress applied in the direction of the magnetic field, the equivalent stress is the applied stress only for SR and DH proposals. The discontinuity of S model for $\theta=\pi/2$ ($\sigma_1=0$) is highlighted.

III. APPLICATION IN THE CASE OF BIAxIAL MECHANICAL LOADINGS

Experiments have been performed on iron-cobalt laminations [8]. They consist in anhysteretic magnetic measurements carried out under biaxial mechanical stress in homogeneous magnetic and mechanical conditions, for stress levels varying from -60MPa to +60MPa.

The expected susceptibility according to K, SR, S and DH criteria has been estimated (the experimental data for the susceptibility under uniaxial mechanical loading have been extracted from the measurements with $\sigma_2 = 0$). The experimental conditions correspond to biaxial stress (σ_1, σ_2) with the magnetic field applied along eigendirection 1 (DH equivalent stress is then defined by $\sigma_{eq} = \sigma_1 - \frac{1}{2}\sigma_2$). Figure 2 shows a map of the relative error between predicted χ_p and measured χ_e susceptibilities ($e = 100 \times |\chi_p - \chi_e|/\chi_e$). For all criteria, the errors observed in equibicompaction (-60 MPa, -60 MPa) for $H=2500$ A/m are very high, with a level of 635% for K and SR, 371% for S and 238% for DH.

Fig. 2. Relative error (percent) for the predicted susceptibility ($H=250$ A/m) according to several equivalent stress proposals. (a) K ($K=1$), (b) SR, (c) S, (d) DH.

In Figure 2, the error values have been truncated at 50% for reading convenience. DH criterion appears to be closest to experimental results.

IV. CONCLUSION

Several equivalent stress for magneto-mechanical behavior are compared. The main weakness of these models is their inability to describe the effect of a bicompression stress on the magnetic behavior. Only one equivalent stress (DH) can describe fully multiaxial stress state, without any hypothesis concerning the relative orientation of the magnetic field direction in the principal stress coordinate system. This latter proposal is also the closest to experimental results obtained in biaxial configurations. A detailed comparison to experimental results will be discussed in the full paper.

Abstract— This paper presents a numerical method for calculating shape of ferrofluid droplet that undergoes three influences: external magnetic field, gravitational force and surface tension. The shape is calculated using an equilibrium energy condition in the coupled system of electromagnetic field and ferrofluid in the presence of gravity and surface tension on the ferrofluid boundary. The shape of the ferrofluid is traced using level set method(LSM), where the continuum shape sensitivity of the material derivative concept is used for the velocity field on the boundary. The presented algorithm is implemented with standard finite element procedure and tested in a shape problem of ferrofluid droplet placed above an electromagnet.

I. INTRODUCTION

In this paper we present a method of numerical simulation for calculating shape of ferrofluid with considering the effects of external magnetic field, surface tension and gravitational field. The different physical phenomena have mutual influence and they are put together to set a nonlinear-coupled system. This paper aims to analyze the coupled system equation and calculate the ferrofluid shape. The numerical algorithm for shape calculation is developed by using an equilibrium energy condition of the coupled system of electromagnetic fields and surface tension in the presence of gravitational field. It is too difficult to calculate the shape using fluid dynamics driven by magnetic force, gravity and surface tension. Thus in this work we make use of the energy equilibrium condition at the final shape. We also employ level set method(LSM) to easily capture varying interface between the ferrofluid and the surrounding air. The physical model consists of magnetostatic equations, surface tension condition and an advection equation for the level set function. Each model is numerically implemented and coupled using a standard finite element procedure. The shape derivative of continuum sensitivity by the material derivative concept is used for the velocity field that is required for the level set technique. The proposed method is numerically tested and validated in a shaping problem of ferrofluid droplet placed above a DC electromagnet.

II. LEVEL SET METHOD

The basic idea of the level set method is to represent domains and their boundaries not via parameterization, but as level sets of a continuous function, the so-called level set function. It is expressed in an implicit form of a high dimensional function, and then the boundary changes are traced by the deformation of this function [1], [2]. In this

shape problem, the interface boundaries are varied in order to minimizing or maximizing the total system energy.

III. ALGORITHM FOR SHAPE FORMATION OF FERROFLUID

A. System Energies of Ferrofluid Droplet

The energy functions of magnetic, gravitational systems and surface tension are respectively expressed as

$$W_m = \int_{\Omega} \frac{1}{2} \mathbf{B}(\phi) \cdot \mathbf{H}(\phi) d\Omega \quad (1)$$

$$W_g = \int_{\Omega} \rho g y d\Omega \quad (2)$$

$$W_s = \int_{\Gamma} 2\sigma H d\Gamma \quad (3)$$

where, ρ is material density, g is material density and y is position of surface. σ and H denote coefficient of surface tension and curvature of boundary.

In magnetic system with current source the shape of ferrofluid varies to maximize its field energy W_m . On the contrary, in the gravitational system its shape varies to minimize its potential energy W_g . Surface tension changes also the shape to minimize the surface tension energy W_s . Therefore, this shape problem can be formulated as a kind of optimization problem with an objective function of energy functional as

$$\text{Maximize : } W_m - W_g - W_s$$

subject to two equality constraints of magnetostatic field equation and constant area as

$$\nabla^2 A = -\mu(\phi)J \quad (4)$$

$$\int_{\Omega} H(\phi)d\Omega = S^* \quad (5)$$

where the design variable is represented by Ω .

B. Velocity Fields and Constraint of Constant volume

Design variables are the movable boundary between ferrofluid and free space. The design boundary $\partial\Omega$ is represented using the level set function such that $\phi(\mathbf{x},t)=0$ for any time. Since the level set function holds at any time t , its total derivative is expressed by using an Eulerian formulation of the boundary variation as

$$\frac{d\phi}{dt} = \frac{\partial\phi}{\partial t} + V_n |\nabla\phi| = 0 \quad (6)$$

where the velocity field determines shape variation, that also causes change the objective function. Thus, calculation of

appropriate velocity field for increasing the energy functional is an important part for the shape problem.

When the constraint of constant area is imposed on the shape problem, the velocity field is modified from V_n to \hat{V}_n using Lagrange multiplier technique as

$$\hat{V}_n = (V_{n1} + V_{n2} + V_{n3}) - V_0 \quad (7)$$

$$V_0 = \frac{\int_{\gamma} (V_{n1} + V_{n2} + V_{n3}) d\Gamma}{\int_{\gamma} d\Gamma} \quad (8)$$

where V_{n1} , V_{n2} and V_{n3} are the normal components of the velocity field vectors in the magnetic system, the gravitational system and surface tension condition, respectively.

C. Continuum Sensitivity Analysis for Velocity Fields

The total derivative of objective function in electromagnetic systems can be derived using the material derivative concept of continuum mechanics and an adjoint variable technique. Here we call it continuum sensitivity for shape derivative. The continuum sensitivity formula in magnetostatic systems is represented as

$$\frac{dW_m}{dt} = \int_{\gamma} \frac{1}{2} \left(\frac{\mu_r - 1}{\mu_0 \mu_r} \right) \left(B_n^2 + \frac{1}{\mu_r} B_t^2 \right) V_{n1} d\Gamma \quad (9)$$

where, V_{n1} the normal component of the velocity field vector, γ design boundary [3].

The sensitivity formula is the relation of the objective function and the velocity field in (9). If the velocity field is taken as

$$V_{n1} = \frac{1}{2} \left(\frac{\mu_r - 1}{\mu_0 \mu_r} \right) \left(B_n^2 + \frac{1}{\mu_r} B_t^2 \right) \quad \text{on } \gamma, \quad (10)$$

the objective function is increased.

The potential energy of gravitational system depends on only the y-coordinate position and the fluid shape varies to minimize the gravitational potential energy. According to Reynolds' transport theorem for differentiating a volume integral, the material derivative of the potential energy is given by

$$\frac{dW_g}{dt} = \int_v \frac{\partial}{\partial t} (\rho g y) dv + \int_s (\rho g y) V_{n2} ds \quad (11)$$

where V_{n2} is the normal component of the velocity field vector and the integrand in the second term is zero since

$$\frac{\partial}{\partial t} (\rho g y) = \rho g \frac{\partial y}{\partial t} \Big|_{y=const.} = 0 \quad (12)$$

That is, the gravitational sensitivity has only surface integration. If the velocity field is taken as

$$V_{n2} = -\rho g y \quad \text{on } \gamma, \quad (13)$$

the objective function of gravitational system is decreased on the contrary to the magnetostatic system.

The surface tension energy depends on the radius of curvature at the material surface. The derivative of surface tension energy is expressed as

$$\frac{dW_s}{dt} = \int_{\gamma} 2\sigma (\nabla H \cdot \mathbf{n} + H^2) V_{n3} d\Gamma \quad (14)$$

where V_{n3} is the normal component of velocity field vector and the second term is zero. Thus, the sensitivity of surface tension energy is taken in order to decrease the energy as

$$V_{n3} = 2\sigma H \quad \text{on } \gamma. \quad (15)$$

Fig. 1. Schematic of surface tension on ferrofluid surface.

The velocity field of sum of the magnetic velocity, the gravitational velocity and surface tension with constant area constraint is inserted into the level set equation of Hamilton-Jacobi equation in order to obtain shape evolution for maximization of the objective function.

$$\frac{\partial \phi}{\partial t} + (V_{n1} + V_{n2} + V_{n3}) |\nabla \phi| = 0 \quad (16)$$

The iterative procedure for optimization is transformed into a time domain problem of a Hamilton-Jacobi equation. The time in the partial differential equation (PDE) has no physical meaning. Thus, it is called "pseudo time" for optimization procedure.

IV. NUMERICAL TEST

To validate the algorithm, we tested a shape problem of Fig. 2. Its numerical results showed that the level set method coupled with physical systems of magnetic field, gravitational force and surface tension is feasible and effective for capturing its shape variation.

Abstract — This paper is a contribution to the electromagnetic field evaluation due to underground power cables. Open boundary 2D problems may be treated combining the finite element method (FEM) inside a region surrounded by a regular (cylindrical) fictitious surface with a semi-analytical boundary element method (BEM) to describe the field outside this region. For the outside region, a generalization of Pollaczek's solution is applied, taking into account eddy currents in the soil and the proximity effect between the soil/air plane surface and the cylinder fictitious surface with finite radius. The method is validated by using typical underground power cables where analytical methods may be applied accurately.

I. INTRODUCTION

Spreading of urban centres, and ever increasing demand for electrical power within them, is leading to the use of underground cable systems at high voltage. The growing use of cable systems makes the analysis of wave propagation characteristics and transients an important task. On the other hand, danger to human health has been a matter of concern and controversy particularly for magnetic fields produced by underground power transmission systems.

All these aspects have demanded great efforts in the research on methods to evaluate accurately magnetic field quantities, either related to the constitutive parameters, namely the series-impedance, or even to the magnetic induction field, particularly on the soil surface.

In the past, analytical methods [1]-[5] have been experimented to evaluate magnetic field quantities due to underground power cables. However, analytical methods can not be used always accurately. Those are the cases, for instance, where cables are buried inside underground pipes or galleries with irregular cross sections.

This paper is a contribution to the electromagnetic field evaluation of open boundary problems combining the finite element method (FEM) inside a region surrounded by a regular fictitious surface with a semi-analytical boundary element method (BEM) to describe the field outside this region. Hybrid methods have already been applied [6], [7] in order to adapt the FEM to treat open boundary field problems. In this paper, a two-dimensional (2D) periodic time-harmonic electromagnetic field problem is considered for the underground transmission system in which eddy currents inside phase conductors, sheaths and the soil are taken into account. A fictitious cylindrical surface located in the soil is considered in a way that the open space is partitioned into two regions: the inner region containing power cables and other apparatus eventually with irregular shapes; and, the outer

region composed by the soil and air separated by a surface taken as a plane.

A FEM formulation is used for the inner region [8]-[9].

For the outside region, a generalization of Pollaczek's solution [5] is applied, like the one described in [1], taking into account eddy currents in the soil and the proximity effect between the soil/air plane surface and the cylinder fictitious surface with finite radius. In this way, the outside field description is based on a Fourier series development over the cylinder fictitious surface for the potential and for its normal derivative values. These quantities, discretized and organized into finite dimension vectors, are related by using formulae derived analytically and expressed as a square coefficient matrix. A Discrete Fourier Transform (DFT) is then used to transform the relationship to the space domain where it assumes the form of another coefficient matrix relating the actual potential values with their normal derivatives over a set of discrete nodes on the fictitious separating surface. These nodes are coincident with the discrete nodes of the FEM mesh taken for the inner region.

Finally, the method is validated by using typical underground power cables where analytical methods may be applied accurately [1], [2]. Series-impedance as well as magnetic induction field values are evaluated and compared with results obtained by using those analytical methods. Excellent accuracy is found for the set of considered configurations and examples.

II. FIELD FORMULATION

The magnetic field for the internal region may be established, as described in [6], [8], by using an appropriate variational formulation where the magnetic vector potential appears as the primary quantity. The FEM is the adequate method for the corresponding numerical solution. The FEM formulation may be expressed, as done in [6], involving both the unknown potential values of the FEM nodal points as well as the potential normal derivative values on the nodes of the fictitious surface. The relationship allows boundary conditions on the above referred surface to be matched with the field formulation for the outer region.

For the outer region an analytical formulation is used based on the development presented in [1]. In this way, the matrix relating the actual phasor values over a finite set of points over the fictitious boundary of the magnetic vector potential with those of its normal derivative, similarly as done in [6], may be derived.

III. MAGNETIC INDUCTION FIELD

The magnetic induction field, $\mathbf{B} = B_x \vec{u}_x + B_y \vec{u}_y$, at any point (x,y) in the air, over the soil, originated by an underground cable involved by a fictitious cylindrical surface buried at the depth h , is given by

$$B_x = \int_{-\infty}^{+\infty} -|a|U(a) e^{jax} da, \quad B_y = \int_{-\infty}^{+\infty} -jaU(a) e^{jax} da \quad (1)$$

where

$$U(a) = \frac{1}{\pi} \frac{2j}{\mu_r |a| + \sqrt{a^2 - q^2}} e^{-h\sqrt{a^2 - q^2}} \sum_{m=-\infty}^{+\infty} G_m \left(\frac{a - \sqrt{a^2 - q^2}}{jq} \right)^m \quad (2)$$

with

$$q^2 = -j\omega\mu_r\mu_0\sigma \quad (3)$$

ω being the angular frequency, where μ_r , σ are the relative permeability and the conductivity, respectively, of the soil, and G_m are the coefficients, adopted in the development presented in [1], determined from the magnetic vector potential at the FEM nodal points over the fictitious surface whose values are obtained from the numerical solution of the matrix equation built by using the FEM/BEM hybrid method.

Fig. 1 – FEM mesh in the plane (x,y) for the inner region corresponding to the two underground cables considered in the paper.

IV. NUMERICAL RESULTS

Numerical results were obtained for two problems with analytical solution. The purpose is to compare results obtained with the FEM/BEM hybrid method used in this paper with analytical results obtained with the method described in [1]. The first problem, indicated in Fig. 1-a), considered in [2], consists in a 50 Hz underground cable buried at a depth 1,5 m in a soil with conductivity $\sigma=0,01$ S/m where $r_c=36$ mm, $r_{bi}=65$ mm, $r_{be}=67,6$ mm, $r_e=74$ mm taking the conductivity of the conductor and the sheath respectively equal to $5,8 \times 10^7$ S/m and $4,76 \times 10^6$ S/m. For this problem the fictitious surface coincides with the cable outer surface. The second problem, Fig. 1-b), considered in [1], consists in a underground cable buried at a depth 112,5 mm in a soil with conductivity $\sigma=1$ S/m for a working frequency 10 MHz, assuming the phase conductor as a perfect conductor where $r_c=45$ mm and $r_e=56,25$ mm. In this problem the fictitious surface located in the soil with radius $r_0=73,08$ mm and the cable are not coaxial where the distance between their axes is equal to 5,91 mm.

Fig. 2 – Normalized *r.m.s.* values of the magnetic induction field at the soil/air plane surface: (a) for the problem of Fig. 1-a); (b) for the problem of Fig. 1-b).

Fig. 2 shows results for the normalized *r.m.s.* value of the magnetic induction field at the soil/air plane, taking $\mu_0 I_{r.m.s.}/h$ as the normalizing factor, $I_{r.m.s.}$ representing the *r.m.s.* value of the cable current. These results mean that, comparing with analytical results, a deviation less than 1% is obtained for the first problem (Fig.1-a) and a deviation less than 2% is obtained for the second problem (Fig. 1-b)). Results were derived for $M \leq 5$, where M is the truncation order of the series development in (2).

Series-impedance elements per unit length were also obtained for the described cables. Relative deviations less than 0,3 % were found, again in comparison with analytical results.

Voltage and current sources for massive conductors suitable with the $A - \chi$ Geometric Formulation

Paweł Dłotko¹, Ruben Specogna², and Francesco Trevisan²

¹Jagiellonian University, Institute of Computer Science, Lojasiewicza 4, 30348 Kraków, Poland,

²Università di Udine, Via delle Scienze 208, 33100 Udine, Italy, ruben.specogna@uniud.it.

Abstract—The aim of the paper is to present an automatic and general technique, suitable with the $A - \chi$ geometric eddy-current formulation, to impose sources over massive conductors of any shape. For this purpose, the *localized source approach* is used, which does not require the solutions of steady-state conduction problems in the pre-processing stage. Nevertheless, this approach needs a *thick cut* in each active conductor, which is usually found “by hand”. In this paper, an automatic and general algorithm to compute such thick cuts is introduced. Some benchmark problems are presented to demonstrate the generality and the robustness of the algorithm.

Index Terms—Cell Method, Finite Integration Technique (FIT), Discrete Geometric Approach (DGA), eddy-currents, current and voltage sources, thick cuts.

I. INTRODUCTION

The so-called “Discrete Geometric Approach” (DGA) [1], similarly to the Finite Integration Technique (FIT) [2] or the Cell Method [3], allows to solve directly Maxwell’s equations in an alternative way with respect to the classical Galerkin method in Finite Elements.

In this paper, an automatic technique to enforce sources on massive conductors, suitable with the eddy-current $A - \chi$ geometric formulation [4], is introduced. In particular, the localized source approach [5], [6] is considered here. It presents many advantages with respect to the distributed source approach [6]; For example it does not require steady-state conduction problem solutions in the pre-processing stage. Furthermore, the localized source approach is based on global quantities –voltages and currents– which enable a straight-forward coupling between the eddy-current formulation and electric circuits.

The domain of interest D of the eddy-current problem has been partitioned into an active conductive region D_s , a passive conductive region D_c and a non-conductive region D_a . We assume that the region D_s –where sources are enforced– consists of the union of N disjoint conductors D_s^j , $j = 1, \dots, N$, which are homeomorphic¹ to a torus and such that $D_s = \bigcup_{j=1}^N D_s^j$; No assumption are given about the conductors belonging to D_c .

The domain D is covered by a finite element mesh of tetrahedra; The corresponding simplicial complex [3] is denoted as \mathcal{K} . From \mathcal{K} , the barycentric dual complex \mathcal{B} is also introduced [3]. The incidence matrix between edges e and nodes n is

¹From the topological viewpoint, they are the same. This assumption is not restrictive, since sources can be imposed only on torus-like conductors. Thus, the active conductor can also be knotted.

denoted by \mathbf{G} , by \mathbf{C} is denoted the incidence matrix between faces f and edges e and by \mathbf{D} the incidence matrix between tetrahedra v and faces f . The matrices $\tilde{\mathbf{G}} = \mathbf{D}^T$, $\tilde{\mathbf{C}} = \mathbf{C}^T$ and $\tilde{\mathbf{D}} = -\mathbf{G}^T$ describe the mutual interconnections of the dual barycentric complex (dual volumes \tilde{v} , dual faces \tilde{f} , dual edges \tilde{e} , dual nodes \tilde{n}) [3].

The localized source approach needs a *thick cut* [6] for each active conductor, which is usually found “by hand”. When dealing with complicated geometries or a big number of active conductors, an automatic technique to find such thick cuts can be very useful. This is the reason why we propose a completely automatic and general topology-based algorithm to construct thick cuts, which does not require any prior knowledge about the geometry of the active conductors.

II. THICK CUTS FOR THE TORI

For each edge e belonging to the j -th torus D_s^j , an integer is specified. The values are specified in such a way that the sum (with incidence) of the values of the edges belonging to a generic cycle is equal to n (or $-n$) if and only if the cycle goes n times around the torus, inside it (all trivial cycles go around the torus zero times)². The integer values relate to each edge $e \in D_s$ are stored into arrays $(\mathbf{c}^j)_e$, $j = 1, \dots, N$, one for each torus. The array \mathbf{c}^j is by definition a thick cut³ for D_s^j .

On the left of Fig. 1, an example of torus-like conductor is considered. On the right of Fig. 1, the black edges are the edges e having non-zero value in the thick cut $(\mathbf{c}^1)_e$. Considering the union of dual faces one-to-one with edges belonging to the thick cut, a surface S^j which “cuts” the torus is obtained on the dual complex⁴, see for example on the right in Fig. 1.

In the full paper, a fast and robust algorithm to automatically compute the thick cuts in D_s^j will be described in detail.

²Formally speaking, since the 1-st homology group $H_1(\mathcal{K}_s^j) = \mathbb{Z}$ [7] then there exists one generator $[g] \in H_1(\mathcal{K}_s^j)$, where \mathcal{K}_s^j is the sub-complex of \mathcal{K} containing entities in D_s^j . For a given cycle c the sum of $(\mathbf{c}^j)_e$ with incidence is equal $n \in \mathbb{Z}$ if $c \in [ng]$, where $[ng]$ indicates the homology class of the cycle ng .

³More precisely, the thick cut is a generator of the 1-st cohomology group $H^1(\mathcal{K}_s^j)$ [7].

⁴Thanks to the Poincaré-Lefschetz duality $H^1(\mathcal{K}_s^j) \cong H_2(\mathcal{B}_s^j, \partial\mathcal{B}_s^j)$ [7], thus the 1-st cohomology group of \mathcal{K}_s^j can be reinterpreted as the 2-nd relative homology group in the dual complex \mathcal{B}_s^j . The generator of this group consist of triangles that form a surface S^j on dual complex having the boundary on ∂D_s^j and which is not itself boundary of any volume in D_s^j .

Fig. 1. On the left, an example of torus-like conductor. On the right, a zoom on a portion of the conductor in the neighborhood of the non-zero valued edges in the thick cut (the thick black edges). The collection of dual faces, dual to non-zero valued thick cut edges, form a surface S^j on the dual complex that “cuts” the conductor.

III. LOCALIZED VOLTAGE SOURCES

The localized voltage source approach [6], also referred to as “generalized source potential” in [5], is now recalled. Defining the array \mathbf{U}_s as

$$(\mathbf{U}_s)_e = \sum_{j=1}^N U_{tot}^j (\mathbf{c}^j)_e, \forall e \in D_s, \quad (1)$$

where U_{tot}^j is the enforced voltage on the j -th torus. Then the $A - \chi$ formulated eddy-current problem in the frequency domain becomes [6]

$$\begin{aligned} (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e &= 0 & e \in D_a \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e + i\omega(\boldsymbol{\sigma}_s \mathbf{A}_s + \boldsymbol{\sigma}_s \mathbf{G}_s \boldsymbol{\chi}_s)_e &= (\mathbf{i})_e & e \in D_s \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e + i\omega(\boldsymbol{\sigma}_c \mathbf{A}_c + \boldsymbol{\sigma}_c \mathbf{G}_c \boldsymbol{\chi}_c)_e &= 0 & e \in D_c \\ i\omega(\mathbf{G}_s^T \boldsymbol{\sigma}_s \mathbf{A}_s)_n + i\omega(\mathbf{G}_s^T \boldsymbol{\sigma}_s \mathbf{G}_s \boldsymbol{\chi}_s)_n &= (\mathbf{G}_s^T \mathbf{i})_n & n \in D_s \\ i\omega(\mathbf{G}_c^T \boldsymbol{\sigma}_c \mathbf{A}_c)_n + i\omega(\mathbf{G}_c^T \boldsymbol{\sigma}_c \mathbf{G}_c \boldsymbol{\chi}_c)_n &= 0 & n \in D_c, \end{aligned} \quad (2)$$

where $\boldsymbol{\nu}$, $\boldsymbol{\sigma}_x$, $x \in \{s, c\}$, are the discrete counterparts of the constitutive relations [4]; The subscript s, c denote the sub-arrays or sub-matrices relative respectively to entities belonging to D_s or D_c . Moreover we set $\mathbf{i} = \boldsymbol{\sigma}_s \mathbf{U}_s$.

The term $(\mathbf{G}_s^T \mathbf{i})_n, \forall n \in D_s$, assures that the continuity law is satisfied, therefore the ungauged $A - \chi$ formulation can be used [4], [6] to solve (2).

Finally, the total current I_{tot}^j flowing in the j -th active conductor can be easily determined in a post-processing stage as

$$I_{tot}^j = -i\omega \mathbf{c}^{jT} \boldsymbol{\sigma}_s (\mathbf{A}_s + \mathbf{G}_s \boldsymbol{\chi}_s) + (\mathbf{c}^{jT} \boldsymbol{\sigma}_s \mathbf{c}^j) U_{tot}^j. \quad (3)$$

IV. LOCALIZED CURRENT SOURCES

In the $A - \chi$ geometric formulation, I_{tot} can only be specified using (3), which also gives a relationship between I_{tot} and U_{tot} . The symmetric algebraic system of equations, having also U_{tot} as unknown, becomes

$$\begin{aligned} (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e &= 0 & e \in D_a \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e + i\omega \boldsymbol{\sigma}_s (\mathbf{A}_s + \mathbf{G}_s \boldsymbol{\chi}_s)_e + (\mathbf{v})_e &= 0 & e \in D_s \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A})_e + i\omega \boldsymbol{\sigma}_c (\mathbf{A}_c + \mathbf{G}_c \boldsymbol{\chi}_c)_e &= 0 & e \in D_c \\ i\omega(\mathbf{G}_s^T \boldsymbol{\sigma}_s (\mathbf{A}_s + \mathbf{G}_s \boldsymbol{\chi}_s))_n + (\mathbf{w})_n &= 0 & n \in D_s \\ i\omega(\mathbf{G}_c^T \boldsymbol{\sigma}_c (\mathbf{A}_c + \mathbf{G}_c \boldsymbol{\chi}_c))_n &= 0 & n \in D_c, \\ -\mathbf{c}^{jT} \boldsymbol{\sigma}_s (\mathbf{A}_s + \mathbf{G}_s \boldsymbol{\chi}_s) + (\mathbf{c}^{jT} \boldsymbol{\sigma}_s \mathbf{c}^j) \frac{U_{tot}^j}{i\omega} &= \frac{I_{tot}^j}{i\omega} & j = 1, \dots, N, \end{aligned} \quad (4)$$

where $(\mathbf{v})_e = -\sum_{j=1}^N (\boldsymbol{\sigma}_s \mathbf{c}^j)_e U_{tot}^j$ and $(\mathbf{w})_n = -\sum_{j=1}^N (\mathbf{G}_s^T \boldsymbol{\sigma}_s \mathbf{c}^j)_n U_{tot}^j$.

Both the localized voltage sources and the localized current sources are easily generalized when a general external circuit is connected to the port of some active conductor. In this case, both U_{tot} and I_{tot} of that conductor have to be added as unknowns of (4). Correspondingly, an equation describing the external circuit has to be written into the linear system of equations (4).

V. NUMERICAL RESULTS

The localized voltage and current source approach was tested on many examples of massive conductors. For example, on the left of Fig. 2, the resulting current density in a planar inductor is shown. On the right of Fig. 2, another example consisting of a knotted torus is presented.

Fig. 2. On the left, the current density in a planar inductor. On the right, the current density in a knotted torus.

In the full paper, a number of benchmark problems will be presented and the results will be compared with the ones obtained by both the complementary $T - \Omega$ geometric formulation and with a Finite Element code.

VI. CONCLUSIONS

An automatic and robust algorithm to impose voltage or current sources on massive conductors suitable with the $A - \chi$ geometric eddy-current formulation was presented. The algorithm was tested on a number of real-sized three-dimensional finite element meshes, showing its utility for practical applications.

ahmed_chebak@uqar.qc.ca, philippe.viarouge@gel.ulaval.ca, jerome.cros@gel.ulaval.ca

Abstract— The paper presents an efficient method for computing the no-load eddy current losses in the soft magnetic composite (SMC) stator of high speed slotless permanent magnet (PM) machines by using a fast 3D time-harmonic FEA avoiding time consuming 3D time-stepping transient FEA. The magnets are modeled as equivalent surface current sheets with time-varying sinusoidal current densities. This method is used to perform a correction mechanism that is embedded in the optimal CAD process of slotless SMC PM machines to take into account the influence of the 3D end effects on the full-load stator eddy current losses computed from 2D analysis. The proposed method improves the efficiency and convergence of the global design optimization process of the machine.

I. INTRODUCTION

The stator yoke of high-speed slotless PM machines can be made of soft magnetic composite material (SMC) instead of conventional laminated steel to minimize the eddy current losses due to high operation frequency, and to reduce production steps and manufacturing costs for high volume applications. If the conductivity of SMC materials is not negligible, the distribution of the magnetic losses is not independent of the magnetic circuit geometry as in laminated iron core, because the eddy currents not only circulate in the iron particles but also in the whole SMC core. The design methodology of such machines is a complex task because it needs an accurate knowledge of the eddy current circulation that is influenced by the machine structure, dimensions and supply [1]. There are also 3D end-effects on the eddy current distribution that become more significant when the axial length to pole pitch ratio of the SMC stator yoke is decreasing [1]-[2]. In such a case, the 2D assumption does not provide a good accuracy of the eddy current losses prediction required to perform an optimal motor design. A solution has been proposed by the authors in [2] where the 2D analytical design model of slotless machines is associated to an optimization procedure and an iterative correction mechanism performed by 3D Finite Element Analysis (FEA) to take into account the influence of the 3D end effects on the full-load stator eddy currents losses that are computed from the 2D analytical analysis (cf. Fig.1). For each intermediate optimal solution, a 3D time-stepping FE simulation is performed for no-load operation to quantify the 3D effects on the eddy current losses. A suitable correction factor that represents the 3D to 2D no-load eddy current losses ratio is derived and implemented in the analytical design model before the next optimization step. Because 3D time-stepping transient FEA with magnet rotation is time consuming, an alternative is

proposed in this paper that is based on a fast 3D time-harmonic FEA. The rotating magnets are modeled as fixed equivalent surface current sheets with time-varying sinusoidal current densities. The proposed method highly improves the efficiency of the iterative 3D correction mechanism.

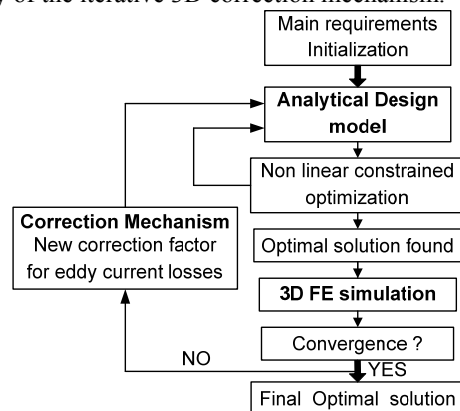

Fig. 1. Design optimization method with eddy current losses correction mechanism [2]

II. EDDY CURRENT LOSSES COMPUTATION WITH 3D TIME-HARMONIC FEA

The stator magnetic losses under full load operation can be predicted by an analytical model derived from the distribution of the electromagnetic field [1]. The field computation is based on the 2D solution of the Maxwell's equations in the magnets/air-gap/windings/stator core regions, for two different sources: the rotating magnets and the armature currents. The model takes into account the eddy currents induced in the conductive homogeneous SMC material and the time and space harmonics of the magnetic field. The representation of the magnet magnetization vector is applicable to radial or parallel magnetized magnets and discrete Hallbach arrays. In the radial case, the spatial magnetization distribution can be expressed by a complex Fourier series:

$$M_{r,rot}(\theta_s, t) = \sum_{k=-\infty}^{+\infty} \bar{M}_{r,k} e^{j(kp\theta_s - kp\Omega t)} \quad (1)$$

p is the number of pairs of rotor poles, $\bar{M}_{r,k}$ is the complex Fourier coefficient of the magnetization vector and Ω is the rotor speed. The no-load eddy current losses in the SMC stator yoke can be derived from the integration of the eddy current density [1]:

$$P_{ec,rot} = \frac{-2\pi L}{\mu_0 \mu_{rs}} \sum_{k=-\infty}^{+\infty} kp\Omega \text{Imag} \left[r \frac{\partial \bar{R}_{m,k}^{(4)}(r)}{\partial r} \bar{R}_{m,k}^{(4)*}(r) \right]_{R_{si}}^{R_{so}} \quad (2)$$

$$\bar{R}_{m,k}^{(4)}(r) = \bar{A}_{m,k}^{(4)} I_\alpha(\bar{\tau}_{m,k} r) + \bar{B}_{m,k}^{(4)} K_\alpha(\bar{\tau}_{m,k} r) \quad (3)$$

Imag is the imaginary part of the complex variable, R_{si} and R_{so} are the inner and outer radius of the stator core. I_α and K_α are modified Bessel functions of the first and second kind of order $\alpha=|k|p$, with $\bar{\tau}_{m,k}^2 = -jkp\Omega\mu_0\mu_{rs}\sigma_s$. $\bar{A}_{m,k}^{(4)}$ and $\bar{B}_{m,k}^{(4)}$ are constants coefficients in the stator core region ($i=4$) that can be determined by using the boundary conditions.

If one represents the rotating magnets as motionless magnets with time-varying sinusoidal magnetization at an angular frequency $\omega=p\Omega$, the new spatial magnetization distribution can be expressed as:

$$\begin{aligned} M_{r,st}(\theta_s, t) &= \sum_{k=-\infty}^{+\infty} \bar{M}_{r,k} \cos(p\Omega t) e^{jkp\theta_s} \\ &= \sum_{k=-\infty}^{+\infty} \frac{\bar{M}_{r,k}}{2} \left(e^{j(kp\theta_s - p\Omega t)} + e^{j(kp\theta_s + p\Omega t)} \right) \end{aligned} \quad (4)$$

Each pulsating magnet field harmonic of order k is equivalent to the superposition of two counter rotating field harmonics $H_{d,k}$ and $H_{i,k}$ with an amplitude proportional to $\bar{M}_{r,k}/2$ and respective angular speeds $+\Omega/k$ et $-\Omega/k$. The stator eddy current losses are then equal to the sum of the losses associated to each counter rotating field because there are no losses due to their interaction:

$$\begin{aligned} P_{ec,st} &= P_{ec,st,d} + P_{ec,st,i} = 2.P_{ec,st,d} \\ &= \frac{-4\pi L}{\mu_0 \mu_{rs}} \sum_{k=-\infty}^{+\infty} p\Omega \text{Imag} \left[r \frac{d\bar{R}_{m,d,k}^{(4)}(r)}{dr} \bar{R}_{m,d,k}^{(4)*}(r) \right]_{R_{si}}^{R_{so}} \end{aligned} \quad (5)$$

$$\begin{cases} \bar{R}_{m,d,k}^{(4)}(r) = \bar{A}_{m,d,k}^{(4)} I_\alpha(\bar{\tau}_{m,d,k} r) + \bar{B}_{m,d,k}^{(4)} K_\alpha(\bar{\tau}_{m,d,k} r) \\ \bar{\tau}_{m,d,k}^2 = -jp\Omega\mu_0\mu_{rs}\sigma_s \end{cases} \quad (6)$$

On can notice from (2) and (5) that for $k=1$ the stator no-load eddy current losses due to the rotating magnets are equal to twice the losses due to the equivalent motionless pulsating magnets ($P_{ec,rot}=2.P_{ec,st}$) because $\bar{R}_{m,k}^{(4)}$ et $\bar{R}_{m,d,k}^{(4)}$ are respectively dependant of $\bar{M}_{r,k}$ and $\bar{M}_{r,k}/2$. It is different for $k \neq 1$ because the field harmonics are rotating at $+\Omega$ in the case of the real rotating magnets and at $\pm\Omega/k$ in the case of the motionless pulsating magnets ($\bar{\tau}_{m,k}^2 \neq \bar{\tau}_{m,d,k}^2$). But this difference is negligible in the case of slotless machines because their relatively large effective magnetic air-gap highly limits the contribution of harmonics of order $k>1$ to the no-load losses. In such machines, it is then possible to compute the eddy current losses due to the real rotation magnets by computing twice the losses due to equivalent motionless pulsating magnets with time-harmonic FEA.

III. PM EQUIVALENT MODEL IN 3D TIME-HARMONIC FEA

The pulsating magnets can be implemented in 3D time-harmonic FEA by using equivalent surface current sheets with time-varying sinusoidal current densities at $\omega=p\Omega$ [3]. Such a representation is illustrated on Fig.2 in the case of radial and parallel magnetized magnets.

Fig. 2. PM equivalent models with (a) radial and (b) parallel magnetization

IV. VALIDATION AND COMPARATIVE ANALYSIS

The method has been applied to the optimal design of a 500W 20000rpm 3-phase 2 poles slotless PM motor with radial magnets. Fig.3 presents the variations of the correction factor that represents the 3D to 2D no-load eddy current losses ratio computed respectively by 3D time-stepping transient FEA as in [2] and by 3D time-harmonic FEA according to the proposed method, when the axial length of the motor varies. The correction factor obtained with 3D time-harmonic FEA is slightly higher but it has no influence on the optimal motor design solution. But the efficiency of the global design optimization process is highly improved in terms of computing time because the evaluation of the 3D losses correction factor is much faster.

Fig. 3. Variation of correction factors with axial length to pole pitch ratio

V. CONCLUSION

The implementation of equivalent motionless pulsating magnets modeled as equivalent surface current sheets with time-varying sinusoidal current densities in 3D FE solvers is an interesting feature to compute eddy current losses in slotless SMC PM machines by fast 3D time-harmonic FEA.

Decoupling of Nonequidistant Time Steps by Fixed Point Method for Nonlinear Eddy Currents

Gergely Koczka, Oszkár Bíró

Institute for Fundamentals and Theory in Electrical Engineering
Kopernikusgasse 24/3, A-8010 Graz, Austria
gergely.koczka@tugraz.at

Abstract— A method is presented to get the steady state solution of nonlinear eddy current problems with periodic excitation using the \mathbf{T}, ϕ formulation in the time domain. The fixed point method is used to linearize the equations. A new decoupling technique is introduced for the case of nonequidistant time steps. The results are compared to the solution obtained by equidistant time steps and by a transient time stepping method in a three-dimensional example.

I. INTRODUCTION

Obtaining the steady-state solution of nonlinear eddy current problems with periodic excitation is very time consuming by stepping through transients in the time domain. An algorithm based on the fixed point technique has been presented in [1] and [2] for decoupling the equations of equidistant time steps using the \mathbf{A}, \mathbf{v} - \mathbf{v} formulation both in two (2D) and three dimensions (3D). It has been extended in [3] for the \mathbf{T}, ϕ method. With this approach, half as many complex linear equation systems have to be solved as there are steps within a period. The efficiency of the algorithm can be improved by decreasing the number of time steps without loss of accuracy. This can be achieved by using a nonequidistant time discretization which is capable of approximating the wave form of the excitation with less time steps. The aim of this paper is to generalize the method of [1], [2] and [3] for variable time steps. The equations of the \mathbf{T}, ϕ formulation are used. The results of the time periodic methods are compared to a transient time stepping approach for a 3D problem.

II. FIXED POINT METHOD USING THE \mathbf{T}, ϕ FORMULATION

The quasi static Maxwell's equations using the \mathbf{T}, ϕ formulation lead to

$$\nabla \times \rho \nabla \times \mathbf{T} + \frac{\partial}{\partial t} (\mu \mathbf{T} - \mu \nabla \phi) = -\nabla \times \rho \nabla \times \mathbf{T}_0 - \frac{\partial}{\partial t} (\mu \mathbf{T}_0) \quad (1)$$

$$\frac{\partial}{\partial t} \nabla \cdot (\mu \mathbf{T} - \mu \nabla \phi) = -\frac{\partial}{\partial t} \nabla \cdot (\mu \mathbf{T}_0) \quad (2)$$

where \mathbf{T} is the reduced electric vector potential, ϕ is the magnetic scalar potential, \mathbf{T}_0 is the impressed electric vector potential, ρ is the resistivity and μ is the permeability. The permeability is non-linear, i.e. it depends on \mathbf{T} and ϕ . The excitation is periodic i.e. $\mathbf{T}_0(t) = \mathbf{T}_0(t+T)$, and the periodic solution has to be determined ($\mathbf{T}(t) = \mathbf{T}(t+T)$, $\phi(t) = \phi(t+T)$), with $T > 0$. To achieve symmetry, the time derivative of the equation $\nabla \cdot \mathbf{B} = 0$ has been used in (2).

Introducing the fixed point permeability (μ_{FP}), linearizing (1) and (2), as shown in [3] and using Galerkin method for

discretizing the partial differential equations, the following iterative method is obtained:

$$S(\rho)x^{(s+1)} + \frac{d}{dt} M(\mu_{FP}^{(s)})x^{(s+1)} = f + \frac{d}{dt} g + \frac{d}{dt} M(\mu_{FP}^{(s)} - \mu^{(s)})x^{(s)}, \quad (3)$$

where $S(\rho)$ is the stiffness matrix depending on the resistivity, $M(\mu)$ is the mass matrix depending on μ , $x^{(s)}$ contains the unknowns \mathbf{T} and ϕ in the s -th iteration step. f and g contain the excitations, $\mu^{(s)}$ is the permeability and $\mu_{FP}^{(s)}$ is the fixed point parameter in the s -th iteration.

III. THE TIME PERIODIC METHOD

An ordinary differential equation system with periodic conditions has to be solved in all fixed point iterations. These equation systems have a general form:

$$Ax(t) + B \frac{d}{dt} x(t) = f(t) + \frac{d}{dt} g(t). \quad (4)$$

In contrast to [1]-[3], a time periodic method using the general time discretization $0 = t_0 < t_1 < \dots < t_n = T$ will be employed. The time derivatives are discretized by the implicit Euler scheme

$$dx(t_k)/dt \approx (x_k - x_{k-1})/(t_k - t_{k-1}) \quad (5)$$

where x_k is the approximate value of $x(t_k)$. With this discretization, (4) becomes

$$Ax_k + B \frac{x_k - x_{k-1}}{t_k - t_{k-1}} = f_k + \frac{g_k - g_{k-1}}{t_k - t_{k-1}}. \quad (6)$$

The discrete derivative operator in (5) can be represented as a multiplication by a matrix D , due to the periodic condition ($x_0 = x_n$). D is a block structured matrix. The entries of the k -th block-row of D are $I(t_k - t_{k-1})$, $-I(t_k - t_{k-1})$ and zeros, where I is the identity matrix with the same size as A or B . Equation (6) has a closed form:

$$\{Ax\} + D\{Bx\} = \{f\} + D\{g\}, \quad (7)$$

with the notation $\{Cx\} := [x_1^T C^T \quad x_2^T C^T \quad \dots \quad x_n^T C^T]^T$ and

$\{x\} := [x_1^T \quad x_2^T \quad \dots \quad x_n^T]^T$ where C is an arbitrary matrix.

The following relationship is a property of these notations:

$$D\{Bx\} = \{B(D\{x\})\}. \quad (8)$$

Since all blocks in D are constants times the identity matrix, the $n \times n$ matrix \tilde{D} can be defined so that its elements are the same as the multipliers in the blocks of D .

To solve (7) efficiently, an eigenvector decomposition of D ($DV = V\Lambda$) is needed, where the matrix V contains the eigenvectors and Λ is a diagonal matrix containing the eigenvalues of D , similarly as in [1]. The matrix V and Λ share a similar block structure with D , and they can be determined from the eigenvectors and eigenvalues of \tilde{D} . This decomposition and the use of the property (8) brings (7) to the following form:

$$\{Ay\} + \Lambda\{By\} = \{F\} + \Lambda\{G\}. \quad (9)$$

where $y = V^{-1}\{x\}$, $F = V^{-1}\{f\}$, $G = V^{-1}\{g\}$. Since Λ is diagonal, (9) can be solved decoupled for each time instant:

$$Ay_k + \lambda_k By_k = F_k + \lambda_k G_k \quad k = 1, 2, \dots, n, \quad (10)$$

where λ_k is the k -th eigenvalue of \tilde{D} . D being a real matrix, all complex eigenvalues of D have a complex conjugate pair, so the number of equations to be solved is half as many as there are time steps in a period.

IV. CONVERGENCE ANALYSIS

With the results of the previous section, the whole fixed point iteration can be described as follows:

$$x^{(s+1)} = V \left\{ \left(S(\rho) + \lambda_k M(\mu_{FP}^{(s)}) \right)^{-1} \left((V^{-1}\{f\})_k + \lambda_k (V^{-1}\{g\})_k + \lambda_k \left(V^{-1} \left\{ M(\mu_{FP}^{(s)} - \mu_i^{(s)}) x_i^{(s)} \right\} \right)_k \right) \right\}, \quad (11)$$

where the superscript (s) denotes the value of a variable in the s -th iteration step. $\{M(\mu_{FP} - \mu_i) x_i\}$ denotes the vector

$\left[x_1^T (M(\mu_{FP} - \mu_1))^T, \dots, x_n^T (M(\mu_{FP} - \mu_n))^T \right]^T$. $(V^{-1}\{f\})_k$ is the k -th transformed time step of $V^{-1}\{f\}$. The following theorem is used to prove the convergence:

The sequence $x_{k+1} = Bx_k + c$ is convergent, if and only if $\rho(B) < 1$, where $\rho(B)$ is the spectral radius of B .

The spectral radius of the linear operator in (11) can be estimated as:

$$\rho(\bullet) < C \text{cond}_\rho(V) \left\| \frac{\mu_{FP} - \mu}{\mu_{FP}} \right\|. \quad (12)$$

where \bullet represents the operator, $\text{cond}_\rho(V) = \rho(V)\rho(V^{-1})$ is the spectral condition number (this is not the same as $\text{cond}_2(V) = \|V\|_2 \|V^{-1}\|_2$, which is sometimes called spectral condition number), $\|\bullet\|$ is a corresponding norm, C is a constant independent of μ , μ_{FP} and V . It follows from (12) that the convergence of the fixed point method strongly depends on the transformation V , and the choice of the fixed point permeability. The fixed point permeability can be chosen similarly as the fixed point parameter in [1].

V. ANALYSIS OF THE TRANSFORMATION

The choice of the transformation matrix (V) is an important part of this method, since if its condition number is higher than one, then the fixed point algorithm will not be able to converge. Since V contains the eigenvectors of D , the

matrix $V\Gamma$ will contain the eigenvectors also, if Γ is a diagonal matrix, because the eigenvectors are unique only up to a constant multiplier. Tests with different transformation matrices have shown that a simple scaling with a diagonal matrix is not enough to get a well conditioned transformation matrix. The transformation matrix can be decomposed as a product of two matrices as

$$V = QW \quad (13)$$

where Q is a real matrix with the condition number 1, and W is an unitary matrix. The transformation can be done in two steps:

$$y = Wx, z = Qy. \quad (14)$$

This decomposition will be shown in the full paper.

VI. RESULT

The geometry of the 3D example is defined in [3]. The B - H curve is the same as in [1], the conductivity of the cube is 10^6 S/m and the highest value of the current density is 10^8 A/m² in the coil. The excitation has a half period sinusoidal form, and a half period zero value (Fig. 1.).

Fig. 1. The time function of the excitation.

Fig. 2. a. shows the results of the different methods. Fig. 2. b. illustrates the convergence of the nonequidistant time periodic method (NEqTPM) with a well conditioned and an ill conditioned transformation.

Fig. 2. a.: Comparing the results of the NEqTPM (blue line, 22 TS/per) with an equidistant discretization (red line, 32 TS/per) and a transient time stepping method (4-th period, 32 TS/per) (green line). b.: Maximal, and average material changes of the NEqTPM with well- (blue) and ill- (red) conditioned transformation.

Abstract— This paper proposes a general approach for the frequency-domain homogenization of electromagnetic periodical structures. This method allows us to calculate macroscopic equivalent properties including local effects. Based on a local resolution with adapted formulation we can find respectively the equivalent permeability and conductivity. An example of the modeling of eddy current losses in windings is presented.

I. CONTEXT

Eddy current losses can be directly taken into account by a finite element resolution. However meshing every elementary conductor by respecting the skin effect is required. Such modeling is very expensive and generally impossible to accomplish in three-dimensional cases.

In cases of periodical structures (as the windings) a methodology of homogenization can be set up. Then materials are represented with equivalent magnetic and electric properties [1], [2], [3].

In this paper, we describe our homogenization method for periodical structures, in the case of linear problems feed by sinusoidal sources (frequency domain). It is based on a local finite element resolution taking into account any shape of elementary structure. Equivalent complex macroscopic reluctivity and conductivity can then be computed in order to represent local effects. This technique has been applied to compute eddy current losses in windings.

II. METHODOLOGY

Our method is based on the resolution of local Maxwell equations, on an elementary cell of the periodical structure. Local fields are linked with macroscopic fields to find equivalent properties.

A. Local and macroscopic fields

At local level, assuming that properties of materials (resistivity ν and reluctivity ρ) are linear, we have:

$$\begin{aligned} \text{curl } \mathbf{e} &= -j\omega \mathbf{b} & \text{div } \mathbf{b} &= 0 \\ \text{curl } \mathbf{h} &= \mathbf{j} & \text{div } \mathbf{j} &= 0 \\ \mathbf{h} &= \nu \mathbf{b} = \frac{1}{\mu} \mathbf{b} & \mathbf{e} &= \rho \mathbf{j} = \frac{1}{\sigma} \mathbf{j} \end{aligned} \quad (1)$$

At macroscopic level, electric and magnetic fields \mathbf{H} and \mathbf{E} also verify Maxwell equations. Our goal is to determine macroscopic equivalent behavior laws from local periodical

effects. For this, we suppose that the macroscopic field has very few variations on a great number of elementary cells. So, the calculation at local level can be performed on an elementary cell of the periodical structure with periodical conditions. In practice, we write local fields as follows:

$$\begin{aligned} \mathbf{h} &= \mathbf{H} + \mathbf{h}_\mu & \mathbf{b} &= \mathbf{B} + \mathbf{b}_\mu \\ \mathbf{e} &= \mathbf{E} + \mathbf{e}_\mu & \mathbf{j} &= \mathbf{J} + \mathbf{j}_\mu \end{aligned} \quad (2)$$

where \mathbf{h}_μ , \mathbf{b}_μ , \mathbf{e}_μ and \mathbf{j}_μ are periodical fields. We can notice that these fields also verify the Maxwell equations, without any relationship between \mathbf{h}_μ and \mathbf{b}_μ or \mathbf{e}_μ and \mathbf{j}_μ . They represent local effects (difference with the macroscopic field) and are at the origin of additional losses. Since the macroscopic magnetic flux is obtained through the integration of local flux on any surface, we can link \mathbf{j} and \mathbf{J} , \mathbf{b} and \mathbf{B} by:

$$\langle \mathbf{b} \rangle = \mathbf{B} \quad \langle \mathbf{j} \rangle = \mathbf{J} \quad (3)$$

Where $\langle \mathbf{j} \rangle$ represent the average field of \mathbf{j} on the cell. It is important to notice that it is not possible to express directly \mathbf{H} and \mathbf{E} from their average values $\langle \mathbf{h} \rangle$ and $\langle \mathbf{e} \rangle$ on the cell. In practice, local curls of current \mathbf{j}_μ can produce a macroscopic field $\langle \mathbf{h}_\mu \rangle \neq 0$. As a result, \mathbf{H} differs from $\langle \mathbf{h} \rangle$.

To find macroscopic behavior we consider uniform field \mathbf{B} and \mathbf{J} at the local level. From Maxwell-Ampere Maxwell-Faraday equations, the macroscopic fields \mathbf{H} and \mathbf{E} can then be expressed in the following form:

$$\begin{aligned} \mathbf{H} &= \mathbf{J} \wedge \frac{\mathbf{x}}{2} + \mathbf{H}_c \\ \mathbf{E} &= -j\omega \mathbf{B} \wedge \frac{\mathbf{x}}{2} + \mathbf{E}_c \end{aligned} \quad (4)$$

where the components of \mathbf{x} are the coordinates (x, y, z) and \mathbf{H}_c , resp. \mathbf{E}_c , are the value of the macroscopic field at $\mathbf{x}=\mathbf{0}$, that we can choose at the center of the local domain of study. This allows us to define macroscopic equivalent properties such as:

$$\begin{aligned} \langle \mathbf{H} \rangle &= \mathbf{H}_c = [\nu_{eq}] \mathbf{B} \\ \langle \mathbf{E} \rangle &= \mathbf{E}_c = [\rho_{eq}] \mathbf{J} \end{aligned} \quad (5)$$

B. Local fields resolution

The first and natural way consists of applying \mathbf{J} and \mathbf{B} on the cell to solve the problem at the local level [2]. Then, \mathbf{h} and \mathbf{e} on the cell are determinate. Unfortunately, we do not obtain \mathbf{H} and \mathbf{E} . The solution for finding equivalent properties can be achieved by equalizing electromagnetic powers, from the local and macroscopic level. Globally this methodology requires some precautions (for applying \mathbf{B} and \mathbf{J}) and needs more simulations than the second approach presented below.

The alternative way we propose consists to apply the macroscopic field \mathbf{H} (resp. \mathbf{E}) on the cell. Then the knowing of local fields \mathbf{b} (resp. \mathbf{j}) allows to determine \mathbf{B} (resp. \mathbf{J}) from equation (3) and finally to establish equivalent properties.

For example, the tensor of permeability $[\mu_{eq}] = [v_{eq}]^{-1}$, can be obtained by solving local problem on the cell with a \mathbf{t} - ϕ formulation. Starting from (1), we solve the cell problem:

$$\begin{aligned} \text{curl}(\rho \text{curl} \mathbf{h}) + j\omega \mu \mathbf{h} &= 0 \\ \text{div} \mu \mathbf{h} &= 0 \end{aligned} \quad (6)$$

We introduce \mathbf{t}_μ and ϕ_μ from:

$$\begin{aligned} \text{rot} \mathbf{h}_\mu = \mathbf{j}_\mu &\Rightarrow \mathbf{j}_\mu = \text{rot} \mathbf{t}_\mu \\ \text{div} \mathbf{j}_\mu = 0 &\Rightarrow \mathbf{h}_\mu = \mathbf{t}_\mu - \text{grad} \phi_\mu \end{aligned} \quad (7)$$

Using equations (2) and (4) with $\mathbf{J} = \mathbf{0}$ we obtain:

$$\begin{aligned} \text{curl}(\rho \text{curl} \mathbf{t}_\mu) + j\omega \mu \mathbf{t}_\mu - \text{grad} \phi_\mu &= -j\omega (\mu \mathbf{H}_c) \\ \text{div} \mu (\mathbf{t}_\mu - \text{grad} \phi_\mu) &= \text{div} (\mu \mathbf{H}_c) \end{aligned} \quad (8)$$

with periodical boundary conditions for \mathbf{t}_μ and ϕ_μ on the cell problem. Applying \mathbf{H}_c along the three directions of the cell allows us to obtain easily $[\mu_{eq}]$. For example, with an applied field $\mathbf{H}_c = \{ H_{cx}, 0, 0 \}$ along the x direction, and after calculating \mathbf{B} from $\langle \mu (\mathbf{h}_\mu + \mathbf{H}_c) \rangle$ after solving (8), we have:

$$\mu_{xx} = \frac{B_x}{H_{cx}} \quad \mu_{xy} = \frac{B_y}{H_{cx}} \quad \mu_{xz} = \frac{B_z}{H_{cx}} \quad (9)$$

We can notice that with the previous \mathbf{t}_μ - ϕ_μ formulation the equivalent properties $\mathbf{J}(\mathbf{E})$ can not be determined. In practice, to apply a field \mathbf{E} , we choose an \mathbf{a} - v formulation. In this case, the following system is solved:

$$\begin{aligned} \text{curl}(v \text{curl} \mathbf{a}_\mu) + \sigma(j\omega \mathbf{a}_\mu + \text{grad} v_\mu) &= j\omega (\sigma \mathbf{E}_c) \\ \text{div} \sigma(j\omega \mathbf{a}_\mu + \text{grad} v_\mu) &= \text{div} (\sigma \mathbf{E}_c) \end{aligned} \quad (10)$$

with periodical conditions for \mathbf{a}_μ and v_μ . \mathbf{J} can be obtained after resolution from $\langle \sigma (\mathbf{e}_\mu + \mathbf{E}_c) \rangle$.

III. EXAMPLE

We have applied our method in order to determine macroscopic equivalent properties for a coil. Windings are the seat of losses due to the presence of eddy currents. These have as origin two effects: effect of each conductor

on itself (skin effect) and proximity effect (influence of the magnetic field on the neighboring conductors).

Fig. 1. Representation of the coil arrangement with associated elementary cell.

To determine the equivalent reluctivity tensor, as proposed, a \mathbf{t}_μ - ϕ_μ formulation with periodic condition (8) is used. Thanks to the imaginary part of the equivalent reluctivity, we can obtain a representation of the local eddy current losses due to proximity effects [1], [3]. To validate it, we have modeled a coil (with 80 elementary conductors) exposed to an external field (Fig. 1.). Then we have compared the active and reactive part in the domain of study in two cases:

- when each conductor is described (reference),
- when the coil is homogenized.

The obtained results (Fig. 2.) are very satisfactory considering the small number of conductors in the winding.

Fig. 2. Comparison (in %) of the active and reactive power between the homogenized model and the reference model. (The frequency which correspond to a skin depth equal to the diameter of the wire is represented with a vertical line.)

The method has been used to determine equivalent conductivity by solving (10). In the case of a coil, it allows to take into account skin effect.

IV. CONCLUSION

A general methodology for determining equivalent properties for electromagnetic periodical structure has been proposed. The importance of the choice of the formulation has been highlighted. The proposed method can be applied to any case of electromagnetic periodical structure, in two and three dimensions.

Abstract—Lowest-order frequency-domain surface-impedance boundary conditions are reformulated as a finite-element approach with particular shape functions and as a finite-integration technique with a particular geometry.

I. INTRODUCTION

When the skin depth is expected to be small compared to the wire diameter, it may be convenient to model the eddy-current effect in a wire by a *surface-impedance boundary condition* (SIBC), thereby omitting the volumetric discretization of the inner wire geometry [1]. The relation between the tangential components E_γ and H_β of the electric and magnetic field strengths, assuming an infinite half-plane ($\alpha \geq 0$) of material with permeability μ and conductivity σ is then

$$E_\gamma = -\frac{1+j}{2}\omega\mu\delta H_\beta; \quad \delta = \sqrt{\frac{2}{\omega\mu\sigma}} \quad (1)$$

where ω is the angular frequency and δ the skin depth [2]. Higher-order SIBCs accounting for the curvature of the boundary and for field variations along the boundary have been proposed [3] and have been applied to a variety of problems (e.g. [4]). SIBCs have been combined with the finite-element (FE) method, the boundary-element method and the finite-integration technique (FIT) [5], [6] and have been formulated in frequency and time domain. This paper focuses on reformulating the SIBC using the typical mechanisms of the FE method and of the FIT. The idea is to come to a geometric interpretation for the Leontovich SIBC in the frequency domain.

II. INTERPRETATION AS A BOUNDARY INTEGRAL TERM

The weak form of the time-harmonic magnetoquasistatic formulation in terms of the magnetic vector potential \mathbf{A} reads

$$\int_{\Omega} (\nu \nabla \times \mathbf{A}) \cdot (\nabla \times \mathbf{w}_i) dV + \int_{\partial\Omega} (\mathbf{H} \times \mathbf{w}_i) \cdot d\mathbf{A} + j\omega \int_{\Omega} \sigma \mathbf{A} \cdot \mathbf{w}_i dV = \int_{\Omega} \mathbf{J}_s \cdot \mathbf{w}_i dV \quad (2)$$

with $\nu = 1/\mu$ the reluctivity, \mathbf{w}_i belonging to an appropriate set of edge shape functions, Ω the computational domain and \mathbf{J}_s the applied current density. The boundary integral term originates from partial integration and vanishes in the case of homogeneous Dirichlet or Neumann boundary conditions. In the case of SIBCs, the boundary integral term combined with (1) simplifies to

$$\int_{\partial\Omega} \nu \xi \mathbf{A} \cdot \mathbf{w}_i dA \quad (3)$$

Fig. 1. Circuit equivalent of the SIBC for the 3D FE case: Reluctance Λ_{ij} perpendicular to edge i and conductance G_{ij} along edge i in function of reluctivity ν , conductivity σ , skin depth δ , edge length h_i and dual edge length \tilde{b}_i .

with $\xi = (1+j)/\delta$. With discretization by $\mathbf{A} = \sum_j \tilde{\mathbf{a}}_j \mathbf{w}_j$ and some rearrangement, the boundary integral terms resembles

$$\sum_j \tilde{\mathbf{a}}_j \underbrace{\int_{\partial\Omega} \nu \frac{\mathbf{w}_i \cdot \mathbf{w}_j}{\delta} dA}_{\Lambda_{ij}} + \sum_j j\omega \tilde{\mathbf{a}}_j \underbrace{\int_{\partial\Omega} \sigma \frac{\delta}{2} \mathbf{w}_i \cdot \mathbf{w}_j dA}_{G_{ij}}. \quad (4)$$

Λ_{ij} has the unit of a reluctance (1/H), whereas G_{ij} has the unit of a conductance (S). Both add up with already existing reluctance and conductance terms in the discretized partial differential equation. The meaning of both becomes very clear when mass lumping would be applied. Then,

$$\int_{\partial\Omega} \mathbf{w}_i \cdot \mathbf{w}_j dA = \begin{cases} \frac{\tilde{b}_i}{h_i} & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}. \quad (5)$$

Here h_i is the length of edge i and \tilde{b}_i is the length of a dual edge lying in $\partial\Omega$ and crossing edge i . The entries become

$$\Lambda_{ij} = \nu \frac{\tilde{b}_i}{\delta h_i}; \quad (6)$$

$$G_{ij} = \sigma \frac{\delta \tilde{b}_i}{2 h_i}. \quad (7)$$

Hence, Λ_{ij} is the reluctance of the flux path perpendicular to edge i with length \tilde{b}_i and cross-section $h_i \delta$, whereas G_{ij} is the conductance of the current path along edge i with length h_i and cross-section $\tilde{b}_i \frac{\delta}{2}$ (Fig. 1). This interpretation becomes even more clear when considering the 2D case (Fig. 2).

III. INTERPRETATION AS A SPECIAL FE DOMAIN

Another interpretation is obtained by considering the highly conductive domain Ω_c as part of the computational domain $\Omega \cup \Omega_c$. Additional prism elements are constructed by lifting

the triangles at $\partial\Omega$ into Ω_c . In theory, these prisms extend from $\alpha = 0$ up to $\alpha = \infty$. Moreover, when $\partial\Omega_c$ is convex, the prisms are partially overlapping, whereas when $\partial\Omega_c$ is concave, the prisms do not span Ω_c completely. For every edge j incident to $\partial\Omega$, special shape functions are defined. Inside Ω , \mathbf{w}_j keeps its useful form whereas inside Ω_c , the complex-valued decaying function $\hat{\mathbf{w}}_j e^{-\xi\alpha}$ with $\hat{\mathbf{w}}_j$ the trace of \mathbf{w}_j at $\partial\Omega$, is used. These functions guarantee the tangential continuity at $\partial\Omega$. The expressions in (2) have to be integrated in $\Omega \cup \Omega_c$. The Ritz-Galerkin approach consists in using test functions which are conjugate to the trial functions. Hence, the test functions in Ω_c are $\hat{\mathbf{w}}_i e^{-\xi^*\alpha}$ where ξ^* denotes the conjugate of ξ . The contribution of Ω_c is

$$\sum_j \left(\Lambda_{ij} + \hat{\Lambda}_{ij} + j\omega \mathbf{G}_{ij} \right) \hat{\mathbf{a}}_j \quad (8)$$

where $\hat{\Lambda} = \hat{\mathbf{C}}^T \hat{\mathbf{M}}_\nu \hat{\mathbf{C}}$,

$$\hat{\mathbf{M}}_{\nu,pq} = \frac{\delta}{2} \int_{\partial\Omega} \nu \mathbf{z}_q \cdot \mathbf{z}_p \, dA, \quad (9)$$

\mathbf{z}_i are lowest-order face functions and $\hat{\mathbf{C}}$ is the discrete curl matrix restricted to $\partial\Omega$. Eq. (9) simplifies to

$$\hat{\mathbf{M}}_{\nu,pq} = \begin{cases} \frac{\nu\delta}{2A_p} & \text{if } p = q \\ 0 & \text{if } p \neq q \end{cases} \quad (10)$$

with A_p the cross-section of face p . This extra term does not appear in the interpretation of the SIBC as a boundary integral term. Although not relevant for the convergence of the method, $\hat{\Lambda}$ is important to obtain a complete geometric interpretation of the SIBC.

IV. INTERPRETATION BY THE FINITE INTEGRATION TECHNIQUE

The finite-integration technique (FIT) considers a staggered grid pair [7]. The discrete counterparts of the curl, divergence and gradient operators are incidence matrices and do not involve any discretisation. The Hodge operators are discretized into material matrices. The reluctance matrix \mathbf{M}_ν models the magnetic paths formed by primary faces and dual edges whereas the conductance matrix \mathbf{M}_σ considers the electric paths formed by primary edges and dual faces. Closely similar methodologies are described in [8] and [9]. In the particular case where an orthogonally intersecting grid pair is considered, \mathbf{M}_ν and \mathbf{M}_σ are diagonal matrices. The SIBC is easily introduced in FIT by considering an additional layer of primary grid cells of thickness δ , with conductivity σ and reluctivity ν (Fig. 2). Dual grid lines are present at a distance $\frac{\delta}{2}$. The generic construction of FIT material matrices leads to the same additional contributions Λ_{ij} , $\hat{\Lambda}_{ij}$ and \mathbf{G}_{ij} as described in the previous sections. Here, only the simplest case where the primary grid resolves the geometry, is considered. The non-matching case is treated in [6]. An additional difficulty arises when the SIBC is excited from the outside. In that case, one additional unknown $\hat{\mathbf{a}}_s$ is introduced per SIBC region and connected with the externally applied voltage [4].

Fig. 2. Circuit equivalent of the SIBC for the 2D FIT case: Reluctance Λ_α perpendicular to the boundary, reluctance Λ_β and conductance \mathbf{G}_z parallel to the boundary, grid fluxes $\hat{\mathbf{B}}_\alpha$ and $\hat{\mathbf{B}}_\beta$, grid current $\hat{\mathbf{J}}_z$, skin depth δ , primary grid lengths ℓ_z and h_β , dual grid length \hat{h}_β , line-integrated magnetic potential $\hat{\mathbf{a}}_z$.

V. EXAMPLE

As an example, the transmission-line parameters of a winding are calculated [4]. The convergence of the formulations with and without $\hat{\Lambda}$ are the same, indicating the inferior importance of $\hat{\Lambda}$. The SIBCs replace the volume discretizations of the individual wires. After assembling, the system matrices are reduced by algebraic manipulation in order to obtain the transmission-line impedance matrix.

VI. CONCLUSIONS

The lowest-order frequency-domain SIBC can be interpreted within the framework of the FIT as an additional layer of primary cells with the skin depth as thickness. The typical FE formulation of the SIBC as a boundary integral term can also be found by considering specialized shape functions in the highly conductive domain.

Abstract — A highly efficient method based on the current sheet integral equation is extended to thin metallic shields operating in the vicinity of nonlinear magnetic media. The polarization fixed point technique is applied, with the magnetic media replaced by a linear medium of permeability equal to that of free space and a distribution of magnetic polarization which depends nonlinearly on the magnetic induction. In a periodic regime, the integral equation is solved for each harmonic separately.

I. INTRODUCTION

For thin conducting shields, when their thickness is smaller than the depth of penetration corresponding to the harmonics involved, the analysis of the periodic electromagnetic field can be simplified by considering an equivalent surface distribution of the electric current induced in the shields. A surface impedance which takes into account the relationship between the field quantities on the two sides of the shield was introduced in [1]. An original solution for very thin shields was proposed in [2], where the surface density of the current induced is expressed in terms of unknown scalar quantities associated with the nodes of the surface discretization grid. In [3], simple vector functions are employed, such that the current continuity is preserved everywhere, the unknowns to be determined being scalar coefficients associated with the interior nodes of the grid and with only one unknown for each hole contour in the case of multiply connected shields. These unknowns are computed by applying a Galerkin technique to the current sheet integral equation.

The computation of the currents induced in the shields is drastically complicated when there are ferromagnetic bodies in their neighbourhood. A static magnetic permeability that is iteratively corrected by various criteria has been used in [4], which allows a phasor representation of the field quantities. Since the time constants involved in the electromagnetic shielding problems are relatively small, only a reduced number of harmonics is required and, thus, the harmonic balance method [5] could also be applied efficiently. Unfortunately, these methods do not allow the construction of an integral equation for the current induced in the shield in the presence of nonhomogenous media that have a permeability that is iteratively modified.

In this paper, the solution of the periodic electromagnetic field problem is obtained by using a surface integral equation for the currents induced in the shield even in the presence of nonlinear ferromagnetic materials. As in [6], a model is used where the nonlinear materials are replaced by a free space, but with a fictitious distribution of magnetization. The current

sheet integral equation is written for each harmonic and, at each iteration, we first determine the magnetic induction in the ferromagnetic material and, then, the magnetization is corrected in time domain in terms of the corresponding magnetic induction. The computation process is started by only considering the fundamental harmonic, with the results being afterwards improved by including higher harmonics. At most, three harmonics are sufficient for practical structures.

II. NONLINEARITY TREATMENT BY THE FIXED POINT METHOD AND ITERATIVE ALGORITHM

For ferromagnetic media we use the constitutive relation

$$\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{I} \quad (1)$$

where the magnetic polarization \mathbf{I} is corrected iteratively in terms of the magnetic induction \mathbf{B} [7],

$$\mathbf{I} = \mathbf{B} - \mu_0 \mathbf{F}(\mathbf{B}) \quad (2)$$

$\mathbf{H} = \mathbf{F}(\mathbf{B})$ being the constitutive relation for the magnetic medium.

An initial value of polarization is arbitrary chosen. We use the representation

$$\mathbf{I}(t) = \sum_{n=1,3,\dots} (\mathbf{I}'_n \sin(n\omega t) + \mathbf{I}''_n \cos(n\omega t)) \quad (3)$$

with only the first N harmonics retained. For each harmonic n of polarization, written in phasor form as

$$\mathbf{I}_n = \mathbf{I}'_n + j\mathbf{I}''_n \quad (4)$$

we solve the field problem in the presence of the shield and determine the harmonic n of magnetic induction,

$$\mathbf{B}_n = \mathbf{B}'_n + j\mathbf{B}''_n \quad (5)$$

The time domain expression of \mathbf{B} is derived in the form

$$\mathbf{B}(t) = \sum_{n=1,3,\dots,2N-1} (\mathbf{B}'_n \sin(n\omega t) + \mathbf{B}''_n \cos(n\omega t)). \quad (6)$$

Then, at each time step, (6) is used to correct the magnetic polarization. The computational effort is substantially reduced if one starts with only the fundamental and, then, the solution accuracy is increased by adding a few more harmonics.

III. INTEGRAL EQUATION FOR THE SHIELD CURRENT SHEET AND ITS NUMERICAL SOLUTION

For each harmonic n of the surface density of the current induced over the surface S of the thin shield we have

$$\begin{aligned} & \rho_s \mathbf{J}_s(\mathbf{r}) + j\lambda_n \int_S \frac{\mathbf{J}_s(\mathbf{r}')}{R} dS' \\ & = -j2\pi f(A_0(\mathbf{r}) + \mathbf{A}_I(\mathbf{r})) - \nabla V(\mathbf{r}) \end{aligned} \quad (7)$$

where $\rho_s = \rho/\Delta$ is the surface resistivity of the shield, with Δ the shield thickness, $j \equiv \sqrt{-1}$, $\lambda_n \equiv nf\mu_0/2$, $R = |\mathbf{r} - \mathbf{r}'|$ with \mathbf{r} and \mathbf{r}' , respectively, the position vectors of the observation point and of the source point, A_0 is the magnetic vector potential due to the given sources, and \mathbf{A}_I is the magnetic vector potential due to the harmonic n of polarization in the region Ω occupied by ferromagnetic bodies,

$$\mathbf{A}_I = \frac{1}{4\pi} \int_{\Omega} \frac{(\nabla' \times \mathbf{J}(\mathbf{r}'))}{R} dS'. \quad (8)$$

The scalar potential term $-\nabla V$ in (7) can be ignored.

Fig. 1. Surface elements associated with the node i

Equation (7) is solved numerically as shown in [3]. S is approximated by a polyhedral surface with plane triangular surface elements. To each node i we associate a surface vector function \mathbf{U}_i , having the value $\mathbf{U}_i^{(p)} = \frac{1}{2S_p} \mathbf{I}_i^{(p)}$ for each

element (p) containing the node i (Fig. 1), and a zero value for all the surface elements which do not contain the node i . The surface current density is written as a linear combination of the functions \mathbf{U}_i as

$$\mathbf{J}_s(\mathbf{r}) \approx \sum_{i=1}^N \alpha_i \mathbf{U}_i(\mathbf{r}). \quad (9)$$

The unknown coefficients α_i are determined by taking the inner products of the two sides of (7) with \mathbf{U}_n , $n = 1, 2, \dots, N$, over the shield surface.

IV. CORRECTION OF MAGNETIC POLARIZATION

The region Ω with ferromagnetic material is discretized in polyhedral volume elements Ω_k of an arbitrary shape. In each Ω_k the magnetic induction is taken to be constant, namely,

equal to its average value over the element,

$$\tilde{\mathbf{B}}_k = \tilde{\mathbf{B}}_{0k} + \tilde{\mathbf{B}}_{Jk} + \tilde{\mathbf{B}}_{Ik} \quad (10)$$

where $\tilde{\mathbf{B}}_{0k}$ is due to the given sources, $\tilde{\mathbf{B}}_{Jk}$ is due to the shield's current sheet,

$$\tilde{\mathbf{B}}_{Jk} = -\frac{\mu_0}{4\pi v_k} \int_S \oint_{\partial\Omega_k} \frac{\mathbf{J}_s(\mathbf{r}') \times \mathbf{n}_k}{R} dS_k dS', \quad (11)$$

with v_k being the volume of Ω_k , and $\tilde{\mathbf{B}}_{Ik}$ is due to the magnetic polarization. Each element Ω_m with its polarization \mathbf{I}_m contributes to $\tilde{\mathbf{B}}_{Ik}$ by

$$\tilde{\mathbf{B}}_{Ikm} = -\frac{1}{4\pi v_k} \left(\oint_{\partial\Omega_k} \oint_{\partial\Omega_m} \frac{(\mathbf{n}_k \cdot \mathbf{n}_m) \bar{\mathbf{1}} - (\mathbf{n}_k \mathbf{n}_m)}{R} dS_m dS_k \right) \cdot \mathbf{I}_m \quad (12)$$

where $\bar{\mathbf{1}}$ is the identity dyadic and $(\mathbf{n}_k \mathbf{n}_m)$ is the dyad of the unit vectors \mathbf{n}_k and \mathbf{n}_m normal to the boundaries $\partial\Omega_k$ and $\partial\Omega_m$ of the elements Ω_k and Ω_m , respectively. Analytical expressions can be obtained for the integrals in (11), (12) over the closed surface of one of the volume elements since this surface has plane sides. Details regarding the numerical computation and illustrative examples will be presented at the Conference.

ACKNOWLEDGMENT

Evaluating the Guidance Force Capabilities of Flat Passive Maglev Guideway Topologies Using the $\mathbf{A}-\phi$ Formulation

Jonathan Bird

University of North Carolina - Charlotte

Abstract— When a Halbach rotor is rotated and translationally moved over a flat conductive sheet guideway eddy currents are induced that can create simultaneous lift and thrust forces. This technique could enable Maglev cost to be reduced significantly since the guideway construction costs would be minimized. This paper investigates different flat guideway and rotor topologies that also create lateral re-centering forces.

I. INTRODUCTION

Despite high-speed maglev (magnetic levitation) vehicles being commercially available, city and intercity urban planners throughout the world continue to balk at the immense capital cost associated with installing currently available high-speed maglev designs. Rather, high-speed rail or more reliance on highways and aircraft continue to be the typical chosen path. This is unfortunate because maglev has some unique and beneficial characteristics, such as low pollution emissions, low maintenance and high-speed.

If the maglev guideway costs can be brought radically down in cost, to that which is typically incurred when constructing rail or high-ways, then perhaps maglev would be more frequently implemented. In order to reduce construction costs to the minimum the maglev guideway needs to be passive (non-electrified) and preferably horizontally flat. By using a horizontal flat passive guideway maglev could be more easily integrated into existing transportation infrastructure. Flat guideways can make use of electromagnetic directional switching [1] rather than impractical mechanically moving guideways. They are also less likely to accumulate debris and snow compared to vertically mounted guideways and they create less aerodynamic vehicle drag. However, using a flat guideway mandates that the magnetic forces alone create sufficient vehicle restorative forces to ensure stability.

Three possible flat aluminum sheet guideway topologies are considered in this paper and are shown in Fig. 1, Fig. 2 and Fig. 3. Only one side of the guideway track is shown. Using these flat guideways it is proposed that a vehicle could create simultaneous suspension and thrust forces by electromechanically rotating the magnetic rotors, shown above the guideways. The simultaneous thrust, lift and guidance forces are created by the induced eddy currents in the guideway [2-4]. The thrust is highly dependent on the slip, s

$$s = \omega_m r_o - v_x, \quad (1)$$

where ω_m = rotor mechanical angular velocity, r_o = rotor outer radius and v_x = translational velocity. The lift force is less

dependent on slip, especially at high translational velocity [5]. All three models use a 4 pole-pair Halbach rotor, with magnets arranged as illustrated in Fig. 4. The guideway and rotors are configured so that additional lateral re-centering (z-axis) forces are created when the magnetic rotors are offset. This re-centering is dependent on the relative difference between the flux impinging on either side of the guideway.

Numerous magnetic wheels would be needed for a full size vehicle and dynamic control would be essential. An onboard power source or power transfer to the vehicle will be needed and the vehicle will need to run on wheels at low speeds. Relatively high efficiency is achieved when using multiple wheels in series [3]. This paper focuses on determining which, if any, proposed guideway can create sufficient lateral re-centering guidance forces whilst not seriously deteriorating the thrust and lift forces.

II. MODEL FORMULATION SUMMARY

A novel 3D finite element $\mathbf{A}-\phi$ steady-state convective diffusion model presented in [4] was used to calculate the forces. The formulation used for the conducting and non-conducting regions is given in (2) and (3) respectively. The boundary conditions and more model details are provided in [4,5]. The Halbach rotor's field $\mathbf{B}_{\text{rotor}}$ is calculated semi-

analytically and incorporated into the model formulation via the guideway boundary conditions. The x-axis translational motion is model using a convective term in (2) while the rotation of the rotor(s) is modeled in steady-state using the electrical frequency, ω_e , term in (2). The, ω_e , is related to the mechanical rotor frequency by $\omega_e = (P/2)\omega_m$, where P =number of pole pairs. The problem space is illustrated in Fig. 5.

$$\nabla^2 \mathbf{A} = \mu_0 \sigma \left(j\omega_e \mathbf{A} + v_x \frac{\partial \mathbf{A}}{\partial x} \right), \text{ in } \Omega_c \quad (2)$$

$$\nabla^2 \phi = 0, \text{ in } \Omega_{nc} \quad (3)$$

TABLE I SIMULATION AND EXPERIMENTAL PARAMETERS

Rotor:	Outer radius, r_o	50 mm
	Inner radius, r_i	34.2 mm
	Width, w	175 mm
	Magnet (NdFeB), B_r	1.42
	Magnet relative permeability	1.055
	Pole-pairs, P	4
Guideway:	Conductivity (Al)	$2.459 \times 10^7 \text{ Sm}^{-1}$
	Single sheet width	77 mm
	Thickness, d	6.3 mm
	Airgap between rotor and guideway, g	9.5 mm

Fig. 6 Lateral restorative forces created by induced current on the left and right sides of the split-sheet guideway as the rotor is laterally offset. Rotor width is 175mm. The lateral forces on either side of the guideway cancel out for most of the rotor offset distance.

III. RESULTS AND DISCUSSION

The parameters shown in Table I have been used in this analysis. These parameters were chosen in order to agree with future experiment scale model measurements. Initially the split-sheet topology shown in Fig. 1 was studied [4,5] however, since the lateral forces are dependent on the difference between the flux seen on either side of the split-sheet guideway the lateral restorative forces are relatively small; particularly so if the rotor width is large (see Fig. 6). However, a large rotor width is necessary in order to create sufficient lift force, as shown in Fig. 7.

In order to improve lateral re-centering forces the guideway and dual magnetic rotor designs shown in Fig. 2 and Fig. 3 have been proposed. The guideway topology shown in Fig. 2 is more complex. Hence, the configuration shown in Fig. 3 may

be more desirable from a cost perspective. But this design will come at the price of a reduced thrust and thrust efficiency.

An illustration of the induced A_z vector potential field on the guideway surface is shown in Fig. 8 for the dual rotor design. The full paper shows that the dual design creates greater re-centering guidance force. It does this by utilizing the lateral field difference created by the transverse magnetic flux, (Fig 9)

Fig. 7 The effect of the rotor width on the lift-to-weight ratio as a function of RPM for the case when the Halbach rotor is at the center of the split-sheet guideway. A 5 ms^{-1} translational velocity and 9.5mm air gap was used. Numerical results calculated using the $\mathbf{A}-\phi$ coupled finite element analytic model discussed in [4,5]. Experimental results discussed in [4, 5] also shown.

Fig. 8 Magnetic vector potential field on the guideway surface when the Dual Halbach rotors (175mm total width) are offset and rotated and translationally moved. The Halbach rotor is modeled analytically thus not shown in figure.

Abstract—Finite element method (FEM) simulations are analyzed for high voltage equipment featuring resistive field grading. In such simulations, the order of the used mesh and the polynomial order of the ansatz functions is varied. The resulting effects on the accuracy and the simulation time is developed. Simulation results of a simplified benchmark geometry and applications to large scale 3D high voltage equipment are presented herein.

I. RESISTIVE FIELD GRADING MATERIAL MODELING

Resistive field grading materials, such as provided with SiC or ZnO microvaristor polymer compounds, have a modifiable effect on the electric field both in and close to them [1]. First applications with ZnO μ -varistors can be found in [2], on the simulation of nonlinear stress grading materials in [3] and [4]. The effect of higher order elements on the accuracy of mechanical stress simulations is discussed in [5] and for electrostatic simulations in [6]. In this paper, it is enhanced for nonlinear electro-quasistatic simulations.

The electric field in the computational domain Ω is assumed to be electro-quasistatic [7]. From Maxwell's equations, the partial differential equation for the scalar electric potential φ can be derived which reads

$$\operatorname{div}(\kappa(\operatorname{grad} \varphi) \operatorname{grad} \varphi) + \partial_t \operatorname{div}(\varepsilon \operatorname{grad} \varphi) = 0. \quad (1)$$

It considers capacitive (ε) and field-dependant i.e. nonlinear resistive ($\kappa(\operatorname{grad} \varphi)$) effects. Equation (1) is discretized in time via a higher order implicit Runge-Kutta scheme and in space with the help of a strongly modified Whitney-FEM C++ library [8].

II. BENCHMARK PROBLEM

A simplified geometry setup described in [6] is employed. It is a eighth of a sphere capacitor. The mesh with first geometric order elements is plotted in Fig. 1 and contains 1 400 tetrahedra. Simulations for first and second order polynomial ansatz functions are performed for geometric elements of first and second order, respectively. A nonlinear resistive material is used in such a way that there is a known analytic solution for a static electric flow field simulation. The difference between elements of first and second geometric order is shown in Fig. 2.

This work is supported by the "Arbeitsgemeinschaft industrieller Forschungsvereinigungen e.V." (AiF) under Grant 15455 N/2.

Fig. 1. Mesh with first order tetrahedra of the CAD model of the eighth sphere capacitor. It has an inner radius of 0.1 m and an outer radius of 1.0 m.

Fig. 2. Spatial discretization of the boundary surface of a eighth sphere capacitor. Quadratic triangulars on the right with curved edges allow for better geometry approximation than linear triangles on the left hand side.

Fig. 3. Scalar potential φ of first and second order element mesh simulations and analytic solution for the sphere capacitor benchmark.

In Fig. 3, the simulation results using nonlinear resistive material behavior are plotted against the radial distance for second order ansatz functions. In the zoomed view it can clearly be seen that the solution of the second order element mesh agrees with the known analytic solution, but the solution of the first order element mesh is off.

Relative errors of the scalar potential are presented in Fig. 4 and Fig. 5 using geometric elements of both first and second order. In Fig. 4, first order ansatz functions are used for the simulations whereas second order ansatz functions are used for the simulations shown in Fig. 5. The results show that the geometric element order should not be greater than the polynomial order of the ansatz functions in order to improve the accuracy using a higher order mesh.

Fig. 4. Relative error of the scalar potential for the sphere capacitor benchmark with first order ansatz functions. The errors of simulations using geometric elements of first and second order are shown.

Fig. 5. Relative error of second polynomial order with first and second order element mesh for the sphere capacitor benchmark.

The computational times for running electro-quasistatic simulations are compared in Table I. They confirm the results of the static electric flow simulation. For ansatz functions of first and second order (poly. order), the number of degrees of freedom (DoF), of linear systems (lin.sys.) and the computational times (solver time) are listed for the same mesh with first and second order elements (geom. order). Since the results with same order of geometric elements and ansatz functions are less error-prone, less Newton-iterations have to be performed and thus less linear systems have to be solved. This results in less simulation time.

III. LARGE SCALE 3D HIGH VOLTAGE EQUIPMENT

The effects of the use of higher order elements are shown in the benchmark problem. This is applied to realistic large scale

TABLE I
EFFICIENCY OF TRANSIENT SIMULATIONS FOR THE SPHERE BENCHMARK.

3-D Calculation of Surface Electric Field around Conductor of UHVAC Transmission Lines

Dongping XIAO, Wei HE, Mingyou CHEN, Fan YANG

State Key Laboratory of Power Transmission Equipment & System Security and New Technology (Chongqing University), Chongqing 400030, China
xiaodongping@cqu.edu.cn

Abstract—A 3-dimension model and a improved computational technique are proposed for calculating the surface electric field generated by the sagged conductors of UHVAC transmission lines, by taking advantage of the fact that the equation of the catenary exactly describes the line sag. This method is suitable for analyzing the effects of various factors on the surface electric field around bundle conductors, including the span, conductor type and meteorological condition, which have not been mentioned by available literatures. The results of a sample calculation for 1000kV compact transmission lines are given for variation in line parameters. It is hoped that the work will be useful to the transmission line engineer.

I. INTRODUCTION

With the ever-increasing need to electrical energy in China, ultra-high voltage alternating current (UHVAC) transmission lines are being constructed, and more projects are in programming. Advancing voltage degree induces the increase of surface electric field around conductor, and thereby corona disadvantages enhance [1].

When the conductor surface electric field exceeds the corona onset electric field, a partial breakdown ensues in the surrounding air near the conductor surface and it is called corona discharge [2]. Electric field at the surface of conductor and its adjacent is the direct factor resulting discharge activity. A crucial task of transmission line engineer is to select the optimum conductor size and bundle conductors' configuration to yield as low a surface potential gradient and electric field as possible.

In the case of field distribution around conductor in three phase AC transmission lines, analytical or numerical computations have been handled as 2-D model in which conductor is regarded as infinitely long and straight cylindrical electrode [1],[3]-[4]. The simple model neglects sag of overhead lines and induces some error, especially for UHV transmission lines. In order to obtain more accurate results, a 3-D model based on charge simulation method (CSM) is proposed in this paper. Then the field distribution around the surface of any subconductor in a bundle can be calculated accurately. The model is mainly optimized from the following improved aspects:

- 1) Considering the sag of overhead transmission lines and calculating the 3-D electric field;
- 2) Adopting adaptive optimization algorithm to determinate the location of simulation charges in subconductor.

II. METHODOLOGY OF CALCULATION

A. Overhead transmission line Equation

The conductor suspended between two towers of equal height can be described by equation of overhead catenary [5]:

$$z = \frac{\sigma_0}{g} \left(\cosh \frac{gx}{\sigma_0} - \cosh \frac{gL}{2\sigma_0} \right) + H \quad (1)$$

where L and H are the distance and the height of the points of suspension, g and σ_0 are the load and horizontal stress of conductor.

It is worth mentioning that most are: g and σ_0 are changing with altitude, temperature, velocity of wind, thickness of ice-coating, etc. Even for identical configuration of the transmission lines in different geographic environment and meteorological condition, there are different sags which will affect the electric field surrounding bundle conductor. The problem has not been discussed in available literatures.

B. Surface Electric Field Calculation

For the UHVAC conductors, the potential coefficient p , the potential ϕ and the electric field E can be defined as follows:

$$[\phi] = [P][\tau] \quad (2)$$

$$p_{ij} = \frac{1}{4\pi\epsilon_0} \int_{l_i} \left(\frac{1}{r_{ij}} - \frac{1}{r'_{ij}} \right) dl_i \quad (3)$$

$$\vec{E} = \sum_i -\nabla \phi_i \quad (4)$$

where τ is the simulating line charge density which can be calculated based on CSM. r_{ij} and r'_{ij} are the distance from the line charge i and its image to the j th field point, respectively. They are the function of coordinate x , y and z .

Currently available equations for p_{ij} are difficult to use directly in 3-D model, and require both a fundamental knowledge of electromagnetics and computer aided drawing skills.

In order to obtain accurate results, as well as to consider compute time-consuming, the following need to be accounted:

- 1) the amount and position of the simulating charges in the bundle conductors;
- 2) the numerical integral arithmetic of (3) combining with (1).

C. Adaptive Optimization Algorithm for Simulating Charges

It is logical to assume that one simulating line charge in each subconductor, and it is initially located in the center of

the subconductor. The optimization position, representing with the parameter d , is at somewhere among the connection direction of the equivalent phase center and subconductor center as indicated in Fig.1. It can be determined by adaptive optimization algorithm to satisfy the boundary condition [6]. The computational error for the potential of checking points can less than 0.1%, or even lesser.

Fig.1 Configuration of simulating charge, matching and checking points for one phase line

D. Numerical Integral

Combining (1) with (3), the potential coefficient p_{ij} is merely the function coordinate x :

$$p_{ij} = \frac{1}{4\pi\epsilon_0} \sum_{k=-K}^{k=K} \int_{(k-\frac{1}{2})L}^{(k+\frac{1}{2})L} \left(\frac{1}{\rho_{ij}} - \frac{1}{\rho_{ij}'} \right) \cosh \frac{a(x_i - kL)}{L} dx_i \quad (5)$$

$$= \frac{1}{4\pi\epsilon_0} \sum_{k=-K}^{k=K} \int_{(k-\frac{1}{2})L}^{(k+\frac{1}{2})L} f(x_i) dx_i$$

where L is the length of span and K is the numeral of spans.

The integral interval is divided into elementary segments, then equation (5) can be calculated by the compound Simpson integration. The intervals are properly partitioned to improve analysis precision and recede time-consuming:

$$\int_{k-\frac{1}{2}L}^{k+\frac{1}{2}L} f(x_i) dx_i = \frac{h}{3} \left[f\left(k-\frac{L}{2}\right) + f\left(k+\frac{L}{2}\right) + 2 \sum_{n=1}^{m-1} f(x_{i2n}) + 4 \sum_{n=0}^{m-1} f(x_{i(2n+1)}) \right]$$

where h is the step size of discretization.

III. RESULTS AND CONCLUSION

The present 3-D model and improved computational technique can be used to calculate the surface electric field of any bundle conductor.

Fig.2 is an example of outputs for 1000kV (line-line) compact transmission lines operating in good weather. The bundled conductors of phase A is showed as Fig.1. GJ-500/45 with 30mm in diameter is adopted and the span length is 400m.

Fig.2 E distribution curves of bundle conductors of phase A

The curve of electric field distribution along the circumference of a subconductor is similar to sinusoid. The maximum electric field E_{\max} is located on the external surface of subconductor, as for the connection of the phase and the subconductor centers. And the minimum is located on the internal surface.

There are numerous factors that influence the surface electric field distribution. Energized line voltage, tower configuration, the number of conductors per bundle, bundle spacing and phase spacing has been discussed by literatures. However, the previous methods are invalid to be used to analyze the effects of different electric field distribution along conductors, the influence of span, different types of conductors and meteorological condition upon the surface electric field. The proposed 3-D model can solve the problem.

1) The overhead conductor suspended equal height is symmetrical with respect to the center of a span. Hence, E_{\max} varying along a subconductor is also symmetrical with respect to the center of a span. A 15m sag corresponds to about 5% increase or decrease in surface electric field. The center phase and outer phase conductors have inverse change characteristic.

2) The fields around the surface of subconductors increase as the span length increases. The calculations show when the span length extends from 400m to 450m the E_{\max} should increase approximately 6.5% for the center phase conductors and 8.1% for the outer phase conductors. The center phase is more affected by the changes in span length. Span length is an important factor in surface electric field.

3) If bundle conductors are replaced by 8×LGJ-500/45 (with 34.32mm in diameter) or 8×ACSR-720/50 (with 36.2mm in diameter), the fields on the surface of subconductors decrease beyond 20%. As such, conductor sector is recognized as a most significant factor in surface electric field.

4) The effect of air temperature upon the surface electric field is more distinct than other meteoric factors, such as velocity of wind, thickness of ice-coating, etc. The increase in air temperature reduces the surface electric field on outer phase conductors but increases it on center phase conductors for compact transmission lines.

Analytical Prediction of Eddy-Current Loss in Armature Windings of Permanent Magnet Brushless AC Machines

Y. Amara, P. Reghem and G. Barakat

Groupe de Recherche en Electrotechnique et Automatisme du Havre - EA 3220, Department of Electronic and Electrical Engineering, University of Le Havre
25 rue Philippe Lebon - B.P. 1123 - 76063 Le Havre cedex, France

Abstract — This paper presents an analytical model for prediction of eddy current loss in armature windings of permanent magnet brushless AC machines. The developed model can either be used in the case of internal or external rotor radial-field machines topologies. First, a 2D exact analytical solution of armature reaction magnetic field distribution in a actual geometry of slotted surface mounted PM radial flux synchronous machines is established. It involves solution of Maxwell's equations in slots, airgap and PM's region. Then, magnetic vector potential solution in the slots is used for prediction of resistance limited eddy current in armature windings. Finally, results from this analytical model are compared to corresponding finite element analyses. This analytical model is then used to estimate eddy current loss in armature windings.

I. INTRODUCTION

This paper attempts to provide analytical tools to facilitate the analysis and design of a class of radial flux PM synchronous machines (fig. 1). The developed model gives exact magnetic field distribution due to armature reaction in the slots (radial slots) [1]. The developed model embraces both internal and external rotor topologies (fig. 1). The permanent magnet supporting armature can either be made of magnetic or non-magnetic material. The slotted stator has a classical configuration with radial teeth. The slots and teeth can be equally distributed or not [2], [3]. They can be arranged to accommodate any winding configuration (overlapping and non overlapping windings).

The developed model is then used to estimate resistance limited eddy current in armature windings and corresponding loss. It is also used to quantify the effect of segmenting armature windings conductors as means of reducing the loss. The validity of the developed model is verified by time-stepped transient finite element analysis.

II. ARMATURE REACTION FIELD ANALYTICAL SOLUTION

In order to establish the exact analytical solution, two concentric regions are considered (Fig. 2) (slots (I), airgap, permanent magnets and region under magnets (II)) Region under magnets is only considered in case of a non-magnetic permanent magnets supporting armature. Permeability of all ferromagnetic parts is assumed to be infinite. The permeability of permanent magnets is assumed to be equal to that of air. The governing field equations, in terms of the Coulomb gauge, $\nabla \times \mathbf{A} = 0$, are:

$$\begin{cases} \nabla^2 \mathbf{A} = -\mu_0 \mathbf{J} & \text{in region I} \\ \nabla^2 \mathbf{A} = 0 & \text{in region II} \end{cases} \quad (1)$$

\mathbf{A} (the magnetic vector potential) only has A_z component which is independent of z (infinitely long machine in axial direction). \mathbf{J} is the current density vector.

Fig. 1. Radial-field PM machines topologies: internal rotor (a) and external rotor (b).

Fig. 2. Polar coordinates system.

Combining equations (1) with boundary conditions, and using separation of variables method, help establish a set of linear equations ($N_H \times N_H$) (where N_H is the number of considered harmonics), where coefficients of magnetic vector potential solution in region II are the unknown. Solving these linear equations and using interface conditions give coefficients of magnetic vector potential in the slots. Obtained linear system is solved using Gaussian elimination method. The developed model takes into account rotor movement.

The general solution of equation (2), in a slot 'i', can be written as follows:

$$A^{(i)} = \left[a_0^{(i)} + \sum_{m=1}^{+\infty} \left[F_m^{(i)} \left(\left(\frac{r}{R_1} \right)^{\left(\frac{m\pi}{w} \right)} + \left(\frac{r}{R_1} \right)^{-\left(\frac{m\pi}{w} \right)} \right) \cos \left(\frac{m\pi}{w} (\varphi - \varphi_i) \right) \right] \right. \\ \left. + \frac{\mu_0}{2} J^{(i)} \left(R_1^2 \ln(r) - \frac{r^2}{2} \right) \right] \quad (2)$$

where $J^{(i)}$ is the current density of slot 'i'.

III. ANALYTICAL PREDICTION OF EDDY CURRENT

The time dependence of magnetic vector potential solution in a slot ‘ i ’ is proportional to the time dependence of current density in this slot. If the current density is sinusoidal, the time harmonic content of induced eddy current will be limited to the fundamental component. Since armature windings conductors are always designed to have dimensions smaller than the skin depth, the induced eddy current density can be obtained from the following:

$$J_e(r, \varphi, t) = -\sigma \cdot \frac{\partial A^{(i)}(r, \varphi, t)}{\partial t} + C(t) \quad (3)$$

$$C(t) = C_0(t) + \sum_{m=1}^{+\infty} C_m(t) \quad (4)$$

where σ is the electric conductivity of the windings material (copper). $C(t)$ is a function of time which is introduced to insure that the total current flowing in each conductor is equal to the source current.

IV. COMPARISON WITH FINITE ELEMENT ANALYSIS

Table I presents the machine’s parameters used for the exposed results in this digest. A time-stepped transient finite element analysis was made to calculate the eddy current distribution in the armature windings for frequencies ensuring that the conductor dimensions are smaller than the skin depth. Figure 3 shows eddy current density distribution along the radial direction collinear with a slot axis at a given instant. Figure 4 compares the analytically predicted variation of J_e with time and the corresponding finite element results at a point situated in the middle of a conductor. It can be seen that, in both cases, the analytical predictions agree very well with the finite element simulations. Figure 5 shows a slot conductor eddy current loss calculated by finite element simulation on one hand, and on the other hand, the corresponding limited resistance eddy current loss predicted by the developed analytical model. It should be noticed that the eddy current loss at 35 Hz is about 8% of Joules losses due to source current. This comparison clearly shows the accuracy of the developed analytical model and validates by the way its effectiveness in the adequate frequency domain.

In the final paper, a study of the effect of segmenting armature windings conductors as means of reducing the loss will be presented and discussed.

V. CONCLUSION

This paper presents a general analytical solution of the armature reaction magnetic filed distribution in an actual geometry of radial flux permanent magnet brushless AC machines. The developed analytical solution of magnetic vector potential in the slots is used to predict the resistance limited eddy current losses in the armature windings.

TABLE I – MACHINE’S PARAMETERS

Pole number	6
Slot number	18
Number of slots per pole per phase	1
Number of turns	2
R_0, R_1, R_2 and R_3 (mm)	50, 58, 60 and 84
w (rad)	$\pi / 18$

Fig. 3. Current density along a radius aligned with a slot axis.

Fig. 4. Current density versus time at a point in the middle of a slot.

Fig. 5. Eddy current loss in a slot conductor versus frequency.

The obtained results have been validated by a time-stepped transient finite element analysis.

Developed model capabilities will be more deeply presented in the full paper and, in particular, the segmenting armature windings conductors effect on the loss reduction.

Abstract— The dual formulations of finite element method (FEM) and the finite integral technique (FIT) using dual meshes for eddy current problems are studied. Based on the algebraic discretization of Maxwell equations on dual meshes, two sets of dual formulations are derived. A rational comparison between these formulations is performed. The complementary energy bounds are illustrated through an example.

I. INTRODUCTION

The dual finite element formulations are traditionally obtained from the variational method in solving, respectively, one of the governing equations (e.g. Faraday's law and the Ampere's theorem) in strong sense and the other in weak sense. Advances in computational electromagnetics show the interests of differential forms and working with the global variables. The magnetic field computation is more suitably studied in the framework of discrete geometry, algebra and networks. By associating the field quantities with the edges and facets of the primal and dual meshes, the matrix equation systems can be derived pure algebraically from the differential equations. Such a procedure has the advantages of showing the algebraic and topology properties of the field computation methods [1][2], and their analogy to the circuit analysis.

The difference and the similarity of the two frequently used methods, the finite element method (FEM) and the finite integral technique (FIT), are also clearly drawn in the framework of discrete geometry. They differ only by the Hodge discretization. We have hence a better understanding of the material matrices resulted from the edge elements and facets elements. They have in fact a tight relation to the circuit elements on the dual circuit networks.

The complementarity of dual formulations of FEM and FIT on dual meshes has been studied in a previous work [3], where the study focuses essentially the cases of static fields. The present work extends the study to the case of eddy current problems. We will show that the dual formulations can be established on the dual sets of the meshes; and illustrate that the complementary energy bounds exist for both set of dual formulations and they are due to the geometry discretization.

II. DUAL FORMULATIONS OF EDDY CURRENT PROBLEMS

Let \mathcal{M}_p and \mathcal{M}_D are the two interlocked (primal and dual) meshes on the solution domain of the field problem. Let us denote by \overline{W}_p^p ($p=0, 1, 2, 3$) the spaces of DoFs on nodes, edges, facets and volumes of \mathcal{M}_p ; and \overline{W}_D^p ($p=0, 1, 2, 3$), the spaces of DoF on nodes, edges, facets and volumes of \mathcal{M}_D . The

incident mappings between \overline{W}_p^{p-1} and \overline{W}_p^p are expressed by the incident matrices G , C and D ; and the mappings between \overline{W}_D^{p-1} and \overline{W}_D^p are their transposes D^T , C^T and G^T .

By working with global variables, and replacing the differential operators by incident mappings, the governing equations of the eddy current problems can be written in algebraic forms. According to the assignment of the Faraday's law and the Ampere's theorem on the primal or dual sequences of the dual meshes, we can get two sets of equations:

$$\begin{aligned} C \bar{e}_p &= -d_t \bar{b}_p, & C^T \bar{h}_d &= \bar{j}_d, \\ \bar{h}_d &= M_{1/\mu} \bar{b}_p, & \bar{j}_d &= M_\epsilon \bar{e}_p \end{aligned} \quad (1)$$

and

$$\begin{aligned} C^T \bar{e}_d &= -d_t \bar{b}_d, & C \bar{h}_p &= \bar{j}_p, \\ \bar{b}_d &= M_\mu \bar{h}_p, & \bar{e}_d &= M_{1/\sigma} \bar{j}_p \end{aligned} \quad (2)$$

where $\bar{e}_p, \bar{h}_p \in \overline{W}_p^1$; $\bar{b}_p, \bar{j}_p \in \overline{W}_p^2$ and $\bar{h}_d, \bar{e}_d \in \overline{W}_D^1$; $\bar{j}_d, \bar{b}_d \in \overline{W}_D^2$. They are respectively, the circulations of electric or magnetic field along the edges of the primal or dual meshes and the magnetic flux or electric current across the facets of the primal or dual mesh. The matrices $M_{1/\mu}$, M_σ and M_μ , $M_{1/\sigma}$ are the metric dependent material matrices corresponding to the Hodge discretization of the constitutive laws.

The field variables can be represented by the combined vector-scalar potential pairs. Their discrete relations on the primal mesh are:

$$\bar{e}_p = -d(\bar{a}_p + G \bar{\psi}_p)/dt \quad \text{and} \quad \bar{h}_p = \bar{t}_p + G \bar{\phi}_p$$

where $\bar{\psi}_p, \bar{\phi}_p \in \overline{W}_p^2$ and $\bar{a}_p, \bar{t}_p \in \overline{W}_p^1$. They are, respectively, nodal values of the primitive in time of the electric scalar potential and of the magnetic scalar potential, circulation along edges of the magnetic vector potential and of the current vector potential. Replacing \bar{e}_p of (1) and \bar{h}_p of (2) by their respective potential pairs, and eliminating the variables on the dual mesh, we get two dual matrix equation systems:

$$\begin{aligned} C^T M_{1/\mu} C \bar{a}_p + \frac{d}{dt} M_\sigma \bar{a}_p + \frac{d}{dt} M_\sigma G \bar{\psi}_p &= \bar{j}_{0d} \\ \frac{d}{dt} G^T M_\sigma \bar{a}_p + \frac{d}{dt} G^T M_\sigma G \bar{\psi}_p &= 0 \end{aligned} \quad (3)$$

where \bar{j}_{0d} represents the current excitation. And

$$C^T M_{1/\sigma} C \bar{t}_p + \frac{d}{dt} M_\mu \bar{t}_p + \frac{d}{dt} M_\mu G \bar{\phi}_p = -\frac{d}{dt} M_\mu \bar{t}_{0p}$$

$$\frac{d}{dt}G^T M_\mu \bar{t}_p + \frac{d}{dt}G^T M_\mu G \bar{\phi}_p = -\frac{d}{dt}G^T M_\mu \bar{t}_{0p} \quad (4)$$

where \bar{t}_{0p} is the circulation of the current vector potential on the edges of the primal mesh.

Algebraically, the two well known methods FEM and FIT lead to the same form of dual matrix equations as (3) and (4). They differ only on the Hodge discretization, i.e. the obtaining of the material matrices. In the context of FEM, the matrices M_σ , $M_{1/\mu}$ and M_μ , $M_{1/\sigma}$ are calculated with the Galerkin approach by using, respectively, Whitney edge and facet elements on the primal mesh. Whereas in the case of FIT, the elements of material matrices are calculated algebraically by taking the ratio of the mean edge DoF and average of facet DoF of the primal-dual mesh doublets [2]. No shape function is required. In the particular case of an orthogonal mesh, the matrices M_σ , $M_{1/\mu}$ and M_μ , $M_{1/\sigma}$ are diagonal.

Making the analogy to the circuit network, M_σ (resp. M_μ) and $M_{1/\mu}$ (resp. $M_{1/\sigma}$) correspond to the conductance (resp. permeance) network on the primal mesh and the reluctance (resp. resistance) network on the dual mesh. This analogy is clearly observed in the FIT because the elements of the material matrices are nothing else but the circuit elements on the branches of the primal and dual circuit networks.

III. DUAL SET OF DUAL EDDY CURRENT FORMULATIONS

The dual formulations (3) and (4) are derived by working, respectively, with the electric field and magnetic field on the edges of the primal mesh. However, nothing prohibits us from working with the field variables on the edges of dual meshes. Let us use again the potential variables by writing

$$\bar{e}_d = -d(\bar{a}_d + D^T \psi_d)/dt \quad \text{and} \quad \bar{h}_d = \bar{t}_d + D^T \bar{\phi}_d$$

on the dual meshes, with $\bar{\psi}_d$, $\bar{\phi}_d \in \bar{W}_D^2$, \bar{a}_d , $\bar{t}_d \in \bar{W}_D^1$. By introducing the above potential pairs in (1) and (2) respectively, we obtain a new set of dual formulations:

$$C \tilde{M}_{1/\mu} C^T \bar{a}_d + \frac{d}{dt} \tilde{M}_\sigma \bar{a}_d + \frac{d}{dt} \tilde{M}_\sigma D^T \bar{\psi}_d = \bar{j}_{0p}$$

$$\frac{d}{dt} D \tilde{M}_\sigma \bar{a}_d + \frac{d}{dt} D \tilde{M}_\sigma D^T \bar{\psi}_d = 0 \quad (5)$$

and

$$C \tilde{M}_{1/\sigma} C^T \bar{t}_d + \frac{d}{dt} \tilde{M}_\mu \bar{t}_d + \frac{d}{dt} \tilde{M}_\mu G \bar{\phi}_d = -\frac{d}{dt} \tilde{M}_\mu \bar{t}_{0d}$$

$$\frac{d}{dt} D \tilde{M}_\mu \bar{t}_d + \frac{d}{dt} D \tilde{M}_\mu D^T \bar{\phi}_d = -\frac{d}{dt} D \tilde{M}_\mu \bar{t}_{0d} \quad (6)$$

Note that the material matrices in (5) and (6) are nothing else but the inverses of which in (4) and (3). In the context of FEM, the matrices cannot be derived because of the lack of interpolation basis functions on the dual mesh. On the contrary, in the case of FIT, the task becomes feasible since no shape function is needed to derive the matrices. In fact, in case of orthogonal mesh, the matrices are easily computed by just inverting diagonal terms.

Comparing (6) to (3), we solve in reality the same type of

equations from the circuit network point of view, even though we use different working variables. In fact, in (3), we solve the conductance network on \mathcal{M}_p and the reluctance network on \mathcal{M}_D . While in (6), we have the resistance network on \mathcal{M}_p and the permeance network on \mathcal{M}_D . They are just the inverse of the one from each other. To the equations (4) and (5), we have the similar observations.

IV. COMPLEMENTARY ENERGY BOUNDS

The theoretical prove of the energy bounds for eddy current problem is difficult because the no-conservative nature of the problem. There were in depth discussions about this subject (refs will be provided in full paper). It was observed that the complementary energy bounds of dual FEM formulations do exist numerically and pointed out that they could be due to the numerical discretization [4].

From the similarity between FEM and FIT, we expect that the complementary energy bounds exists as well for the dual FIT formulations. To illustrate this, we solved an eddy current problem which consists of a cross form of conductor place in a uniform time harmonic magnetic field. Fig. 1 shows the joule losses convergence with respect to the mesh finesses inside of conductor, obtained respectively, by the FEM and FIT. The energy bounds are clearly observed. Since FIT is purely based on the algebraic discretization. The study supports the idea that the complementary energy bounds are due to the numerical discretization.

In addition, if we look at the dual set of dual formulations (5) and (6), since (6) (resp.(5)) solves the same networks as (3) (resp.(4)). We expect (6) and (5) provides the same energy bounds as (3) and (4). Even tough the two set of equations work with opposite working variables.

Abstract — A new program solution is presented to analyze the transient performance of grounding systems. In contrast to recently known numerical procedure based on the finite element method (FEM) in frequency domain, in this new methodology for the first time the differential equations of the electromagnetic field have been solved using the FEM directly in time domain. The results of calculations have been verified by comparison with the results of measurements found in the literature.

I. INTRODUCTION

The primary goal of grounding systems is to ensure the safety of personnel and prevent damage of installations while their secondary goal is to provide common reference voltage for all interconnected electrical and electronic systems. To optimize the design of grounding systems, as well as to minimize the disturbance level in the protected area, the program tool able to simulate the transient performance of grounding systems is fundamental. For that very reason, the goal of this work was to develop the methodology (the proper numerical model) which allows a complete three-dimensional (3-D) electromagnetic study of grounding systems by using the finite element method (FEM).

So far, three basic concepts have been used to simulate the transient performance of grounding arrangements: the circuit approach [1], the transmission line approach [2], and the electromagnetic field approach [3]. In this paper, the solution to analyze the transient behavior of grounding system is based on the electromagnetic field theory and on the implementation of the FEM. The validity of the suggested method of analysis has been verified by the comparison of obtained results with the results found in [4].

II. NUMERICAL MODEL OF TRANSIENT ELECTROMAGNETIC FIELD BASED ON FEM

A. Mathematical Background

The governing partial differential equation for transient problems can be derived from Maxwell's equations. In terms of the magnetic vector potential \mathbf{A} and the electric scalar potential φ , it can be formulated as:

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{A} - \nabla \frac{1}{\mu} \nabla \cdot \mathbf{A} + \sigma \frac{\partial \mathbf{A}}{\partial t} + \sigma \nabla \varphi = 0, \quad (1)$$

where μ is the permeability and σ the electrical conductivity.

By applying the finite-elements procedure, the soil and the air domain of the problem are discretized by the prismatic elements of the first order and the conductors of the grounding system are discretized by the line elements of the first order.

Thereby, the unknowns \mathbf{A} and φ in arbitrary point within the prismatic and line finite elements are approximated between the computed values of the corresponding potentials in the finite element's nodes (A_{xi} , A_{yi} , A_{zi} , and φ_i) in terms of interpolation functions (polynomials) N_i respectively as:

$$\mathbf{A} = \sum_{i=1}^6 (\bar{1}_x A_{xi} N_i + \bar{1}_y A_{yi} N_i + \bar{1}_z A_{zi} N_i), \quad \varphi = \sum_{i=1}^6 \varphi_i N_i, \quad (2)$$

$$\dot{\mathbf{A}} = \sum_{i=1}^2 (\bar{1}_x \dot{A}_{xi} N_i + \bar{1}_y \dot{A}_{yi} N_i + \bar{1}_z \dot{A}_{zi} N_i), \quad \dot{\varphi} = \sum_{i=1}^2 \dot{\varphi}_i N_i. \quad (3)$$

To obtain the symmetry of the finite element's matrix (as it will be shown in the full paper), the special modified electric scalar potential V is introduced as:

$$\varphi = \frac{\partial V}{\partial t} = \dot{V}. \quad (4)$$

Regarding (4), the application of the FEM and the Galerkin's formulation of the weighted residual method to (1) result in the following matrix equation:

$$[\mathbf{K}] \{\mathbf{A}, V\} + [\mathbf{C}] \{\dot{\mathbf{A}}, \dot{V}\} = \{\mathbf{R}\} \quad (5)$$

where $\{\mathbf{A}, V\}$ is the column vector of the unknown nodal potentials; $\{\dot{\mathbf{A}}, \dot{V}\}$ is the column vector of the time derivatives of $\{\mathbf{A}, V\}$; $[\mathbf{K}]$ is the stiffness matrix which is associated with the potentials \mathbf{A} and V , and the Laplacian operator Δ ; $[\mathbf{C}]$ is the damping matrix which represents the contribution of the induced current term $\sigma \partial \mathbf{A} / \partial t$ to the system; whereas $\{\mathbf{R}\}$ is the forcing function column vector.

For the time integration, the Euler's method is used in which the derivative of the potential is substituted by the difference of the potentials, as follows:

$$\dot{\mathbf{A}}^{(n)} = \frac{\mathbf{A}^{(n)} - \mathbf{A}^{(n-1)}}{\Delta t}, \quad (6)$$

$$\dot{V}^{(n)} = \frac{V^{(n)} - V^{(n-1)}}{\Delta t} = \varphi^{(n)}. \quad (7)$$

If we introduce (6) and (7) into (5), the following expression for the calculation of the potential in the new time step (n), depending on the preceding time step ($n-1$), is obtained:

$$\left[\mathbf{K} + \frac{\mathbf{C}}{\Delta t} \right] \{\mathbf{A}^{(n)}, V^{(n)}\} = \{\mathbf{R}^{(n)}\} + \left[\frac{\mathbf{C}}{\Delta t} \right] \{\mathbf{A}^{(n-1)}, V^{(n-1)}\}. \quad (8)$$

Finally, the obtained set of linear algebraic equations is solved by the algebraic multi-grid (AMG) method [5].

B. Implementation of the Numerical Model

The developed program for the 3-D calculation of transient electromagnetic field, which has been written in Fortran, consists of three modules: the pre-processor, the processor,

and the post-processor. In the pre-processor, where first of all the 3-D mesh of the prismatic and line finite elements of the first order is built by the automatic mesh generator [6], also the geometrical and physical input data, as well as the forcing (injected) potential function, are defined. In the processor, the transient calculation is carried out, as shown in Fig. 1.

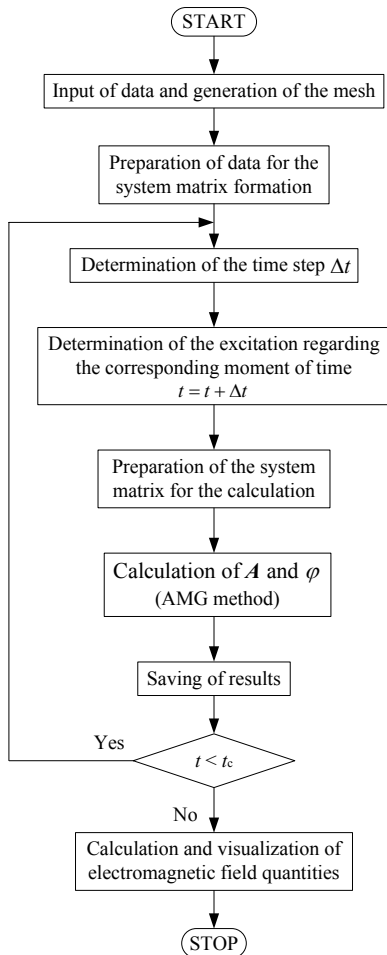

Fig. 1. Flow chart of the electromagnetic transient calculation

Finally, the post-processor allows interactive calculation and visualization of any desired quantity of electromagnetic field (e.g., current I , electric field intensity E , magnetic flux density B , etc.).

III. APPLICATION AND DISCUSSION

Following up Geri's research work [4], concerning the development of the mathematical model based on a circuit approach, in this paper, the program solution (the numerical model based on the FEM) is presented to analyze the transient behavior of the grounding rod when fed by an injected time variable potential function. The steel grounding rod with the length of 6 m, the diameter of 20 mm, and the conductivity of $5,88 \times 10^6$ S/m is buried vertically into the uniform soil with the resistivity of $40 \Omega\cdot\text{m}$, as shown in Fig. 2, where also the defined boundary conditions on the outer planes of the problem are presented.

Fig. 2. Schematic view of the vertical grounding rod under analysis

In order to verify the reliability of the program solution, in Fig. 3, the comparison of the current variation, obtained as a response to the shape of the injected potential function, with the current variation from [4] is presented.

Fig. 3. The transient voltage and currents of the grounding rod

A detailed description of the actual implementation of the model will be given in the full paper where also the application of the model to horizontal grounding wire will be presented.

A New Formulation Using Differential Permeability Based on the Source-Field Method

N.Sadowski, J.P.A. Bastos and J.V. Leite

Abstract — The source-field method is a very effective way to treat 3D magnetostatic and magnetodynamic cases for linear and non-linear studies. In this work, we propose a variation of this method based on the concept of differential permeability. With this new approach, it is possible to handle non-linear cases and also more complex hysteretic materials. The electric circuit is coupled with the magnetic structure and a time stepping technique is used.

I. INTRODUCTION

We have been intensively working with the “source-field” method for solving static and dynamic cases. This formulation is very effective and robust [1][2]. Additionally, we have good experience with the concept of differential permeability. We performed some implementations of this latter but it was applied to the magnetic vector potential [3][4]. According our experience, the hysteresis phenomenon can be adequately solved by a differential permeability approach. Non-linear cases (non-hysteretic) can be also treated with such an approach, with fast convergence. Therefore, in this paper we propose the use of this concept in conjunction with the source-field method. Some preliminary and encouraging results are already presented here.

II. THE SOURCE-FIELD METHOD

Let us recall the basic principles of the source-field method. With this formulation, the magnetic field \mathbf{H} can be divided in two parts, as:

$$\mathbf{H} = \mathbf{H}_s - \text{grad}\Omega \quad (1)$$

where \mathbf{H}_s is the field created solely by the imposed currents of the exciting coils and Ω is the reduced scalar magnetic potential. This potential is related to the field produced by magnet dipoles, induced of permanent. We define now the relationship between the imposed current density \mathbf{J} and the field \mathbf{H}_s : We have $\text{rot}\mathbf{H} = \mathbf{J}$ which can be expressed as

$$\text{rot}(\mathbf{H} - \mathbf{H}_s) = \text{rot}\mathbf{H} - \text{rot}\mathbf{H}_s = 0$$

and we have

$$\mathbf{J} = \text{rot}\mathbf{H}_s \quad (2)$$

Therefore, the “influence” of \mathbf{J} is replaced by the magnetic field \mathbf{H}_s spread in the calculation domain. To do so, \mathbf{H}_s is defined through its circulations on the edges of the tetrahedron first order finite elements. Having these circulations, shape functions of edge elements are used to easily define the vector \mathbf{H}_s . Tree and co-tree technique are necessary to properly find the source-field. More detailed text is given in [1][5].

III. USING THE DIFFERENTIAL PERMEABILITY

Using the proposed approach, we have

$$\Delta\mathbf{B} = \mu_d\Delta\mathbf{H} \quad (3)$$

where μ_d is the differential permeability and $\Delta\mathbf{B}$ and $\Delta\mathbf{H}$ are, respectively, the magnetic induction and field variations. For linear materials $\mu = \mu_d$. Using a time stepping discretization we consider that $t+1$ and t are respectively the current calculation step and the previous one. Then

$$\Delta\mathbf{B} = \mathbf{B}^{t+1} - \mathbf{B}^t \quad \text{and} \quad \Delta\mathbf{H} = \mathbf{H}^{t+1} - \mathbf{H}^t$$

With (3)

$$\mathbf{B}^{t+1} - \mathbf{B}^t = \mu_d(\mathbf{H}^{t+1} - \mathbf{H}^t) \quad (4)$$

or

$$\mathbf{B}^{t+1} = \mathbf{B}^t + \mu_d(\mathbf{H}^{t+1} - \mathbf{H}^t) \quad (5)$$

With (1), equation (5) becomes

$$\mathbf{B}^{t+1} = \mathbf{B}^t + \mu_d(\mathbf{H}_s^{t+1} - \text{grad}\Omega^{t+1} - \mathbf{H}_s^t + \text{grad}\Omega^t) \quad (6)$$

where \mathbf{B}^t is known from the previous step. The main equation on this development is

$$\text{div}\mathbf{B}^{t+1} = 0 \quad (7)$$

Applying the Galerkin method on equation (7), we have

$$\int_V N \text{div}\mathbf{B}^{t+1} dv = 0 \quad (8)$$

$$\int_V N \text{div}\mathbf{B}^{t+1} dv = \oint_{s(v)} N \mathbf{B}^{t+1} \cdot d\mathbf{s} - \int_V \text{grad}N \cdot \mathbf{B}^{t+1} dv = 0 \quad (9)$$

where N is the nodal shape function of the finite element. The first term of the right hand side of (9) is related to the classical boundary conditions for scalar potential [4]. The second one will be active to the numerical implementation, and, using (6), it becomes:

$$-\int_V \text{grad}N \cdot [\mathbf{B}^t + \mu_d(\mathbf{H}_s^{t+1} - \mathbf{H}_s^t) + \mu_d(\text{grad}\Omega^t - \text{grad}\Omega^{t+1})] dv = 0 \quad (10)$$

In order to couple the above equation to the feeding electrical circuit we need to define two new quantities \mathbf{K} and \mathbf{N} as follows [1][2]:

$$\mathbf{H}_s = \mathbf{K}I_0 \quad (11)$$

where I_0 is the current flowing in a conductor; \mathbf{K} is, therefore the corresponding source-field for a unitary current. Using the vector \mathbf{N} as:

$$\text{rot}\mathbf{H}_s = \mathbf{N}I_0 \quad (12)$$

we have then $\text{rot}\mathbf{K}I_0 = \mathbf{N}I_0$ and

$$\text{rot } \mathbf{K} = \mathbf{N} \quad (13)$$

Now we consider the electric circuit equation coupled to the magnetic structure.

$$V_m = R_m i_m + \frac{d\Phi_m}{dt} \quad (14)$$

where V_m , R_m , i_m and Φ_m are, respectively, the voltage, the resistance, the established current and the magnetic flux linkage in a generic electric circuit m . From [1], it can be shown that the magnetic flux can be expressed by:

$$\Phi^{t+1} = \int_{V_b} \mathbf{B}^{t+1} \cdot \mathbf{K} dv \quad (15)$$

and for the time step $t+1$ we have:

$$V_m^{t+1} = R_m i_m^{t+1} + \frac{d}{dt} \int_{V_b} \mathbf{B}^{t+1} \cdot \mathbf{K} dv \quad (16)$$

With the derivative time discretization, it gives:

$$\begin{aligned} \Delta t V_m^{t+1} &= \Delta t R_m i_m^{t+1} + \int_{V_b} \Delta \mathbf{B}^{t+1} \cdot \mathbf{K} dv \\ \Delta t V_m^{t+1} &= \Delta t R_m i_m^{t+1} + \int_{V_b} (\mathbf{B}^{t+1} - \mathbf{B}^t) \cdot \mathbf{K} dv \end{aligned} \quad (17)$$

Using the equation (6) in (17) we obtain:

$$\begin{aligned} \Delta t V_m^{t+1} &= \Delta t R_m i_m^{t+1} + \int_{V_b} (\mu_d (\mathbf{H}_s^{t+1} - \mathbf{H}_s^t + \\ &+ \text{grad } \Omega^t - \text{grad } \Omega^{t+1})) \cdot \mathbf{K} dv \end{aligned}$$

For alleviating the notations and equations writing, the above equation, considering (11), can be expressed as

$$\begin{aligned} \Delta t V_m^{t+1} &= \Delta t R_m i_m^{t+1} + \\ &+ (K^T M_{\mu_d} K i_m^{t+1} - K^T M_{\mu_d} K i_m^t - \\ &- K^T M_{\mu_d} G \Omega^{t+1} + K^T M_{\mu_d} G \Omega^t) \end{aligned} \quad (18)$$

where the numerical integrations are taken into account.

Here, $\text{grad } \Omega^t$ is written as $G \Omega^t$ and M_{μ_d} stands for μ_d . As

for the equation (10) we have, with the same notations:

$$\begin{aligned} -G^T \mathbf{B}^t - G^T M_{\mu_d} G \Omega^t + G^T M_{\mu_d} G \Omega^{t+1} - \\ -G^T M_{\mu_d} K i_m^{t+1} + G^T M_{\mu_d} K i_m^t = 0 \end{aligned} \quad (19)$$

Arranging equations (18) and (19) in matrix form, the resulting system is:

$$\begin{bmatrix} G^T M_{\mu_d} G & -G^T M_{\mu_d} K \\ -K^T M_{\mu_d} G & \Delta t R_m + (K^T M_{\mu_d} K) \end{bmatrix} \begin{bmatrix} \Omega^{t+1} \\ i_m^{t+1} \end{bmatrix} = \begin{bmatrix} G^T M_{\mu_d} G & -G^T M_{\mu_d} K \\ -K^T M_{\mu_d} G & (K^T M_{\mu_d} K) \end{bmatrix} \begin{bmatrix} \Omega^t \\ i_m^t \end{bmatrix} + \begin{bmatrix} G^T \mathbf{B}^t \\ \Delta t V_m^{t+1} \end{bmatrix} \quad (20)$$

This final system is quite similar to the one obtained for the more classical formulation using directly μ . It means that its implementation is relatively easy, since it is based in another one already known and, in our case, available in our calculation system Feecad [5]. Also, the previous \mathbf{B}^t act as a

permanent magnet. Hysteresis can be considered without particular difficulties since μ_d is always positive.

IV. EXAMPLE AND RESULTS

The magnetic circuit of Fig. 1 is used as an example. At this first stage of our development, we just considered a classical non-linear material.

Fig. 1. Magnetic circuit (8247 elements, 1691 nodes)

A ten time steps field calculation was performed by the classical method and the proposed one, using the differential permeability. Of course, as first test, the materials were considered as linear and we obtained strictly the same result. Then, we enforced the non-linearity by a relatively high voltage. Here the two methods provide similar results with small differences. The relative errors for the magnetic energy and co-energy are 0.69% and 0.65%, respectively. The total number of iterations (for the ten steps) for the classical method is 52 and 41 for the proposed one. The corresponding computational times differ on the same proportion.

V. CONCLUSION

We presented in this work a new method for 3D field evaluation based on the concept of differential permeability applied on the source-field method. The magnetic structure is coupled with the electrical circuit and a time stepping technique is used. This formulation can handle, without difficulties, the hysteretic behavior of soft materials, which will be more detailed in the extended version of the paper.

Abstract— In this paper the authors deal with the FE modelling of eddy-current effects in form-wound windings of electrical machines using a previously proposed general homogenization method. The skin and proximity effect in one stator conductor is first quantified by means of a simple low-cost FE model, leading to a complex and frequency-dependent reluctivity for the homogenized winding. This reluctivity is next adopted in a model of a single slot. Resistance and inductance values obtained with the latter model agree well with those obtained with a brute-force approach (modelling and finely discretizing each conductor).

I. INTRODUCTION

Multi-turn windings in electromagnetic devices may be subjected to considerable skin and proximity effect, leading to higher losses and hot spots, and affecting the global characteristics of the device. In principle these effects can be taken into account in a FE simulation of the device by modelling and finely discretizing each separate conductor (with additional electrical circuit equations to connect the so-called massive conductors [1]). For most real-life applications the huge computational cost of such a brute-force approach cannot be justified. Most often the eddy-current effects are thus simply ignored in the resolution stage of the FE simulation (considering winding regions with uniform current density, so-called stranded conductors [1]), after which the eddy-current losses may be estimated *a posteriori*.

Accurate frequency and time domain homogenization methods for windings have recently been proposed in [2], [3]. For the winding type in hand (e.g., round wires with hexagonal-like packing or rectangular conductors with rectangular packing), an elementary FE model is used for determining frequency-domain coefficients regarding skin and proximity effect. These frequency-dependant coefficients can next be straightforwardly translated into constant time-domain coefficients and associated differential equations thanks to the introduction of additional unknowns for the homogenized winding (current components for the skin effect, and induction components for the proximity effect). The number of additional unknowns required and the computational cost depend on the frequency content of the application [3].

The above frequency and time domain methods have so far been applied to inductor-like devices [2], [3]. In this paper we consider the form-wound double-layer stator winding of a 50 Hz 1250 kW three-phase six-pole squirrel-cage induction machine [4]. Flux and current harmonics in the machine are due to the stator and rotor slotting, saturation and PWM supply

This work was partly supported by the Belgian Science Policy (IAP P6/21), F.R.S. – FNRS and the Brazilian National Council for Scientific and Technological Development (CNPq).

(at 2 kHz switching frequency). Compared to previous applications, the flux situation is *a priori* simpler, slot leakage being essentially governed by a 1D differential equation. However, the parallel connection and transposition of the conductors, if any, complicates the analysis. In this digest, a simple series connection of the conductors is supposed.

II. SKIN AND PROXIMITY EFFECT IN ONE CONDUCTOR

The two-layer stator winding of the machine is distributed in 72 rectangular and fully-open slots (width $w_s = 14$ mm, total height 80 mm), each slot comprising 2×9 copper bars of rectangular cross-section (height $h_c = 3.3$ mm, width $w_c = 10.6$ mm) [4]. The vertical insulation space between two conductors of the same group is $h_i = 0.5$ mm. The stack length is $l = 810$ mm (see Fig. 1). Taking as conductivity $\sigma = 6 \cdot 10^7$ S/m, the skin depth $\delta = \sqrt{2/(\omega\mu\sigma)}$, at pulsation ω , varies between 9.2 mm (at 50 Hz) and 1.45 mm (at 2 kHz), and the conductor height to skin depth ratio, h_c/δ , between 0.35 and 2.27.

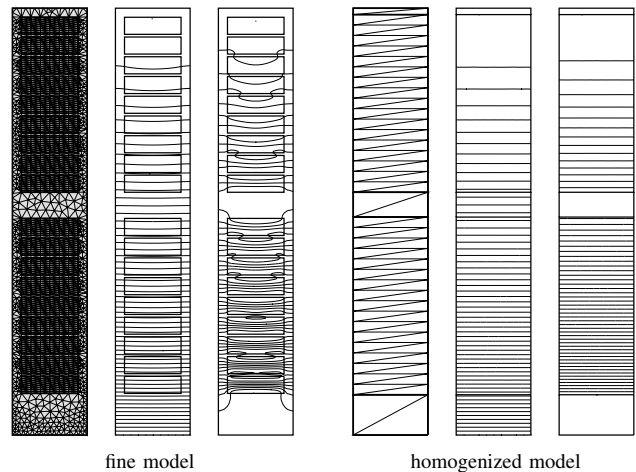

Fig. 1. FE mesh and flux lines (flux component in phase and in quadrature, respectively, with the same imposed 50 Hz current in all 18 conductors), fine model (for brute-force approach) and homogenized model

A. Elementary FE model and frequency-domain calculations

We consider an elementary FE model comprising one copper bar (modelled as a massive conductor) and the insulating space around it. Frequency-domain calculations are carried out in terms of the complex single-component magnetic vector potential \mathbf{a} (in bold), with adequate current and boundary conditions [1].

The complex power \mathbf{S} is then calculated from the local flux density \mathbf{b} and local current density \mathbf{j} :

$$\mathbf{S} = P + \imath Q = \frac{l}{2} \int_{\Omega} (j^2/\sigma + \imath \omega \nu_0 b^2) d\Omega, \quad (1)$$

with P and Q the active and reactive power, \imath the imaginary unit, and $j^2/2 = \mathbf{j}\mathbf{j}^*/2$ and $b^2/2 = \mathbf{b}\mathbf{b}^*/2$ r.m.s.-values squared. Equation (1) can be rewritten considering the average current density \mathbf{j}_{av} and flux density \mathbf{b}_{av} (averaged over the complete model, i.e. copper plus insulation):

$$\mathbf{S} = \frac{l}{2} \int_{\Omega} (j_{av}^2/\sigma_{skin} + \imath \omega \nu_{prox} b_{av}^2) d\Omega, \quad (2)$$

and we thus define the complex skin-effect conductivity σ_{skin} and the complex proximity-effect reluctivity ν_{prox} .

B. Proximity effect

Following the approach developed in [2], [3], a pure proximity-effect excitation is obtained by imposing a unit horizontal flux (with $\mathbf{a} = 0$ and $\mathbf{a} = 1$ on lower and upper boundaries, and the implicit Neumann condition $\partial\mathbf{a}/\partial n = 0$ on left and right slot walls) and zero net current. See the flux patterns in Fig. 2.

Fig. 2. Proximity-effect flux lines at 50 Hz and 10 kHz, with flux component in phase and in quadrature with imposed flux

The complex proximity-effect reluctivity ν_{prox} can also be estimated on the basis of the well-known analytical solution of the 1D diffusion problem (net current or flux in a conducting sheet of thickness h_c [5]) and considering the flux tubes connected in series or in parallel with the copper bar:

$$\nu_{prox} = \nu_0 \left(\left(\frac{w_c}{h_c} \mathbf{Y} + \frac{w_s - w_c}{h_c} \right)^{-1} + \frac{h_i}{w_s} \right)^{-1} \quad (3)$$

$$\text{with } \mathbf{Y} = \frac{1 + \imath}{2} \frac{h_c}{\delta} \cotanh\left(\frac{1 + \imath}{2} \frac{h_c}{\delta}\right). \quad (4)$$

Fig. 3 shows that the analytical approach produces excellent results thanks to the correction (3) for the insulation on all four sides of the conductor.

Fig. 3. Real and imaginary part of the relative permeability $\nu_{prox,rel} = \nu_{prox}/\nu_0$ versus h_c/δ

C. Skin effect

A pure skin-effect excitation is obtained by imposing a sinusoidal current (of unit amplitude, e.g.) in the bar, with condition $\mathbf{a} = 0$ on the complete boundary. The relative

increase in joule losses, i.e. the ratio R_{AC}/R_{DC} minus 1, is found to vary between 0.01% at 50 Hz ($h_c/\delta = 0.35$) and 12% at 2 kHz ($h_c/\delta = 2.27$).

III. HOMOGENIZATION OF A COMPLETE SLOT

We now carry out frequency-domain calculations with a FE model of a complete slot, with either fine discretisation of each conductor (18 massive conductors) or homogenization of the two groups of 9 conductors each (two stranded conductors). See Fig. 1 for the two meshes used (totaling 3618 first-order triangular elements versus 74). The complex reluctivity ν_{prox} is adopted in the homogenized winding regions, together with an imposed uniform current density. Two cases are further considered, the two conductor groups belonging either to the same phase or to different phases, and with either zero or 120 degree phase shift between the respective currents (of same unit amplitude, $I = 1$). See Fig. 1 for some flux patterns (with all conductors belonging to the same phase).

Using (1) and (2) we obtain the complex power and thus the equivalent resistance $R_{AC} = P/(2I^2)$ and inductance $L_{AC} = Q/(2\omega I^2)$ at a given pulsation ω . Fig. 4 shows the ratios R_{AC}/R_{DC} and L_{AC}/L_{DC} as a function of the h_c/δ . For the one-phase case, e.g., at 50 Hz the resistance increases by 34%, and at 2 kHz by a factor of 300. Clearly, the skin-effect losses are negligible compared to the proximity-effect losses. Notice in Fig. 4 the excellent agreement between the results obtained with the brute-force approach and with the homogenized model.

Fig. 4. Equivalent resistance and inductance (relative to DC values) versus h_c/δ

In the full paper the time-domain modelling will be detailed [3], and the parallel connection and transposition of the conductors considered.

Abstract — Counterpoise wires improve the reliability of overhead power transmission lines. This paper presents an electrokinetic model refinement via a perturbation finite element (FE) method to calculate the grounding resistance of counterpoise wires. The perturbation FE method is herein developed for refining the electric field distribution in soil starting from simplified models, based on electric field distribution from 2-D model, that evolve towards 3-D accurate model. The analysis of the distribution of the electric field and of the electric potential around the tower footing allows accurately determining the tower footing resistance. Computational results will be compared with measurements in the extended paper.

I. INTRODUCTION

For evaluating the behaviour of transmission lines in case of lightning strike the accurate modelling of tower footing resistance is crucial. In particular, the decrease of the earth resistance observed for high values of the current flowing from the tower to earth has to be accurately considered [1].

The complete system comprises e.g. four counterpoise wires, as shown in Fig. 1. Continuous counterpoise reduces the resistance of each tower ground and provides a parallel path with the overhead ground wire for the return of fault currents. Fig. 1 closely represents some towers used in Brazil, especially for 138 kV systems [1]. This problem demands a 3-D modelling. However, as the soil dimensions are much bigger than counterpoise wire dimensions, the problem becomes computationally expensive.

Fig. 1. Transmission tower, aerial cables, tower-footing and four counterpoise wires.

This paper analyses the behaviour of electric field and of electric potential on a counterpoise wire. The purpose of

this analysis is to calculate the grounding resistance of this wire. The electrokinetic model refinement is done via a perturbation finite element (FE) method from 2-D to 3-D.

The perturbation FE method is herein developed for refining the electric field distribution in soil starting from simplified models, based on electric field distribution from 2-D model, that evolve towards a 3-D more accurate model. It is an extension of the method proposed in [2]-[4]. The developments are performed for the electrokinetic scalar potential FE electrokinetic formulation, paying special attention to the suitable discretisation of the constraints involved in each sub-problem.

II. REFERENCE AND MODIFIED PROBLEMS

A. Canonical electrokinetic problem

A electrokinetic problem p is defined in a bounded domain Ω_p , with boundary $\partial\Omega_p = \Gamma_{e,p} \cup \Gamma_{j,p}$, of the two or three-dimensional Euclidean space.

A problem, defined with subscript p , is first considered. Its equations and material relations in Ω_p are:

$$\text{curl } \mathbf{e}_p = 0, \quad \text{div } \mathbf{j}_p = 0, \quad \mathbf{j}_p = \sigma \mathbf{e}_p, \quad (1a-b-c)$$

with boundary conditions (BCs) and interface conditions (ICs).

$$\mathbf{n} \times \mathbf{e}|_{\Gamma_{e,p}} = 0, \quad \mathbf{n} \cdot \mathbf{j}|_{\Gamma_{j,p}} = 0, \quad (1d-e)$$

$$[\mathbf{n} \times \mathbf{e}_p]_{\gamma} = \mathbf{e}_{su,p}, \quad [\mathbf{n} \cdot \mathbf{j}_p]_{\gamma} = \mathbf{j}_{su,p}, \quad (1f-g)$$

where \mathbf{e} is the electric field, \mathbf{j} is the electric current density, σ is the electric conductivity and \mathbf{n} is the unit normal exterior to Ω . The notation $[\cdot] = \cdot|_{\gamma^+} - \cdot|_{\gamma^-}$ refers to the discontinuity of a quantity through any interface γ (of both sides γ^+ and γ^-) (see Fig. 3(a)), which is allowed to be non-zero; the associated surface fields $\mathbf{e}_{su,p}$ and $\mathbf{j}_{su,p}$ are usually unknown, i.e., parts of the solution [4]. It is intended to solve successive problems, the solutions of which being added to get the solution of a complete problem [4]. At the first step, a simplified problem p is solved with the 2-D FE method. Its solution is called reference or source solution. In both cases, it is based on particular assumptions that aim to simplify its solving but that are to be further corrected.

Portions of a 3D structure satisfying a translational or rotational symmetry can be first studied via 2-D models. This consists in neglecting some end effects, zeroing $\mathbf{n} \times \mathbf{e}|_{\Gamma}$ or $\mathbf{n} \cdot \mathbf{j}|_{\Gamma}$. Furthermore, if the field is chosen to be zero out of Ω_p , a discontinuity of one of its faces is then voluntary defined through Γ_p .

With such assumptions, two sub-problems 1 and 2 with adjacent non-overlapping sub-domain Ω_1 and Ω_2 share a connexion interface $\Gamma_{p1} = \Gamma_{p2}$ through which a field discontinuity occurs. The 3-D problem is used to correct the field distribution in a certain neighbourhood Ω_2 on both sides of the interface γ . This is done via ICs

$$[\mathbf{n} \times \mathbf{e}_2]_\gamma = \mathbf{e}_{su,2}, \quad [\mathbf{n} \cdot \mathbf{j}_2]_\gamma = \mathbf{j}_{su,2}, \quad (2a-b)$$

where the so-defined volume source $\mathbf{e}_{su,2}$ is obtained from the reference solution (2D FE method) as

$$\mathbf{e}_{su,2} = [\mathbf{n} \times \mathbf{e}]_\gamma - \mathbf{e}_{su,1}. \quad (3)$$

Given that each solution is calculated on a different mesh, mesh-to-mesh projections of solutions are required [4]. This is a key point of the method for ensuring continuity and will be detailed in the extended paper.

III. APPLICATION

The experimental example considered for validation of the proposed approach is a 10 m length counterpoise wire with 0.1 m of diameter. It is embedded in the soil at a depth of 1.0 m.

Fig. 2 shows the 2-D calculation domain and its mesh. Fig. 3 shows the 3-D calculation domain and its mesh.

Fig. 2. The 2-D studied domain (left) and its 2-D mesh (right).

Fig. 3. (a) The 3-D studied domain and (b) The 3-D mesh.

The wire and the soil are first studied (Fig. 2). Its cross section in the XY plane initially defines an initial 2-D model, with the solution shown in Fig. 4. This 2-D solution is considered to be invariant in the Z direction up to a certain distance. Beyond this distance, the electric field is chosen to be zero, which results in a particular IC to be further corrected. This solution then serves as source for a perturbation problem allowing electric leakage flux in 3-D. The 3-D model allows accurately calculating the electric field in the vicinity of the end of the wire (see Fig. 4), with

its own adapted mesh. This way, they gain in accuracy for the benefit of more accurate grounding footing resistance.

Fig. 4. (a) Electric scalar potential: solution of the 2-D model in XY plane, (b) Electric field: solution of the 3-D model - part of the 3-D correction in the region of the counterpoise wire extremity and (c) Interface γ of the studied domain.

Fig. 5 shows the module of electric field along the line A depicted in Fig. 2(left).

Fig. 5. Module of electric field along the line A (see Fig. 2(left)): solution of the 2-D model (implicitly extended as a constant up to $z = 10$ m) and 3-D solution (in $z = 10$ m) after correction in the vicinity of the surface γ .

The results on the grounding resistance of the counterpoise wire measured and calculated will be compared and presented on the extended paper.

Magneto-convection in an Enclosure with Partially Active Vertical Walls

M. Pirmohammadi¹, M. Ghassemi²

¹ Research Management of R & D Deputy, Mapna Group, Tehran, Iran

² Mechanical Engineering Department, K. N. Toosi University of Technology, Tehran, Iran

Pirmohammadi@Mapna.com

Abstract— Effect of longitudinal magnetic field on natural convection heat transfer in an enclosure with partially active vertical walls is numerically investigated. The active part of the left side wall is at a higher temperature than the active part of the right side wall. The top, bottom and the inactive parts of the side walls are thermally insulated. The governing equations are discretized by the control volume method with Hybrid scheme and solved numerically by SIMPLER algorithm for the pressure-velocity coupling together with under relaxation technique. The results are obtained for Rayleigh numbers (Ra) between 10^4 and 10^6 , Hartmann numbers (Ha) between 0 and 100 and Prandtl number 0.71. The heat transfer characteristics are presented in the form of streamlines and isotherms. Results show that the average and local Nusselt number decreases as Hartmann number increases because Lorentz force interacts with the buoyancy force and suppresses the convection flow by reducing the velocities. Also as Rayleigh number increases the temperature gradient and in fact the Nusselt number increases. In addition, it is shown that generally the local Nusselt number decreases along the left side active wall.

I. INTRODUCTION

The Lorentz force acts against the buoyancy force. This phenomenon is used in material manufacturing industry and turbine blade casting as a control mechanism. Employment of an external magnetic field has increasing applications in material manufacturing industry as a control mechanism since the Lorentz force suppresses the convection currents by reducing the velocities. Study and thorough understanding of the momentum and heat transfer in such a process is important for the better control and quality of the manufactured products. The Garandet et al. [1] proposed an analytical solution to the governing equations of magneto hydrodynamics to be used to model the effect of a transverse magnetic field on natural convection in a two-dimensional enclosure. Al-Najem et al. [2] used the power law control volume approach to determine the flow and temperature fields under a transverse magnetic field in a tilted square enclosure with isothermal vertical walls and adiabatic horizontal walls at Prandtl number of 0.71 and showed that the suppression effect of the magnetic field on convection currents and heat transfer is more significant for low inclination angles and high Grashof numbers. Recently, Pirmohammadi et al. [3] studied the effect of a magnetic field on buoyancy-driven convection in differentially heated square enclosure. They showed that the heat transfer mechanisms and the flow characteristics inside the enclosure depend strongly upon both the strength of the magnetic field as well as the Rayleigh number. It was

concluded that the magnetic field considerably decreases the average Nusselt number.

The present study deals with the natural convection in a square enclosure filled with an electrically conductive fluid with partially thermally active vertical walls in the presence of external magnetic field. The hot and cold regions are located at the middle of vertical walls. The results are displayed graphically in the form of streamlines and isotherms, which show the effect of magnetic field on temperature and flow field.

II. BASIC EQUATIONS

The geometry and the coordinate system are schematically shown in Fig. 1.

Fig. 1. Geometry of enclosure configuration with magnetic effect.

The non-dimensional governing equations in this study are based on the conservation laws of mass, linear momentum and energy are given as:

$$\frac{\partial U}{\partial X} + \frac{\partial V}{\partial Y} = 0 \quad (1)$$

$$U \frac{\partial U}{\partial X} + V \frac{\partial U}{\partial Y} = -\frac{\partial P}{\partial X} + \text{Pr} \left(\frac{\partial^2 U}{\partial X^2} + \frac{\partial^2 U}{\partial Y^2} \right) \quad (2)$$

$$U \frac{\partial V}{\partial X} + V \frac{\partial V}{\partial Y} = -\frac{\partial P}{\partial Y} + \text{Pr} \left(\frac{\partial^2 V}{\partial X^2} + \frac{\partial^2 V}{\partial Y^2} \right) + Ra \text{Pr} \theta - Ha^2 \text{Pr} V \quad (3)$$

$$U \frac{\partial \theta}{\partial X} + V \frac{\partial \theta}{\partial Y} = \left(\frac{\partial^2 \theta}{\partial X^2} + \frac{\partial^2 \theta}{\partial Y^2} \right) \quad (4)$$

In the above equations, the primary non-dimensional parameters, the Rayleigh number and the Prandtl number, are defined as:

$$\text{Pr} = \frac{\nu}{\alpha}, \quad Ra = \frac{g\beta(T_h - T_c)H^3}{\alpha\nu}, \quad Ha = B_0 H \sqrt{\frac{\sigma}{\rho\nu}} \quad (5)$$

Where, ρ is the density, g is the gravitational acceleration, ν is the cinematic viscosity, β is the coefficient of thermal expansion, and B_0 is the magnitude of magnetic field and σ is the electrical conductivity. Also U , V and θ are non-dimensional velocity components and temperature, respectively.

The local Nusselt number $Nu = -\frac{\partial \theta}{\partial X}$ is computed at the hot wall (Nu). The average Nusselt number is expressed as

$$\bar{Nu} = \frac{3}{H} \int_0^{H/3} Nu_y dY.$$

III. RESULTS

The accuracy of results is verified with that of Rudraiah[4] and is presented in Pirmohammadi et al [3].

Figure 2 depicts the vertical velocity component for various Hartmann number for $Ra=10^5$. It is shown that as magnetic field (Ha) increases, the vertical velocity component decreases so that it approaches zero at about $Ha = 100$.

Fig.2 Vertical velocity component for various Ha at $Ra=10^5$

Local Nusselt number (Nu) along the thermally active left side wall for Rayleigh numbers 10^4 and 10^6 and various Hartmann numbers is shown in Fig. 3. As shown the Nu varies directly with Rayleigh number and inversely with Hartmann number. This means that Nu number increases with Rayleigh number and decreases as magnetic field (Ha) increases.

(a) $Ra=10^4$

(b) $Ra=10^6$

Fig.3 Local Nusselt number for various Ha and Ra

Because Lorentz force interacts with the buoyancy force and suppresses the convection flow by reducing the velocities. Also as Rayleigh number increases the temperature gradient and in fact the Nusselt number increases. In addition, it is shown that generally the local Nusselt number decreases along the left side active wall. Also it is shown that for low Rayleigh and high Hartmann numbers the local Nusselt profile along the wall is nearly symmetric and its value decreases.

Comparison between BEM + ACA and classical FEM for 3D low-frequency eddy-current analysis

D. Pusch, J. Smajic and Z. Andjelic

ABB Switzerland Ltd., Corporate Research, CH-5405 Baden 5 Dättwil
e-mail: {david.pusch}{jasmin.smajic}{zoran.andjelic}@ch.abb.com

Abstract—In this paper we are concerned with eddy-current analysis based on fast boundary element methods. A novel compression and preconditioning technique adaptive cross approximation is used to benefit from several advantages when computing problems with highly permeable materials. Several numerical experiments have been performed with the aim to investigate the performance compared to commercial finite element solvers. The results are validated on the TEAM benchmark problem P21.

I. INTRODUCTION

In many industrial applications the electromagnetic physical phenomenon of eddy currents is playing an important role. Following the eddy-current approximation scheme proposed by Mayergoyz [1] we end up with a reduced Maxwell equation system which neglects the displacement currents of the problem. Hence, this leads to Fredholm integral equations of the second kind on the boundary of the investigated domain. Moreover, the applied Galerkin discretization yields a system of matrix equation with four unknowns per node in the space of complex numbers. In fact, we obtain a dense system matrix which is a major bottleneck in using boundary element methods (BEM). In the last decades several methods were developed in order to ensure fast BEM, like the fast multipole technique, hierarchical matrices, panel clustering or wavelet compression, see e.g. [5], [6], [2]. Since in industrial applications we are usually faced with a large number of unknowns, an iterative solution procedure has to be established. In our case we are using a preconditioned generalized minimal residual (GMRES) solver due to the non-symmetry of the system matrix. It turns out, that for bodies with high permeable materials the application of a proper preconditioning is essential.

The paper is organized as follows. In Section II we give a brief explanation of the $\mathbf{H} - \varphi$ formulation. A description of the approximation and preconditioning properties of the adaptive cross approximation method (ACA) for a Galerkin discretization is given in Section III. In the last Sections IV we show numerical results and additional final conclusions.

II. $\mathbf{H} - \varphi$ FORMULATION

Let us consider a simply connected conducting domain Ω with the boundary Γ . Considering the proposed Mayergoyz [1] formulation we have an integral representation for the magnetic field \mathbf{H}^{in} in the inner domain and a potential φ

representation in the unbounded outer air domain

$$\mathbf{H}^{in} = \frac{1}{4\pi} \operatorname{curl}_x \int_{\Gamma} \mathbf{j}^v(\mathbf{y}) K(\mathbf{x}, \mathbf{y}) ds_y \quad \mathbf{x} \in \Omega \quad (1)$$

$$\varphi(\mathbf{x}) = \frac{1}{4\pi} \int_{\Gamma} \sigma^v(\mathbf{y}) G(\mathbf{x}, \mathbf{y}) ds_y \quad \mathbf{x} \in \mathbb{R}^3 \setminus \bar{\Omega}. \quad (2)$$

In equations (1) and (2) we are concerned with the integral kernels $G(\mathbf{x}, \mathbf{y}) = |\mathbf{x} - \mathbf{y}|^{-1}$ and $K(\mathbf{x}, \mathbf{y}) = \exp(-\sqrt{2\pi f \mu \sigma} |\mathbf{x} - \mathbf{y}|) G(\mathbf{x}, \mathbf{y})$. Among the frequency f the integral kernel $K(\mathbf{x}, \mathbf{y})$ includes also the material information, both the conductivity σ and the magnetic permeability μ .

Taking into account the boundary conditions at the interface (continuity of tangential component of \mathbf{H} -field and normal component of \mathbf{B} -field) we finally have to find a solution (\mathbf{j}^v, σ^v) that solves the system of equations:

$$\begin{aligned} \frac{1}{2} \mathbf{j}^v(\mathbf{x}) + \frac{1}{4\pi} \int_{\Gamma} \mathbf{n}(\mathbf{x}) \times [\mathbf{j}(\mathbf{y}) \times \operatorname{grad}_x K(\mathbf{x}, \mathbf{y})] ds_y - \\ \frac{1}{4\pi} \int_{\Gamma} \sigma^v(\mathbf{y}) [\mathbf{n}(\mathbf{x}) \times \operatorname{grad}_x G(\mathbf{x}, \mathbf{y})] ds_y = -\mathbf{n}(\mathbf{x}) \times \mathbf{H}_0(\mathbf{x}) \end{aligned} \quad (3)$$

$$\begin{aligned} \frac{1}{2} \sigma^v(\mathbf{x}) + \frac{\mu}{4\pi \mu_0} \int_{\Gamma} \mathbf{n}(\mathbf{x}) [\mathbf{j}^v(\mathbf{y}) \times \operatorname{grad}_x K(\mathbf{x}, \mathbf{y})] ds_y + \\ \frac{1}{4\pi} \int_{\Gamma} \sigma^v(\mathbf{y}) [\mathbf{n}(\mathbf{x}) \operatorname{grad}_x G(\mathbf{x}, \mathbf{y})] ds_y = -\mathbf{n}(\mathbf{x}) \mathbf{H}_0(\mathbf{x}) \end{aligned} \quad (4)$$

for $\mathbf{x} \in \Gamma$. Note, that \mathbf{H}_0 is a prescribed excitation field and \mathbf{n} the outward unit normal vector.

III. ADAPTIVE CROSS APPROXIMATION

After Galerkin discretization of (3) and (4) we find the following discrete matrix equation system

$$\begin{pmatrix} A_1 & B_1 \\ \frac{\mu}{\mu_0} B_2 & A_2 \end{pmatrix} \begin{pmatrix} \underline{j}_h \\ \underline{\sigma}_h \end{pmatrix} = \begin{pmatrix} \underline{b}_1 \\ \underline{b}_2 \end{pmatrix}. \quad (5)$$

Note, that the system consists of complex submatrices A_1, B_1 and B_2 , which becomes dominant for high permeability. It is well known, the straight forward application of BEM leads to fully populated matrices, which immediately shows the bottleneck of the BEM approach: The demand of memory as well as the evaluation time of a single matrix-times-vector multiplication will behave $\mathcal{O}(N^2)$, where N denotes the number of unknowns in the matrix system (5).

In our calculation we use the adaptive cross approximation technique [2] which provides a hierarchical matrix (\mathcal{H} -matrix).

Fig. 1. \mathcal{H} -matrix structure, red: full blocks, green: low-rank blocks

A rigorous mathematical theory for \mathcal{H} -matrices can be found in [6], a typical structure is sketched in Fig. 1. One advantage of ACA is that an explicit knowledge of the kernel is not necessary, but only pure algebraic transformations on the matrix are needed. More precisely, selected matrix entries have to be evaluated, thus, the algorithm can relatively easily be implemented in an existing software code. The idea to obtain a hierarchical matrix $A_{\mathcal{H}}$ is to split the system matrix into far-field and near-field contributions depending on geometrical information of the considered basis functions and test functions

$$A_{\mathcal{H}} = A_h + \sum_{i=1}^{N_B} u_i v_i^{\top}. \quad (6)$$

The near-field blocks accumulate to a sparse matrix A_h , the separated N_B far-field blocks of the matrix are approximated by low-rank expressions $u_i v_i^{\top}$ up to a certain prescribed accuracy ε . We are now able to apply an efficient data-sparse \mathcal{H} -LU decomposition which is used as preconditioner for the ill-conditioned problem (5), see [2], [3]. Another realization of a preconditioner is a Schur-complement preconditioner, for more details and numerical results we refer to [7].

IV. NUMERICAL RESULTS

For numerical validation we calculate the TEAM problem P21^a-0, see Fig. 2. The problem specification and measure-

Fig. 2. TEAM benchmark problem P21^a-0

ment results can be found in [4]. The first test case considers non-magnetic steel, for which measurements for the total power losses as well as the B -field in x -direction exist. In order to test the BEM approach also for existing magnetic materials in the model, we replace the non-magnetic steel plate with magnetic steel, $\sigma = 6.66 \cdot 10^6 S/m$ and a relative permeability $\mu_r = 200$. Due to the lack of measurements, we compare our results with a commercial 3D FEM solver for electromagnetics.

For the non-magnetic steel plate we have a measured total power loss of $9.17W$, see [4]. In comparison to our simulation, which gives $9.54W$ on a relatively coarse mesh (3576 boundary elements).

Furthermore, the results for magnetic steel are shown in Fig. 3. It can be observed, that for convergence of the total

Fig. 3. Total losses, magnetic steel

power losses we need a fine FEM mesh in order to achieve a satisfying accuracy. On the other hand, the BEM approach gives already very good results even for coarser meshes. Note, that the penetration depth here is $\delta = 1.95$ mm. The corresponding memory consumption for the system matrix for both methods are listed in Table I. The second quantities

TABLE I
MEMORY CONSUMPTION

h [mm]	BEM-ACA [MB]	FEM [MB]
40	25 (58)	134
20	378 (782)	180
10	1523 (10680)	701

in the BEM column are the theoretical memory demands, which would be needed for fully populated matrices. It is obvious, that only the usage of compression techniques yields a reasonable BEM approach.

An Energy-Based Error Criterion for Eddy Current Transient Analysis

Loïc Rondot¹, Dimitrios Ladas² and Vincent Mazaauric²

¹CEDRAT, 15 chemin de Malacher, 38246 – Meylan, France, E-mail: loic.rondot@cedrat.com

²Schneider Electric, Innovation Dept., 38TEC, 30050 – Grenoble Cedex 9, France

Abstract — In order to evaluate the accuracy of FEM modeling of transient-induced macroscopic eddy-currents in magnetic devices, a quadratic energy-based error criterion is proposed. It is suitable for 2D and 3D applications, independent of the formulation, and supporting the body motion. A validation is given on a Thomson effect device.

I. INTRODUCTION

Eddy currents are at the origin of losses and signal distortions in power electrical devices. In order to address their considerable impacts on both the energy efficiency and the performance requirement, eddy currents modeling and its accuracy are discussed from a thermodynamic approach. While this approach was successfully used in [1] to derive a quadratic energy-based error criterion suitable for magneto-harmonic cases, an extension to transient regime should be investigated.

While some former attempts, *e.g.* [2][3], are focused on the consistency of the magnetostatic resolution, the proposed error criterion is fully dedicated to the evaluation of the dynamic aspect in massive conductor where the skin effect occurs. It is independent of the formulation, and allows to take body motion into account.

A presentation of the variational approach of electromagnetism is first proposed. Then the error criterion is naturally derived. Finally, some numerical results obtained by Finite Element computation on a Thomson's effect device are presented.

II. VARIATIONAL FORMULATION

Classically, thermodynamic approaches of electromagnetism do not consider any extension towards time-varying regimes [4][5][6]. Whereas some improvements are summarized in [7] for steady states regimes, no general contribution is available for transient. For this purpose, the magnetodynamic behavior of any electrical system is derived from the functional [8]:

$$P_{\text{mech}} - \frac{dG}{dt} = \min_{H,E} \left(\int_C \sigma^{-1} (\text{curl} H)^2 d^3r + \frac{d}{dt} \int (\mathbf{B} \cdot \mathbf{H} + \mathbf{D} \cdot \mathbf{E}) d^3r \right) \quad (1)$$

where the functional in the RHS exhibits:

- the magnetic field \mathbf{H} related to free and displacement currents according to the Maxwell-Ampere equation. The quasi-static approximation enforces $\mathbf{D} = \mathbf{0}$ in conductors;
- the Joule losses P_J monitored in conductors. This term is even to respect invariance of losses with inversion of time inversion (σ^{-1} is the resistivity);

- the variation with time of the electromagnetic energy coupling the field with the generator I and the mass V_0 ;
- the magnetic $\mathbf{B}(\mathbf{h})$ and electrostatic $\mathbf{D}(\mathbf{e})$ behavior laws derived from thermostatic equilibrium of the Gibbs potential

$$G(T, I, V_0) = \int d^3r \left(\int_0^H (-\mathbf{B}) \cdot d\mathbf{h} + \int_0^E (-\mathbf{D}) \cdot d\mathbf{e} \right) \quad (2)$$

Extending the electric field in the conductor according to Ohm's law $\mathbf{E} = \sigma^{-1} \mathbf{J} - \mathbf{V} \times \mathbf{B}$, Faraday's law $\text{rot } \mathbf{E} = \partial_t \mathbf{B}$ may be viewed as acting locally to check globally a tendency towards reversibility [9]. This striking property provides a thermodynamic oriented insight of the variational theory of electromagnetism [10]. Hence, the functional (1) balances the variations with time of the co-energy ($-G$) and the mechanical power supplied to the whole system P_{mech} .

In order to consider sub-systems for design purpose, it is convenient to introduce the electrical power

$$P_{\text{elec}}(\Omega) = - \oint_{\partial\Omega} (\mathbf{E} \times \mathbf{H}) \cdot \mathbf{n} d^2r \quad (3)$$

After some calculations, it follows

$$P_{\text{elec}}(\Omega) = - \int_{\Omega} (\text{curl} \mathbf{E} + \partial_t \mathbf{B}) \cdot \mathbf{H} d^3r + \int_{\Omega} (\text{curl} \mathbf{H} - \mathbf{J} - \partial_t \mathbf{D}) \cdot \mathbf{E} d^3r + \int_{C \subset \Omega} \mathbf{J} \cdot (\mathbf{E} - \sigma^{-1} \mathbf{J} + \mathbf{V} \times \mathbf{B}) d^3r + P_J(\Omega) + \frac{dF}{dt}(\Omega) \quad (4)$$

$$- \sum_i \oint_{\partial\Omega_i} \left([\mathbf{E} \times \mathbf{H}] \cdot \mathbf{n} - \left[\int_0^B \mathbf{H} \cdot d\mathbf{b} + \int_0^D \mathbf{E} \cdot d\mathbf{d} \right] (\mathbf{V}_i \cdot \mathbf{n}) \right) d^2r + \int_{C \subset \Omega} \mathbf{V} \cdot (\mathbf{J} \times \mathbf{B}) d^3r$$

where F is the Helmholtz's potential and $[\cdot]$ denotes the discontinuity occurring at the interfaces $\partial\Omega_i \subset \Omega$.

At the minimum of the functional (1), the Maxwell equation set and Ohm's law are checked so that:

- the first three residual terms vanish in (4). After some tedious calculations on the motion induced-conductor interface discontinuities, the two last terms provide the mechanical power
- $$-P_{\text{mech}}(\Omega) = \sum_i \oint_{\partial\Omega_i} (\mathbf{n} \cdot \mathbf{V}) [\mathbf{D} \times \mathbf{B}] \cdot \mathbf{V}_i d^2r + \sum_i \int_{C_i} (\mathbf{J} \times \mathbf{B}) \cdot \mathbf{V}_i d^3r + \sum_i \oint_{\partial\Omega_i} \left([(\mathbf{B} \cdot \mathbf{n})\mathbf{H} + (\mathbf{D} \cdot \mathbf{n})\mathbf{E}] - \left[\int_0^H \mathbf{B} \cdot d\mathbf{h} + \int_0^E \mathbf{D} \cdot d\mathbf{e} \right] \cdot \mathbf{n} \right) \cdot \mathbf{V}_i d^2r \quad (5)$$

where the first term denotes a vanishing "impulsion" term within the quasi-static approximation; the second one is related to the power of the Laplace's force; and

the third one gathers the switching reluctance effects occurring at the various interfaces of the domain Ω . For conductors with linear magnetic behavior law, these three contributions may be lumped in the Maxwell's stress tensor. As a result, the relation (4) matches the integral form of the Poynting's conservation equation. Hence,

- the contribution of Ω to (1) reads

$$P_{\text{mech}}(\Omega) + P_{\text{elec}}(\Omega) - \frac{dG}{dt}(\Omega) \quad (6)$$

The Finite Element Method consists in building an approximation of (1),(2) but with a finite number of degrees of freedom chosen on a mesh. In the following, an evaluation of the local power conservation (4) is assessed to introduce the accuracy of any numerical solution.

III. NUMERICAL RESULTS

Whereas the stationary conditions expressed on (1),(2) provide an approximation of the fields, the consistency of the solution with energy conservation may be assessed through the local deviation of the Poynting's equation

$$\varepsilon(\Omega) = P_{\text{elec}}(\Omega) - P_j(\Omega) - \frac{dF}{dt}(\Omega) + P_{\text{mech}}(\Omega) \quad (7)$$

Strictly enforcing two relations among Maxwell-Ampere or Maxwell-Faraday equations and Ohm's law, the error criterion (7) highlights the elements where the third one is ill-checked.

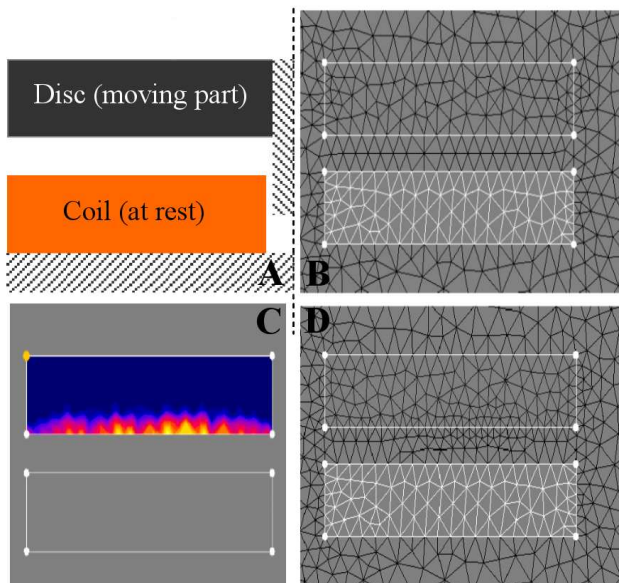

Fig. 1. Thomson effect actuator excited by a voltage source: Left: (a) axisymmetric cross-section, (b) initial mesh at the second time step, (c) error criteria assessed from (7) in the moving part: notice its confinement in the skin depth, (d) mesh enhancement at the second time step: notice the refinement in the skin depth and the related decline of (6) in table 1.

An iterative "bubble" remeshing technique [11] is coupled with the criterion (7) and applied to a Thomson's effect device (Fig.7). While the mesh is improved *locally*, the convergence of the *global* quantities is observed.

TABLE I. Convergence of the functional (1),(2) under mesh refinement. Notice the reduction of the G by Γ^2 to take meshing-induced current variation into account.

Δt (s)	Number of time step 2	Number of time step 3 (before remeshing)	Number of time step 3 (after remeshing)
U (V)	$3.1 \cdot 10^{-1}$	$5.9 \cdot 10^{-1}$	$5.9 \cdot 10^{-1}$
I (A)	$7.3 \cdot 10^{-4}$	$2.1 \cdot 10^{-3}$	$1.4 \cdot 10^{-3}$
G (J)	$-1.61 \cdot 10^{-9}$	$-1.34 \cdot 10^{-8}$	$-5.89 \cdot 10^{-9}$
G/P ($J.A^{-2}$)	$-3.05 \cdot 10^{-3}$	$-3.06 \cdot 10^{-3}$	$-3.09 \cdot 10^{-3}$
$P_{\text{mech}} - dG/dt + P_{\text{elec}}$	-	$2.5 \cdot 10^{-2}$	$9.4 \cdot 10^{-3}$

IV. CONCLUSION

The energy-based error criterion allows to refine the conducting regions where the mesh is not enough refined, with respect to the skin effect occurring therein. In addition to the error criterion, the thermodynamic approach provides the functionals from which the global convergence should be evaluated.

Hence an adaptive meshing strategy compliant with energy efficiency and performance requirements can be addressed.

Abstract: This study focuses on the effects that a ferromagnetic material undergoes when subjected to high stresses under low magnetic fields. In order to predict the magnetic signature, we show that the Jiles law of approach can be used and applied to the induction measured by external sensors, and an analytical solution is derived in the case of our prototype, a ferromagnetic cylinder subjected to an internal pressure up to 100 Bars. Measurements were led at the LMMCF (Laboratory of Magnetic Metrology in Weak Fields – Grenoble France). Comparison between model predictions and measurements shows an error lower than 1%.

I. INTRODUCTION

Magnetic signatures expose all ferromagnetic vessels to risk from mines. Given the risk to seamen, the military handicap borne when a defense vessel is hit, and the economical costs, magnetic signature reduction for warships is essential. Determing methods and degaussing systems are used, but may be inefficient for vessels undergoing a high level of stresses, such as submarines: because of magnetostriction, pressure drastically changes the magnetization.

In order to investigate such effects, a simplified mockup has been built and subjected to internal pressures in a 0-100 Bars range. Magnetic signature has been measured and analyzed under various conditions.

Our aim is to model the magnetic signature variation due to pressure to describe magnetization changes due to strain. Several models can be found in literature. Nevertheless, the magnetostriction model developed by Jiles [1] seems particularly well suited to our approach in terms of level of stress (high) and of applied field (low field, around 50μT). This model clearly states that under strains, magnetization tends towards the anhysteretic magnetization.

In this paper, we propose to apply this model to a complex geometry: a hollow cylinder is used instead of usual rods. In order to achieve this, we extend the original Jiles equation, describing the evolution of magnetization \mathbf{M} inside a ferromagnetic material undergoing stresses. We demonstrate that this law is applicable to the magnetic induction \mathbf{B} measured by magnetic sensors outside the ferromagnetic body. An analytical solution is then found for the cases where the inductor magnetic field is vertical. Measurements show a good correlation with the expected results (error < 1%).

II. THE JILES LAW OF APPROACH

Jiles [1] postulated a law describing the behavior of magnetization \mathbf{M} for a ferromagnetic material undergoing stresses. This law can be expressed as:

$$\frac{\partial \mathbf{M}}{\partial \sigma} |_{\mathbf{H}_0} = \frac{\sigma}{\xi E} (\mathbf{M}_{\text{anh}} - \mathbf{M}) + c \frac{\partial \mathbf{M}_{\text{anh}}}{\partial \sigma} |_{\mathbf{H}_0} \quad (1)$$

where σ denotes the stress, ξ is a coefficient with dimension of energy per unit volume, E the Young modulus, c a unitary coefficient, describing the flexibility of the domain walls, \mathbf{H}_0 is the external applied magnetic field, and \mathbf{M}_{anh} the anhysteretic magnetization, function of stress. This equation requires:

- The knowledge of coefficients c , ξ (E is usually known)
 - The law of evolution of the anhysteretic magnetization with stress $\mathbf{M}_{\text{anh}}(\sigma)$ under the constant applied field \mathbf{H}_0 .
- This law is given in terms of magnetization \mathbf{M} , and thus can be depicted as an intrinsic law. Using results derived in [2] for thin ferromagnetic shells, we show that (1) can be formulated as

$$\frac{\partial \mathbf{B}}{\partial \sigma} |_{\mathbf{B}_0} = \frac{\sigma}{\xi E} (\mathbf{B}_{\text{anh}} - \mathbf{B}) + c \frac{\partial \mathbf{B}_{\text{anh}}}{\partial \sigma} |_{\mathbf{B}_0} \quad (2)$$

where \mathbf{B} is the external measured induction. Equation (2) is the expression of the Jiles law, expressed in terms of measured external induction, rather than in magnetization.

III. EXPERIMENTAL PROTOCOL

Measurements were conducted at the LMMCF (Laboratory of Magnetic Metrology in Weak Fields) is located in Grenoble, France [3]. The used prototype is a ferromagnetic hollow cylinder. The cylinder, filled with hydraulic oil, is subjected to an internal pressure up to 100 Bars, driven by an external pump. Applied field is generated by a system of triaxial coils, in the range of $\pm 80\mu\text{T}$, over a volume of $27 \times 2 \times 2 \text{ m}^3$. Magnetization variations due to stress are measured on external magnetic sensors, located under the cylinder.

Two series of measurements were conducted. The first one was dedicated to the determination of the anhysteretic curves under a constant stress. Anhysteretic curves were plotted for vertical applied inductions \mathbf{B} , ranging from 20 to 80 μT , with increasing steps of 20 μT , and for internal pressures ranging from 0 to 100 Bars, with increasing steps of 20 Bars. Results

7. Material Modelling

show that the anhysteretic inductions for vertical applied fields do not depend upon pressure.

The second series of measurements consisted in recording the evolution of the external induction \mathbf{B}_{mes} on the sensors while the cylinder was subjected to a stress cycle $0 \rightarrow P_{max} \rightarrow 0$ MPa under a given applied vertical inductor \mathbf{B}_0 . Then, the internal pressure was increased to its maximum value, and then set back to zero. The whole cycle was recorded, allowing plotting of \mathbf{B} vs. P curves.

IV. ANALYTICAL SOLUTION TO THE JILES-ATHERTON LAW OF APPROACH FOR A VERTICAL APPLIED FIELD

Given that for a vertical inductor field, measurements showed that $\mathbf{B}_{anh}(\sigma, \mathbf{B}_0) = \mathbf{B}_{anh}(\mathbf{B}_0)$, (2) can be simplified and an analytical solution to this equation is:

$$\mathbf{B}(\sigma, \mathbf{B}_0) = \mathbf{B}_{anh}(\mathbf{B}_0) + [\mathbf{B}_{m0} - \mathbf{B}_{anh}(\mathbf{B}_0)]e^{-\sigma^2/2E\xi} \quad (3)$$

where \mathbf{B}_{m0} is the initial measured induction under zero stress in T, $\mathbf{B}_{anh}(\mathbf{B}_0)$ the anhysteretic value obtained from anhysteretic induction measurements. The only parameter to determine in order to fully explicit the analytical solution is ξ . The value ξ is approached to fit a first HPP cycle with a least-square algorithm. Subsequent measured HPP cycles are then compared to the analytical solution.

Fig. 1. Identification of parameter ξ required for analytical solution: a fitting method based on least square algorithm is used on vertical component variation of induction due to stress, on centered sensor B1.

For fitting, initial magnetization corresponds to the following state: the anhysteretic magnetization (at zero stress) under a vertical inductor field $\mathbf{B}_1 = -41 \mu\text{T}$ is achieved. Then, the applied field was then set to $+40 \mu\text{T}$. The initial measured value of the vertical component of induction on a centered magnetic sensor B1 was $\mathbf{B}_{m0} = 42300 \text{ nT}$. The stress was then raised to 100 Bars.

A least-square algorithm applied to the curve describing the induction variation when stress increases from 0 to 100 Bars provides the value $\xi = 2.55 \cdot 10^{-9}$ (for P expressed in Bars, and $E = 2.05 \cdot 10^{11} \text{ Pa}$). Figure 1 shows the measurements, and the fitted curve obtained by using the identified value ξ with the analytical solution.

To test our analytical solution, and the identification of the parameter ξ , 3 other cycles were measured under different vertical inductor fields. Figure 2 shows comparison between the analytical predicted induction and the measured induction

variation during one of these cycles. The maximum error is lower than 0.34%.

Fig. 2. Comparison between the analytical solution and the measurements for a vertical inductor field $\mathbf{B}_v = 80 \mu\text{T}$ and a given initial magnetic state.

V. CONCLUSION

In this paper, we demonstrated that the law of approach of Jiles could be applicable to model the measured external induction created by a magnetic source. For our application, a more complex geometry was used that the one usually found in literature. A hollow cylinder was tested instead of typical rods. The main difference is that with our geometry, shape factor is not negligible, especially when the inductor field is applied vertically.

Measurements established that, for vertical inductor fields, the anhysteretic curves were not a function of stress, the unfavourable shape effect acting like a mitigating factor for the effects of pressure. This result leads to a great simplification of the Jiles equation, and an analytical solution could be derived. In order to fully explicit this solution, the knowledge of a physical parameter was required, and a fitting method based on a first series of measurements led to determination of this constant.

Comparison between the analytical solution and others series of measurements showed the results were excellent, and the error between the predicted induction and the measured one was lower than 1%.

The inverse problem, i.e. the determination of magnetization in the cylinder by knowledge of the magnetic induction measured on the sensors is under work. It will allow the determination of the intrinsic law of magnetization of the material as a function, not only of the inductor field, but also of the stresses the material is undergoing.

Abstract — This paper describes the large-scale analysis of magnetic beads' behavior in magnetic fields by developing a novel method combining the discrete element method (DEM) and the magnetic interaction calculation with the fast multipole method (FMM). Some numerical examples of large-scale magnetic-bead chain analysis are reported for confirming the effectiveness of the proposed method.

I. INTRODUCTION

The huge numbers of magnetic beads are utilized in the printing process of laser printers, in which the beads form chains and play a brush role in toner transfer. Due to the difficulties of actual measurement, when comprehending the magnetic beads' behavior in forming chains in magnetic field, it is indispensable to carry out the numerical analysis, i.e., a coupled magnetic and contact force analysis. However, the required computational cost to deal with the beads is of $O(N^2)$, where N is the number of beads. Therefore, it is also difficult to apply the numerical analysis to the large-scale problems of magnetic beads.

With the above background, in this paper, we develop a novel method combining the discrete element method (DEM) and the magnetic interaction calculation with the fast multipole method (FMM) [1]. Some numerical results, which demonstrate the effectiveness of the proposed method from the viewpoint of CPU-time, are presented. Finally, the large-scale magnetic-bead chain analysis is also carried out as a practical example.

II. METHOD OF ANALYSIS

A. Magnetic Force Analysis by Using FMM

The magnetic flux density \mathbf{B} generated by magnetic moment \mathbf{m}_j at the center of particle i is given by

$$\mathbf{B}_{ij} = \frac{\mu_0}{4\pi} \left(\frac{3(\mathbf{m}_j \cdot (\mathbf{r}_i - \mathbf{r}_j))(\mathbf{r}_i - \mathbf{r}_j)}{|\mathbf{r}_i - \mathbf{r}_j|^5} - \frac{\mathbf{m}_j}{|\mathbf{r}_i - \mathbf{r}_j|^3} \right), \quad (1)$$

where r_i and r_j are the positions of center of particle i and j , respectively, and μ_0 is the permeability of vacuum. The magnetic moment \mathbf{m}_i at the center of a magnetic particle i in homogeneous magnetic field \mathbf{B} is evaluated as follows:

$$\mathbf{m}_i = \frac{4\pi}{\mu_0} R^3 \frac{\mu_r - 1}{\mu_r + 2} \mathbf{B}, \quad (2)$$

where R is the radius of the particle and μ_r indicates the relative permeability. The magnetic moments corresponding

to each magnetic particle are obtained by updating \mathbf{m}_i with (1) and (2) until they converge to its steady state.

The magnetic particle with magnetic moment \mathbf{m} in the homogeneous field \mathbf{B} is subject to magnetic force expressed as

$$\mathbf{F} = (\mathbf{m} \cdot \nabla) \mathbf{B}. \quad (3)$$

On the other hand, \mathbf{B} can be written by using the local expansion as follows:

$$\mathbf{B} = -\frac{\mu_0}{4\pi} \sum_{n=0}^{\infty} \sum_{m=-n}^n L_n^m \nabla (Y_n^m(\theta, \phi) r^n), \quad (4)$$

where L_n^m is the local expansion coefficient, Y_n^m is the spherical harmonic function of degree n and order m , and (r, θ, ϕ) is its spherical coordinates. The second-order derivative of $Y_n^m(\theta, \phi) r^n$ is necessary for the calculation of magnetic force between magnetic beads by (3).

In order to calculate the second-order derivative of $Y_n^m(\theta, \phi) r^n$ at high speed while maintaining the accuracy in the FMM process, we propose the novel formulae derived from the local-to-local (L2L) translation in the same cell [2] as follows:

$$\begin{cases} \partial B_x / \partial x = -\mu_0 (L_2^0 - \sqrt{6} L_2^2 \cdot re) / 4\pi \\ \partial B_x / \partial y = \partial B_y / \partial x = -\mu_0 \sqrt{6} L_2^2 \cdot im / 4\pi \\ \partial B_x / \partial z = \partial B_z / \partial x = \mu_0 \sqrt{6} L_2^1 \cdot re / 4\pi \\ \partial B_y / \partial y = -\mu_0 (L_2^0 + \sqrt{6} L_2^2 \cdot re) / 4\pi \\ \partial B_y / \partial z = \partial B_z / \partial y = -\mu_0 \sqrt{6} L_2^1 \cdot im / 4\pi \\ \partial B_z / \partial z = \mu_0 L_2^0 / 2\pi \end{cases}. \quad (5)$$

These formulae have advantages that these equations are quite simple and it is not necessary to consider the singularity of Y_n^m .

B. Contact Force Analysis by Using DEM

In the DEM, all the particles are regarded as elastic body to take into account the deformation of the particles due to the collision. The equations of motion are set up by assuming the dashpots, frictions, and springs at the points of contact. The DEM is suitable for the case that a large number of particles are tightly-packed because it can treat the contact force from several particles at one time. The contact model of the particles in the DEM is shown in Fig. 1 and the corresponding equations of motion are given by

$$\begin{cases} f_n = -K_n \delta_n^{\frac{3}{2}} - \eta_n \dot{\delta}_n \\ f_s = -K_s \delta_s - \eta_s \dot{\delta}_s - \mu f_n \end{cases}. \quad (6)$$

Here, f is the force, δ is the displacement, μ is the friction coefficient, and the subscript means the normal and tangential components, respectively. K and η are the spring constant and the dashpot, which are derived from the Hertz's elastic theory of contact.

Fig. 1. Contact model.

C. Procedure of Particle Behavior Analysis Taking Account of Magnetic Force

The flowchart of the analysis of magnetic beads' behavior in magnetic field is shown in Fig. 2. In Fig. 2, Δt_{con} and Δt_{mag} indicate the time interval for contact force analysis and magnetic force analysis, respectively. The magnetostatic interactions are recalculated when the magnetic field around the magnetic particles varies to some extent because of their displacement.

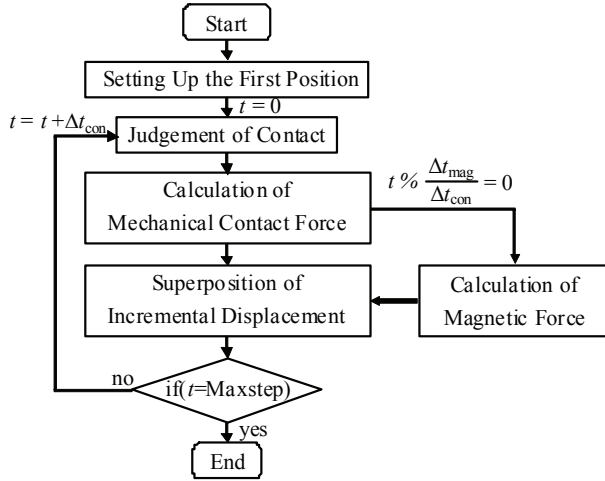

Fig. 2. Flowchart of behavior analysis of magnetic beads taking into account magnetic and contact force.

III. NUMERICAL RESULTS

Here, we investigate the model of 6125 magnetic beads with radius of 100 μm in the gradient magnetic field which is applied at $t = 0$ as a step function. The beads are enclosed in the rectangular solid space consisting of the wall with Young's modulus and Poisson's ratio of 100 GPa and 0.3, respectively. The volume density, relative permeability and Young's modulus of beads are 4900 kg/m^3 , 10.0, and 10 GPa, respectively. As for the time intervals, $\Delta t_{\text{con}} = 1.0 \times 10^{-7}$ s and $\Delta t_{\text{mag}} = 1.0 \times 10^{-5}$ s.

In this paper, we utilized the FMM based on diagonal forms for translation operators [1]. The orders of multipole and local expansions are 15 and 16, respectively. The

maximum order of exponential expansion for diagonal translation in the multipole-to-local conversion is 26.

The computational result at $t = 150$ ms is shown in Fig. 3 [3]. The figure indicates the beads' behavior reaches a steady state and the magnetic-bead chains are successfully simulated, which demonstrates the validity of the proposed method.

The comparison of CPU-time between the direct calculation and the proposed method with FMM is shown in Table I. All the computations were performed on a workstation with Xeon5365, 3.0 GHz, and 12 GB of RAM. The CPU-time in the table corresponds to the computational cost spent on magnetic force calculation for beads in a single step. The numerical value in a parenthesis stands for the CPU-time ratio of the direct calculation to the proposed method. In the case of more than about 5800 beads, the CPU-time reduction is achieved by using the proposed method, which concludes its effectiveness from the viewpoint of large-scale analysis of the magnetic beads' behavior.

Fig. 3 Chains of magnetic beads.

TABLE I
ELAPED TIME FOR BEHAVIOR ANALYSIS

Abstract — This paper proposes the dynamic analysis method of a linear resonance actuator with multi-movers under PWM (Pulse Width Modulation) feedback control employing the 3-D finite element method (FEM). The effectiveness of this method is shown by the comparison with the experimental results. Furthermore, the effect of a link-spring on each mover motion is clarified.

I. INTRODUCTION

Recently, linear resonant actuators (LRA) have been used in a wide range of applications because they have a lot of advantages; high efficiency, simple structure, easy control, and so on, however, they have a problem that the amplitude severely decreases in response to an external load. To control this, a feedback control is adopted where the back EMF of the coil is detected to control the current duty [1].

In this paper, we propose the numerical analysis method for predicting dynamic characteristics of LRA with two movers under PWM feedback control [2] employing the 3-D FEM. The effectiveness of the method is confirmed through the comparison with the measurement. And, the effect of a link-spring on each mover motion is clarified when a single mover is operated with load.

II. ANALYSIS METHOD

A. Magnetic Field Analysis

The equations of the magnetic field and the electric circuit are coupled using the 3-D FEM, which are given by the magnetic vector potential \mathbf{A} and the exciting current I_0 as follows:

$$\text{rot}(\nu \text{rot } \mathbf{A}) = \mathbf{J}_0 + \nu_0 \text{rot } \mathbf{M} \quad (1)$$

$$E = V_0 - RI_0 - \frac{d\Psi}{dt} = 0 \quad (2)$$

$$\mathbf{J}_0 = \frac{n_c}{S_c} I_0 \mathbf{n}_s \quad (3)$$

Where ν is the relativity, \mathbf{J}_0 is the exciting current density, ν_0 is the relativity of the vacuum, \mathbf{M} is the magnetization of permanent magnet, V_0 is the applied voltage, R is the resistance, Ψ is the interlinkage flux of exciting coil, n_c and S_c are the number of turns and the cross-sectional area of the coil respectively, \mathbf{n}_s is the unit vector along with the direction of exciting current.

B. Coupled Analysis with Motion Equation

This actuator is composed of two movers linked together, and the motion equations are given as follows:

$$M_1 \frac{d^2 z_1}{dt^2} + C_1 \frac{dz_1}{dt} + F_{k_1} = F_{z_1} \quad (4)$$

$$M_2 \frac{d^2 z_2}{dt^2} + C_2 \frac{dz_2}{dt} + F_{k_2} = F_{z_2} \quad (5)$$

Where M_1 and M_2 is the mass of movers, z_1 and z_2 are the displacement of movers, F_{z_1} and F_{z_2} are thrust, F_{k_1} and F_{k_2} are spring force, and C_1 and C_2 is the viscous damping coefficient.

Two movers are linked by link-springs described later, and the spring forces are given as follows:

$$F_{k_1} = k_m z_1 + k_l(z_1 - z_2) \quad (6)$$

$$F_{k_2} = k_m z_2 + k_l(z_2 - z_1) \quad (7)$$

Where k_m is main spring constant, k_l is link-spring constant.

The thrust of each mover is calculated using the Maxwell stress tensor method, and is substituted for the equations (4) and (5). The position of each mover is calculated by the time step. PWM feedback control is taken into consideration in this analysis. Fig. 1 shows the flowchart for this coupled analysis.

III. BASIC STRUCTURE AND OPERATING PRINCIPLE

The basic structure of the LRA in this study is shown in Fig. 2. This actuator mainly consists of two movers, a common

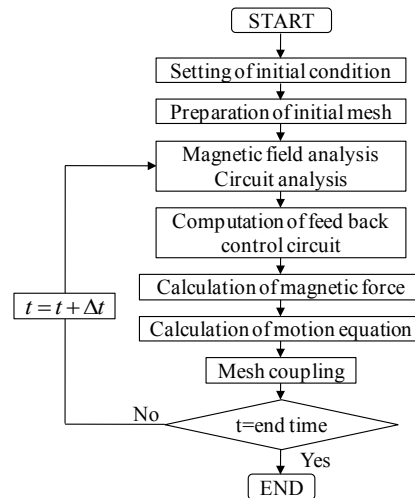

Fig. 1 Flowchart for analysis

stator and resonance springs that support the air-gap (0.36mm). Two parallelly arranged movers are composed of two opposite pole magnets fixed on the back yoke. The common stator is composed of E-type laminated yoke with an exciting coil of 68 turns at its midleg. The resonance spring is composed of main-springs and link-springs which link two movers. Two movers move to reverse direction by exciting the coil. The operation frequency of the LRA is substantially determined by the spring constant and the mass of the mover. This actuator is operated under PWM feedback control, and excitation time (duty) is decided by detecting the back EMF while the coil is not excited.

IV. VERIFICATION OF ANALYSIS METHOD

A. Analyzed Model and Condition

Fig. 3 shows the FEM model. The number of tetrahedron elements is about 670,000, the number of edges is about 790,000, and unknown variables are about 770,000. Table I shows the analysis conditions. The number of steps is 1,300, time division is 10μs, and total CPU time is about 300 hours.

B. Comparison Analyzed Results and Measured Results

Figs. 4 and 5 show the computed and measured waveforms of the amplitude, voltage, and current with no load. As can be seen, both results are well in good agreement, especially, influences of the back EMF and coil inductance on waveforms of voltage and current are accurately expressed, respectively.

V. EFFECT OF LINK-SPRING

This actuator has two link-springs in addition to main resonance springs which protect from the amplitude decreasing owing to the motion of the other mover when the amplitude of one mover is decreased by an external load. In order to verify the effect of link-springs, dynamic analysis is executed under the same conditions as no load. The horizontal load of 0.4N is applied to a single mover from the unloaded steady-state condition. Figs. 6(a) and (b) show the computed amplitude of unloaded and loaded movers without link-springs. From these figures, it is found that the amplitude of the loaded mover is greatly decreased by the load, and current duty is increased by the feedback control, and the amplitude of the unloaded mover is greatly increased.

Figs. 7(a) and (b) show the computed amplitude of unloaded and loaded movers with link-springs. From these figures, on the other hand it is found that a decrease in the amplitude of the loaded mover is controlled, and an increase in the amplitude of unloaded mover is also well controlled. As the results, the amplitude of both movers becomes steady and nearly the same.

From these results, it is clarified that link-springs are very effective in this LRA feedback control system.

VI. CONCLUSION

In this paper, we proposed the dynamic analysis method of a linear resonance actuator with multi-movers under PWM control employing the 3-D FEM. The effectiveness of this method was shown by the comparison with the measured

results. Moreover, the effect of link-springs on amplitude control was clarified.

New FEM Approach for Multi Physics Problems Modeling in EPM Applications

Y. Du Terrail Couvat, A. Gagnoud
SIMaP/EPM Laboratory
ENSEEG, BP 75, 38402 Saint Martin d'Herès cedex, France
Yves.duterrail@simap.grenoble-inp.fr

Abstract — A FEM modeling tool based on multi equations and multi meshes coupling is presented. Data Structures of a DBMS, allow to program and manage sequentially or simultaneously multiple meshes and systems for multiple FEM formulations of physical equations. Principles of mesh coupling for multi physics, for numerical zoom or for different kind of meshes interconnection are detailed. The specific FEM integration algorithm is improved for calculating interpolation relations between coupled regions. Some Electromagnetic applications are presented : strong coupling with induction heating and numerical zoom of eddy current region. A very good agreement of results compared with industrial codes shows the robustness of the proposed modeling. Drawbacks and advantages will be discussed.

I. INTRODUCTION

Electromagnetic Processes of Materials (EPM) systems are typically applications where multi physics problems are always present. Some new interesting ways of investigation appear in modeling coming from other physics thematic and from computer science. This is the case of using multiple, non conformal grids during the simulation as presented by C.Rome in fluid mechanics problems [1] or in domain decomposition techniques as presented by [2]. The topic concerned here is the extension of such methods to multi physics simulations, based on the superposition of different grids adapted to each physical phenomena. The originality of the work proposed here is to realize the coupling of such grids inside a unique matrix system in place of classical data file exchanges between multiple codes. It appears also that the multiple mesh coupling is interesting for other applications like:

- . modeling local problems with a numerical zoom technique (eddy currents, front tracking and segregation defaults during solidification, NDT,...),
- . movements of groups of objects during time (surface heat treatment, particles movements, bubbling,...)
- . connection between different meshes, mixing of different types of finite element.

We have developed a toolbox called AEQUATIO composed of a programmable DBMS, a mesh generator and a finite element solver which allows designing numerical simulators based on multi-equations and multi-mesh coupling.

II. METHODOLOGY

The general form of a PDE equation treated in AEQUATIO is a discretized finite element weak form equation in which each term is the following:

$$\int_{\Omega} C * L * W \quad (1)$$

where C is the coefficient expression constant or variable, for example a physical property, L is the Interpolation polynomial expression, and W the differential weight.

A. Multiple Mesh Coupling

Two methods of mesh coupling are implemented, one for local Zoom and one for multi-physics coupling. Meshes must be associated to one or more FEM weak form equations. Two different meshes are necessarily linked to two different equations.

1) Multi-physics coupling

Considering two or more physical equations, one can construct adapted meshes for each phenomenon with the mesh generator. All data for meshes are stored in virtual memory and accessible everywhere during the simulation process. The coupling between two meshes is done by localizing Gauss integration points of each finite element in the coupled corresponding regions. Localization data, which are the index of the containing element and the reduced coordinates in that element are stored in element data structure.

2) Non conformal mesh coupling

That technique is applied on two or more meshes for local refinement (called here numerical zoom) and also for object movement. A hierarchical rule is applied. For example a zone in a mesh 'M1' may be zoomed by a 'zooming mesh 'M2'. A zone in the latter can also be zoomed by a following higher level mesh 'M3', etc... The principal constraints imposed are that meshes must overlap. Their intersection cannot be a frontier, excepted on domain external boundaries. The coupling between two meshes 'M1' and 'M2' is done by localizing boundary nodes of zooming mesh 'M2' inside zoomed mesh 'M1' and localizing all nodes of 'M1' inside 'M2'. Localization data are stored in the node data structure.

B. Solver algorithms

The coupling between 2 meshes is always done by order 1 or 2 Lagrange interpolation techniques as in [1]. The general management of data matrices and vectors during system construction, and a general integration algorithm have been developed. Also, when boundaries are coupled, boundary nodes equations are replaced by the interpolation law on the coupled state variable. Integrant calculation which contains a coupling term concerning element e1 on 'M1' and element e2 on 'M2' is expressed as follows :

Do for each element $e1$
 Do for each Gauss integration point in the element $e1$
 Localize the integration point in coupling element $e2$
 Do for each node i of the element $e1$
 Do for each node j of the element $e2$
 Calculate integrant expression
 Store integrant value in i,j index of the local rectangular matrix
 end.

III. APPLICATIONS

A. Strong physical coupling in Induction Heating Process

A cylindrical iron ingot of 3 m high and 6 cm diameter is moving vertically inside a 2m high and 10 cm diameter cylindrical coil as represented in figure1. In AEQUATIO, 2 independent meshes are coupled for electromagnetic and thermal equations. For electromagnetism, Maxwell equations in harmonic axi-symmetric form and for thermal transfer Diffusion-transport equation have been coupled [4]. The strong coupling is due to the temperature dependency of electrical conductivity and to the eddy currents thermal sources. AEQUATIO results have been compared with Comsol Multiphysics [5] and Flux-Expert [3] codes (figures 1,2 and Table).

Fig. 1 Induction heating Device and multiple meshes

TABLE I: COMPARATIVE RESULTS

Models	Variables r^*AR max	Q max	T max

B. Numerical Zoom on eddy current region

The 2D Magneto dynamic equation expressed in complex vector potential Az is applied on a domain composed of a coil and a rectangular iron load. The interior border of the load is covered on conductor and air regions by a second mesh whose role is to zoom the skin depth region (see Fig 3). Comparisons are done with Comsol code and give excellent agreement (figure 4). Very fine skin depths may be reached with AEQUATIO.

IV. ADVANTAGES AND DRAWBACKS

As the general assembling of numerical integrants is done in a unique system matrix, Newton non linear algorithms may be used for strong coupling with different and adapted meshes for each physical phenomena. In the case of numerical Zoom, one controls easily the number of unknowns, some scale factors may be reached with hierarchical zooms, and movements of meshes may be introduced without changing the number of unknowns. Principal drawbacks are relative to the implementation of such algorithms on industrial codes and on the user interfaces for pre and post processing which have not been studied here.

Abstract—This paper applies the radial basis function (RBF) collocation method in the moving coordinate systems for the first time to analyze the eddy current magnetic fields and conductor motion in an electromagnetic repulsion mechanism. The magnetic field in the solving domain is considered a superposition of two fields created by the excitation current and eddy current respectively. The governing equations are decoupled with the RBF and solved with time domain iteration. Moving coordinate systems in which the separate fields are calculated are constructed to avoid the model reconfiguration and simulate the motion process. The influence of model parameters to the field and motion is analyzed. The numerical result agrees well with the experiment data.

I. INTRODUCTION

Efficient method to solve the eddy current problem with moving conductors has attracted much attention in engineering applications. This paper presents a novel radial basis function (RBF) collocation method in moving coordinate systems to compute the transient eddy current magnetic field in an electromagnetic repulsion mechanism. Motion process of the conductor in the mechanism is also analyzed and compared with the experiment data.

II. ELECTROMAGNETIC REPULSION MECHANISM

The electromagnetic repulsion mechanism could also be named as electromagnetic switch system and its rotational symmetry structure is shown in Fig. 1.

Fig. 1. Cross-section of the electromagnetic repulsion mechanism.

The switch is a round aluminium plate which could move along an insulated and nonmagnetic shaft. Two hollow cylinder-shaped excitation coils are wound with the same outer radius on the shaft to drive the motion. The millisecond level fast-rising excitation current in the coil is created by the discharge of a capacity. The time-variable magnetic field generates eddy current in the plate and force the plate to move

according to Ampere's force law. There is an initial 3000 (N) resisting spring force imposed by the shaft axle on the plate.

Because the upward and downward motions are driven by circuits with the same parameters, we only analyze the upward motion process excited by the coil below the plate. The numerical model could be simplified as a two dimensional problem. The model parameters of the solving domain are shown in Fig. 2.

Fig. 2. 2D numerical model of the electromagnetic repulsion mechanism. (Unit: mm)

The solving domain Ω is considered homogeneous and isotropic and with a boundary $\partial\Omega$. The cross-section of the plate, which is also the eddy current area Ω_e , is moving with a speed $\mathbf{v} = \mathbf{v}_y$. The initial distance between the plate and the coil is 3 (mm) and the required distance is 7 (mm). The vector potential A , excitation current density \mathbf{J}_s and eddy current density \mathbf{J}_e exist only in the z -direction. Assuming that $A = A_z$, $\mathbf{J}_s = \mathbf{J}_{sz}$ and $\mathbf{J}_e = \mathbf{J}_{ez}$, we could get the governing equations as:

$$\sigma\mu \frac{\partial A}{\partial t} - L(A) = \mu J_s \quad \text{in } \Omega_e \quad (1a)$$

$$\nabla^2 A = -\mu J_s \quad \text{in } \Omega_h \quad (1b)$$

$$A = 0 \quad \text{on } \partial\Omega \quad (1c)$$

where σ is the conductivity, μ is the permeability, $\Omega_h \in (\Omega \cap \overline{\Omega_e})$ and the operator $L(\cdot)$ means

$$\nabla^2(\cdot) - \sigma\mu v \frac{\partial(\cdot)}{\partial y}.$$

III. RBF COLLOCATION TIME DOMAIN ITERATION IN MOVING COORDINATE SYSTEMS

The theory of RBF collocation method could be seen in [1]. Consider $A = A_s + A_e$ and establish two coordinate systems ξ_s and ξ_e where the subscript s and e means the excitation current field and eddy current field respectively. In each coordinate system, $N_I + N_B = N$ collocation nodes are set in Ω and on $\partial\Omega$ to form the RBF. Specially, we assume that nodes $1 \cdots N_P$ are in Ω_e . Using RBF to approximate A_s and A_e in ξ_s and ξ_e , we get:

$$A(\mathbf{x}, t) = \mathbf{Q}_s^T(\mathbf{x})\mathbf{a}_s(t) + \mathbf{Q}_e^T(\mathbf{x})\mathbf{a}_e(t) \quad (2)$$

where \mathbf{Q} is the RBF vector and \mathbf{a} is the unknown coefficient vector. Time domain iteration is constructed to solve \mathbf{a}_s and \mathbf{a}_e . In ξ_s , A_s in Ω satisfies the Poisson equation everywhere. With a known J_s , we could solve \mathbf{a}_s from:

$$\nabla^2(\mathbf{Q}_s^T(\mathbf{x}_{si}))\mathbf{a}_s^{k+1} = \mu J_s^{k+1}(\mathbf{x}_{si}) \quad i = 1, \cdots, N_{Is} \quad (3a)$$

$$\mathbf{Q}_s^T(\mathbf{x}_{si})\mathbf{a}_s^{k+1} = 0 \quad i = N_{Is} + 1, \cdots, N_s \quad (3b)$$

where k means the iteration steps and we have $t_k = t_0 + k\Delta t$.

Consider \mathbf{x}'_e to be the coordinates of nodes of \mathbf{Q}_e in ξ_s . Substituting (2) and (3) into (1) and using Crank-Nicolson time matching scheme to deal with the time differential, we get:

$$\begin{aligned} & \left(\frac{\sigma\mu}{\Delta t} \mathbf{Q}_e^T(\mathbf{x}_{ei}) - \frac{1}{2} L(\mathbf{Q}_e^T(\mathbf{x}_{ei})) \right) \mathbf{a}_e^{k+1} = \left(\frac{\sigma\mu}{\Delta t} \mathbf{Q}_e^T(\mathbf{x}_{ei}) + \right. \\ & \left. \frac{1}{2} L(\mathbf{Q}_e^T(\mathbf{x}_{ei})) \right) \mathbf{a}_e^k - \left(\frac{\sigma\mu}{\Delta t} (A_s^{k+1}(\mathbf{x}'_{ei}) - A_s^k(\mathbf{x}'_{ei})) \right. \\ & \left. + \sigma\mu v^k \frac{\partial A_s^{k+1}(\mathbf{x}'_{ei})}{\partial y} \right) \quad i = 1, \cdots, N_{Pe} \quad (4a) \end{aligned}$$

$$\nabla^2(\mathbf{Q}_e^T(\mathbf{x}_{ei}))\mathbf{a}_e^{k+1} = 0 \quad i = N_{Pe} + 1 \cdots N_{Ie} \quad (4b)$$

$$\mathbf{Q}_e^T(\mathbf{x}_{ei})\mathbf{a}_e^{k+1} = 0 \quad i = N_{Ie} + 1 \cdots N_e \quad (4c)$$

During the motion, the RBF model in each coordinate system is unchanged.

IV. ANALYSIS OF EDDY CURRENT AND MOTION

On the basis of the magnetic field, the distribution of eddy current and driving force imposed by the magnetic field could be obtained to analyze the motion. The parameter v in each iteration steps could be solved with kinetic equations. Besides, the influence of the eddy current magnetic field to the excitation circuit parameters is computed to modify J_s . Motion processes with different model parameters are also analyzed for a further optimization design. Fig. 3 shows the distribution of eddy current density in the plate section at time $t=1$ (ms) from which we could see the skin effect clearly.

Fig. 3. Isopotential lines of eddy current density in the plate section at $t=1$ (ms).

We choose four observation points from Fig. 3 as: P1(30,0), P2(30,2.5), P3(30,5.0), P4(30,7.5) to analyze the variety of eddy current in different parts of the plate. The result is shown in Fig. 4.

Fig. 4. Time-variation curve of the current densities.

The motion process is shown in Fig. 5.

Fig. 5. Variation curve of the moving displacement of the plate.

Fig. 6 shows the influence of the initial voltage of the capacitor U_0 to the electromagnetic force of the plate.

E-mail: michele.forzan@unipd.it

Abstract — Scalar and vector magnetic formulations have been applied to solve the current distribution in a 50 Hz direct resistance heating system of ferromagnetic tubes. The scalar formulation driven via an external circuit has been also applied to solve the Time-Harmonic EM part of the problem coupled with the thermal transient: the computed warm up curves have been compared with experimental data.

I. INTRODUCTION

Direct resistance heating of steel tubes is industrially achieved by supplying strong 50 Hz currents directly to the workpiece by means of suitable contact systems. The current density distribution inside a straight tube depends upon the skin effect, while for bended tube it is influenced also by the ring effect. The thermal sources for the heating are the Joule losses, which depend on the square of the current density: consequently the unbalanced distribution of the current density due to the ring effect produces a significant overheating in the inner part of the curved zone. In previous investigations the possibility of balance the ring effect by means of properly designed laminated cores has been analyzed [1]. The proposed solution has been realized in a laboratory set-up and experimental measurements have been used to verify the reliability of the numerical models. Numerical models have been developed to solve the electromagnetic problem by means of 3D finite element solution: because there is only one conductor carrying the source current, the A-AV formulation has been implemented applying Dirichlet conditions for the scalar electric potential on the edges of the conductor. The solution of the EM problem has been also implemented by means of a magnetic scalar coupled with the electric vector potential formulation. This formulation reduces substantially the computational requirements so that also the 3D coupled electromagnetic thermal solution can be achieved in reasonable times. Moreover the scalar formulation can be more efficiently driven by an external electrical circuit, allowing to feed a constant current in the model instead of an applied voltage [2, 3]. Some comparisons between the results obtained by means of the A-AV formulation with the ones made with T-T₀- ϕ are presented as well as some comparisons between the computed temperature distribution and the experimental measurements resulting from some warm up processes carried out controlling the current intensity during the heating transients.

II. COMPUTATION MODELS

The model represents the laboratory set-up built in NSTU (Novosibirsk State Technical University) and it is constituted by a ferromagnetic tube, a laminated yoke and a thermal insulator that envelops the tube (fig.1).

Fig. 1. Schematic of the bended tube laboratory set-up. The ferromagnetic tube (red region) is surrounded by a thermal insulator (yellow). The C yoke, placed to minimize the ring effect, is represented by the green region.

Only a part of the real system has been considered, applying tangential magnetic field conditions on the boundaries, represented in Fig.2 by the red and green lines. On these boundary faces there are also the terminals of the tube conductor.

Fig. 2. On the left, the boundaries of the model are represented by the red and the green lines; the terminals of the conductive tube are located on the same boundaries. On the right the finite element model of the tube has been realized with a 3D mapped mesh to subdivide the skin depth layer.

As mentioned above, the electromagnetic solution, in particular the distribution of the current density inside the tube, has been obtained by means of two different numerical formulations. The magnetic vector potential \mathbf{A} coupled with the scalar electric potential V formulation leads to a very accurate solution for the current distribution, that can be obtained, in the hypothesis of a time harmonic field of angular frequency ω , directly from the solved nodal state variables:

8. Coupled Problems

$$\dot{\mathbf{J}} = -\sigma (j \omega \dot{\mathbf{A}} + \text{grad } \dot{V}) \quad (1)$$

where σ is the electrical conductivity and the dot over the \mathbf{A} , V potentials indicates the phasor representation. The model has been solved by applying a constant voltage drop between the two terminals of the tube. However, the vector formulation has some drawbacks: it requires huge computational resources, it badly describes the non linear magnetic properties when $\mu_r \gg 1$, and finally, when an iterative algorithm like Newton-Raphson is applied to non linear models, the computation time becomes very high and the convergence is usually poor. For these reasons, the electromagnetic solution has been obtained also by means of the $\mathbf{T}-\mathbf{T}_0-\phi$ formulation with an imposed current driven by an electrical circuit directly coupled with the FEM solver. The electric vector potential \mathbf{T} is defined since in quasi-static hypothesis the divergence of the current density must be 0; in this situation the current density can be computed from:

$$\dot{\mathbf{J}} = \text{rot } \dot{\mathbf{T}} + \text{rot } \dot{\mathbf{T}}_0 \quad (2)$$

and the field \mathbf{H} in the conducting region can be described as:

$$\dot{\mathbf{H}} = \dot{\mathbf{T}} + \dot{\mathbf{T}}_0 - \text{grad } \dot{\phi} \quad (3)$$

while in the air and the magnetic yoke, the field can be computed as the gradient of the scalar magnetic potential [3,4].

III. NUMERICAL AND EXPERIMENTAL RESULTS

The EM solutions obtained with the two different formulations have been compared, verifying the resulting current density distribution in the bended part of the tube.

Fig. 3. Comparison between the current distribution, normalized to the average value, as a function of the azimuthal position obtained with the A-AV formulation (continuous lines) and the $\mathbf{T}-\mathbf{T}_0-\phi$ formulation. The black lines represent the solution without yokes while the red curves are with the laminated yoke.

In fig.3 the current distribution is represented as the ratio between the averaged value and the actual values along a curvilinear path located in the central section of the bended zone. The two calculated distributions are in good agreement; it can be noticed that the current densities, resulting from the curl operation (2) applied on the \mathbf{T} values as resolved on a 2nd order mesh, presents an oscillation due to the derivative operation that is not performed when the A-AV formulation is applied.

The coupled electromagnetic and thermal solution has been done taking into account the dependence of the material properties, i.e. electric conductivity, magnetic permeability, thermal conductivity and specific heat with temperature, while the non linear magnetic property of the steel with magnetic field intensity has been considered constant to avoid the excessive computation time required by the non linear solvers. The EM-thermal solution has been performed with a classic iterative procedure, where the temperature distribution and the joule losses represent the coupling terms. The total transient period, 3600 s, has been subdivided into 40 time steps of 90 s. The entire solution required roughly 20 days of calculation on a Xeon X5355, 2,66 GHz, with 32 GB of RAM.

The numerical transient is compared with the experimental data in the diagrams of Fig.4.

Fig. 3. Comparison between computed thermal transient and experimental measurements. Experimental data are obtained from three thermocouples placed on the tube, as shown in the sketch in the right part of the figure. The same symbols indicate the measured temperature on the diagrams, while the numerical results are represented by lines. A fourth measured point, indicated with X, is located on the thermal insulator.

IV. CONCLUSIONS

The scalar formulation coupled with the circuit equations has been proved to be suitable for the solution of the electromagnetic part of a coupled magneto thermal problem, allowing a faster process in comparison with the one achievable by means of A-AV formulation. Nevertheless, the 3D coupled MT problem requires still a very long computation time: further investigations will be devoted to the development of a parallel solver that will allow a significant speedup of the calculation process.

Streamer Simulation based on Discontinuous Galerkin Method and Hierarchical Reconstruction

Chijie Zhuang*, Rong Zeng**, Bo Zhang, Shuiming Chen and Jinliang He
 State Key Lab of Power Systems, Department of Electrical Engineering,
 Tsinghua University, Beijing 100084, People's Republic of China
 Email: zhuangcj02@mails.tsinghua.edu.cn*, zengrong@tsinghua.edu.cn**

Abstract—This paper renders a discontinuous Galerkin method combined with hierarchical reconstruction to simulate the fluid model of streamer discharges. This method generates little numerical diffusion and oscillations. It is of high resolution and high order accuracy and hence suitable to simulate streamer discharges. A simulation of a parallel-plate discharge using 1.5 dimensional fluid model is presented as an example.

I. INTRODUCTION

Numerical simulations help scientists achieve a better theory on the physics of the streamer formation and propagation. The simplest fluid model for streamer discharges consists of two convection-diffusion-reaction equations coupled with a Poisson's equation[1]:

$$\begin{aligned} \frac{\partial n_e}{\partial t} + \frac{\partial(n_e v_e)}{\partial x} - D_e \frac{\partial^2 n_e}{\partial x^2} &= \alpha n_e |v_e| + S_{ph}, \\ \frac{\partial n_p}{\partial t} + \frac{\partial(n_p v_p)}{\partial x} &= \alpha n_e |v_e| + S_{ph}, \\ \Delta u &= -\frac{e}{\epsilon}(n_p - n_e), E = -\nabla u. \end{aligned}$$

where n_e and n_p are the density of electrons and positive ions, v_e and v_p are their velocity, respectively. D_e is the diffusion coefficient, α is the collision ionization coefficient and S_{ph} is the photo-ionization. u is the voltage and E is the electric field. ϵ is the dielectric coefficient and e is the net charge of a unit electron. v_e, v_p and α are locally decided by the electric field[2].

Due to the convection term in the streamer simulation model, traditional numerical schemes would often generate much numerical diffusions or oscillations and lead to non-physical results. Flux-corrected-transport(FCT) technique combined with finite difference method(FD-FCT) or finite element method(FEM-FCT), finite volume method(FVM) with slope limiters were introduced to overcome this problem[1], [3], [4]. But on the other hand, FD and FVM cannot handle complex geometries easily and need wide stencils to construct high order schemes; FEM does not enforce the local conservation which is preferred for convection problems.

Discontinuous Galerkin method(DG) can overcome these shortages[5]. It uses a finite element space discretization by discontinuous approximations and can easily handle complicated geometries. It incorporates the ideas of numerical fluxes and slope limiters from the high-resolution FD and FV schemes. The DG methods not only enforce the local conservation, but also are very compact. Combined with hierarchical

reconstruction(HR)[6], which can generate essentially non-oscillatory solutions while keeping the resolution and desired order of accuracy for smooth solutions, the resulting DG scheme is of high resolution and high order accuracy.

II. THE SCHEME

Take the following notations:

$$\begin{aligned} n &= (n_e, n_p)^T, f(n) = (n_e v_e, n_p v_p)^T, g(n) = (D_e n_e, 0)^T, \\ q &= g_x, h(n) = (\alpha n_e |v_e| + S_{ph}, \alpha n_e |v_e| + S_{ph})^T. \end{aligned}$$

The convection-diffusion-reaction equations read:

$$n_t + (f - q)_x = h, q = g_x. \quad (1)$$

A. Space discretization

Suppose $I_j = (x_{j-1/2}, x_{j+1/2}), j = 0, 1, 2, \dots, N$, is a partition of the computational domain, $\Delta x_j = x_{j+1/2} - x_{j-1/2}$. The finite-dimensional computational space is

$$V = V_h^k = \{\psi : \psi|_{I_j} \in P^k(I_j)\},$$

where P^k denotes the polynomials of degree up to k defined on I_j . We choose Legendry Polynomials as the basis functions and re-scale them over $[-1, +1]$:

$$v_0^{(j)} = 1, v_1^{(j)} = \xi, v_2^{(j)} = 0.5(3\xi^2 - 1),$$

where $\xi = 2\frac{x-x_j}{\Delta x}$. The numerical solution can be written as:

$$n^h(x, t) = \sum_{i=0}^2 n_i^{(j)} v_i^{(j)}, \text{ for } x \in I_j.$$

Multiply equation (1) by a test function $\psi \in V_h^k$, integrate by parts, replace n, q by n^h, q^h , and choose suitable numerical flux \hat{f}, \hat{q} at the interface $x_{j+1/2}$, one gets:

$$\begin{aligned} \int_{I_j} n_t^h \psi dx - \int_{I_j} (f(n^h) - q^h) \psi dx + (\hat{f} - \hat{q})_{j+1/2} \psi_{j+1/2}^- \\ - (\hat{f} - \hat{q})_{j-1/2} \psi_{j-1/2}^+ = \int_{I_j} h(n^h) \psi dx, \quad (2) \end{aligned}$$

$$\int_{I_j} q^h \psi dx = \hat{g}_{j+1/2} \psi_{j+1/2}^- - \hat{g}_{j-1/2} \psi_{j-1/2}^+ - \int_{I_j} g(n^h) \psi_x dx. \quad (3)$$

where $-$ and $+$ means the left and right side values of the interface, respectively. Numerical flux \hat{f} is chosen according to the upwind principle because the directions of v_e and v_p are

easy to obtain. \hat{q} and \hat{g} are chosen according to the alternating principle.

In fact, the solutions are allowed to have jumps at the interface $x_{j+1/2}$, the cell size Δx_j and degree k can be changed from element to element, which leads to easy adaptivity.

B. Time discretization

Locally solve the auxiliary variable q in equation (3) from element to element, and substitute it into equation (2), one gets an ODE:

$$\frac{dn^h}{dt} = L(n^h) \quad (4)$$

For most cases, equation (1) is convection dominated, an explicit Total Variation Diminishing 3-order Runge-Kunta scheme can be used to solve the ODE[7].

$$\begin{aligned} n^{(1)} &= n^n + L(n^n)\Delta t, \\ n^{(2)} &= \frac{3}{4}n^n + \frac{1}{4}(n^{(1)} + L(n^{(1)})\Delta t), \\ n^{(3)} &= \frac{1}{3}n^n + \frac{2}{3}(n^{(2)} + L(n^{(2)})\Delta t), \\ n^{n+1} &= n^{(3)}. \end{aligned} \quad (5)$$

C. Hierarchical reconstruction

HR computes cell averages of various orders of derivatives of a polynomial, and uses them to reconstruct the non-oscillatory linear polynomial hierarchically. The coefficients of the reconstructed polynomial are used to update the corresponding ones of the original polynomial, see [6] for details. The HR process is applied after every sub-step of the Runge-Kunta scheme. In this way, the scheme guarantees non-oscillatory results.

III. APPLICATION

A simulation of a positive streamer was performed in pure N_2 at atmospheric pressure using 1.5D fluid model. Two infinite large parallel plate electrodes are placed perpendicular to the axis of symmetry. The origin of the cylindrical coordinates is located at the anode. The applied voltages on the anode($x=0$ cm) and cathode($x=1$ cm) are 52 kV and 0, respectively. The charges are assumed to uniformly distributing on a disc perpendicular to the axis of symmetry[8]. The disc radius is assumed to be 0.05 cm. The initial charge has a gaussian shape:

$$n_e(x)_{t=0} = n_p(x)_{t=0} = n_b + n_0 \times \exp\left(-\left(\frac{x-x_0}{\sigma_x}\right)^2\right),$$

where $x_0 = 0.03$ cm, $\sigma_x = 0.027$ cm, $n_0 = 10^{14}$ cm $^{-3}$, and S_{ph} is simplified by the background preionization $n_b = 10^8$ cm $^{-3}$. Neumann boundary conditions are applied for the convection-diffusion equations. The Poisson's equation is solved by the disc method[8].

Fig.1 shows that the electric field in front of a streamer is severely enhanced and is more than 100kV/cm. The streamer propagation velocity is about of the order of 10^8 cm/s. Fig.2 shows that there is a thin layer about 0.1mm thick at the head of a stream, which has a larger net charge density, and the

Fig. 1. electric field distribution along the axis

Fig. 2. net charge distribution along the axis

net charge density is of the order of 10^{-6} C/cm 3 . The sharp gradient of charge density profile was caught by the proposed scheme well.

Abstract — In this paper, the problem of magnetic buoyancy force on nonmagnetic solid object submerged in magnetic liquid is presented and discussed. It is shown that there are contradictions in the understanding and calculation of the buoyancy force using only the conventional Maxwell stress. On the other hand, the approach of Rosensweig's ferrohydrodynamics was also criticized by Rinaldi. For the calculation of buoyancy force of the submerged nonmagnetic object, a new approach of hydrostatic equilibrium considering magnetic body force is proposed.

I. INTRODUCTION

As in Fig. 1, a mutual repulsion force, which is generated between a magnet and a nonmagnetic object when they are submerged in magnetic liquid, is presented. The mutual force is not due to a direct interaction between the two bodies; the force arises because of the magnetic fluid attracted into the space between them. In the previous work [1] by Rosensweig, a magnetic force expression of the nonmagnetic body based on ferrohydrodynamics, including the gravitational effect, was presented. He recognized, though, the fact that there is an arbitrariness of the grouping of magnetic terms in his derived expressions [2] and there have been controversies and confusions for the magnetic force distribution for a hundred years. In a recent research by Rinaldi [3], an assertion, in which Maxwell stress is not a true mechanical stress, was shown and the Rosensweig's electromagnetic force derivations and applications of those were strongly criticized.

In Fig. 2, a hydrostatic model is presented for numerical study and discussion. In this model, a nonmagnetic solid object (solid-A) is submerged in a magnetic liquid subjected to non-uniform magneto-static field. Solid-A has a slightly bigger mass density than that of the magnetic liquid. Solid-A sinks to the bottom of the vessel when there is no permanent magnet under the vessel. On the other hand, if a magnet is put under the vessel, solid-A soars to the height at which the hydrostatic equilibrium is satisfied. Firstly, let's consider this model using only the conventional Maxwell stress. If we choose a closed integral surface path inside solid-A, which has air permeability, for the magnetic force calculation, the result is obviously negligible because there is no magnetic material within the closed surface. If we adopt the alternative point of view in which the integral path is taken on the magnetic liquid surface adjacent to solid-A for the calculation of pushing force, the path is, consequently, the same as the previous one except

the surface-normal direction. This also leads to a meaningless force value because the integration of this is just negative to that of solid-A. Here, there is another conceptual hole in Maxwell stress approach. From a mechanical viewpoint, the total magnetic buoyancy force should be the summation of solid-A's force itself and the pushing force of the magnetic liquid. As seen above, the summation is simply zero because of the opposite integration value. That is, the approach using only the Maxwell stress fails in explaining the mechanics of the magnetic buoyancy force of solid-A. This conclusion also supports the Rinaldi's assertion.

For evaluating the buoyancy force, in this paper, a new approach of hydrostatic equilibrium with consideration of magnetic body force [4] is presented. By using the magnetic body force, the above mentioned criticism can be avoided; not using the Maxwell stress itself but using an equivalence of divergence of the Maxwell stress tensor. For calculating the net uprising force, both of gravitational forces of the magnetic liquid and the solid-A should be considered as well as magnetic body force of the liquid. The proposed hydrostatic approach is made relatively simple than that of Rosensweig because both gravitational and magnetic body forces are dealt with in a same way. If the integration of hydrostatic pressure on the surface of solid-A, which makes the upward buoyancy, is bigger than gravitational downward force of solid-A, the net uprising force can be obtained. As well as detailed hydrostatic procedure, experimental and numerical tests will be presented in the full paper.

Fig. 1. Mutual repulsion of a magnet and a nonmagnetic object when both are submerged in a magnetic fluid.

II. HYDROSTATIC APPROACH WITH BODY FORCE

The momentum equation of hydrodynamics including magnetic body force is as follows,

$$\rho \frac{D\mathbf{v}}{Dt} = -\nabla \cdot \mathbf{T}_{mech} + \rho \mathbf{g} + \eta \nabla^2 \mathbf{v} + \mathbf{f}_m \quad (1)$$

where D/Dt is the substantial or Lagrangian derivative which is defined to trace the liquid motion, ρ is mass density of the liquid, \mathbf{v} is velocity of motion, \mathbf{T}_{mech} is mechanical stress tensor, \mathbf{g} is acceleration vector of gravity, η is viscosity, and \mathbf{f}_m is the magnetic body force. By applying the virtual air gap scheme to the Kelvin's formula [4][5], the magnetic body force can be expressed as

$$\mathbf{f}_m = \frac{\mu_0 + \mu}{2} (\mathbf{M} \cdot \nabla) \mathbf{H} \quad (2)$$

where \mathbf{M} is magnetization and \mathbf{H} is total field intensity. This force density can be regarded as an equivalence of divergence of Maxwell stress tensor. When the liquid is in static state, the hydrostatic momentum equation is reduced to,

$$\nabla p = \rho \mathbf{g} + \mathbf{f}_m \quad (3)$$

where p is the isotropic mechanical pressure with the relation of $\nabla \cdot \mathbf{T}_{mech} = \nabla \cdot p \mathbf{I} = \nabla p$. From (3), a pressure on the surfaces of solid-A can be obtained as follows,

$$p = \int_{L_0}^L (\rho \mathbf{g} + \mathbf{f}_m) \cdot d\mathbf{l} + p_0 \quad (4)$$

where L_0 is an arbitrary fixed position on the free surface of the liquid, p_0 is the atmospheric pressure, L is a position on the surfaces of solid-A [6]. By integrating the pressures along the surfaces of solid-A, total buoyancy force, which is generated by the liquid, can be obtained with consideration of both gravity and magnetic field. Finally, the net uprising force can be obtained by subtracting the weight of solid-A from the total buoyancy force. The assumptions used in this model are two-dimensional geometry, incompressibility of the liquid, neglecting the deformation of the free surface, and material linearity.

By applying the density of the magnetic liquid as 1 g/cm^3 , that of nonmagnetic object as 1.1 g/cm^3 , and the paper normal depth as 1 m , the final net uprising force is calculated as 2.8 N in the specified height from the bottom of the vessel. This resultant value means that the equilibrium height will be higher than the specified position. The final floating height

can be obtained iteratively. At the equilibrium height, the net uprising force should be zero. In Fig. 3, the calculated magnetic body force distribution in the magnetic liquid is shown.

Fig. 2. A hydrostatical model: non-magnetic solid object submerged in magnetic liquid subjected to non-uniform magneto-static field produced by a magnet under a vessel. The field was solved by a finite element analysis.

Fig. 3. Magnetic body force distribution using Kelvin's formula and virtual air gap scheme.

Abstract – For reactive power compensation of EHV/UHV lines, the controllable reactor has more advantages than the fixed value reactor. Among various controllable reactors schemes, the orthogonal flux type controllable reactor is remarked for its low harmonics and fast response time. In this paper, to verify the performance of the controllable reactor, we present an efficient approach for the field-circuit co-simulation of such controllable reactors using Integral Equation Method (IEM) and Simulink.

The indirect coupling procedure is based on exchanging of source variables i.e. current and voltage sources between field IEM simulation and Simulink based circuit simulation. With this method, the dynamic behavior of the controllable reactor can be simulated and analyzed with more accuracy. By using this co-simulation approach, the more complex system level simulation can be applied by using accuracy field model.

The field model of the controllable reactor is established firstly by IEM method and the circuit model is established in the Simulink environment. The simulation results are compared with the results obtained by mathematical model of the controllable reactor.

I. CONTROLLABLE REACTORS

In most of the existing power system, the switchable low voltage reactors/capacitors on tertiary winding of transformer or SVC are used to regulate the voltage, and the temporary over-voltage suppression widely adopts line shunt reactor, which is a fix value reactor. The appearance of controllable reactor gives an alternative of normal shunt reactor, as shown in Fig. 1. As the substitute of line shunt reactor, the functions of controllable reactor are 1) voltage regulation, 2) temporary over-voltage suppression and 3) dynamic voltage support.

Fig. 1 The controllable reactor in the power system

In this paper, the orthogonal flux type controllable reactor^[1] is employed for the co-simulation, which is a kind of saturable reactor with 2 windings: AC winding (main winding), and DC winding (control winding). The respective DC flux and AC flux of the windings are orthogonal in the iron core of the controllable reactor. The equivalent circuit of the controllable reactor is as shown in Fig. 2, where U_{AC} is the input AC voltage of the main winding and I_{AC} is the AC current; U_{DC} is input DC voltage of control winding and I_{DC} is the DC current.

Fig. 2 The equivalent circuit of the controllable reactor

In this paper, the field-circuit co-simulation of such controllable reactors using Integral Equation Method (IEM)^[2] is presented. The filed simulation model considers the impact of the non-linear magnetizing behavior of the iron core and the leakage flux and thus is a closer approximation to the physical model. By coupling this field simulation model with the power system circuit model, the performance of the controllable reactor can be verified with higher accuracy and the parameters of the controllable reactor can be optimized.

II. THE FIELD SIMULATION MODEL OF THE CONTROLLABLE REACTOR

The characteristic of controllable reactor is achieved by the control of the saturation level of the “control discs” in the reactor’s central limb. Fig. 3(a) shows the structure of controllable reactor with air-gaps between the control discs and uncontrolled discs. By adding air-gaps, the control range can be adjusted and thus decrease the total cost of the controllable reactor. The main reactor coil is excited by the AC voltage. The control discs are excited by the auxiliary DC coils wound around each of them. The structure of the control disc is shown in Fig 3(b).

(a) The structure of controllable reactor (b) the control disc
Fig. 3 Structure of the controllable reactor with air-gaps between the discs

III. COUPLING MECHANISM

A. The coupling of the softwares

The circuit model in Simulink is based on the state space approach. The transmission line, the generators and the loads are described in the circuit model by the SimPowerSystem

blocks in the Simulink. The field model described by IEM is presented as a function block, in which the currents of the main winding and control winding of the controllable reactor are the input variables, which are measured from the circuit model; the voltage of the main winding and control winding (the EMF values) are calculated by the IEM and returned as output variables. The structure diagram of the co-simulation is shown in Fig. 4.

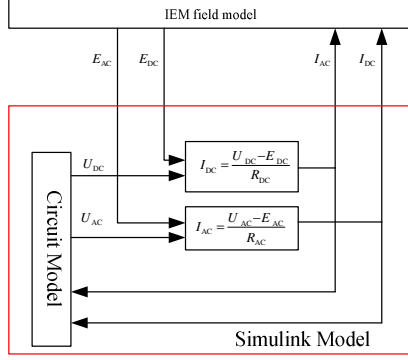

Fig. 4 The structure diagram of co-simulation

B. The Data Transfer

The input and output data that transferred between Simulink and IEM software are exchanged by ASCII format files. The data transfer mechanism can be described as follows:

At the beginning simulation time $t_0 = 0$, outputs of IEM field model are initialized as $E_{AC}^{(0)} = 0$ and $E_{DC}^{(0)} = 0$; the output variables of the Simulink are initialized as $I_{AC}^{(0)} = 0$ and $I_{DC}^{(0)} = 0$. At the time $t_1 = t_0 + \Delta T$, where ΔT is the simulation time step, the output variables of the Simulink $I_{AC}^{(1)}$ and $I_{DC}^{(1)}$ are calculated as:

$$\begin{cases} I_{AC}^{(1)} = \frac{U_{AC}^{(1)} - E_{AC}^{(0)}}{R_{AC}} \\ I_{DC}^{(1)} = \frac{U_{DC}^{(1)} - E_{DC}^{(0)}}{R_{DC}} \end{cases} \quad (3.1)$$

where R_{AC} and R_{DC} are the resistance of the main winding and control winding respectively.

The output variables $E_{AC}^{(1)}$ and $E_{DC}^{(1)}$ of the IEM field model at time t_1 are calculated as:

$$\begin{cases} E_{AC}^{(1)} = n_{AC} \frac{\Phi_{AC}^{(1)} - \Phi_{AC}^{(0)}}{\Delta t} \\ E_{DC}^{(1)} = n_{DC} \frac{\Phi_{DC}^{(1)} - \Phi_{DC}^{(0)}}{\Delta t} \end{cases} \quad (3.2)$$

Where n_{AC} and n_{DC} are the turns number of the main winding and control winding respectively; Φ_{AC} and Φ_{DC} are the AC flux and DC flux respectively.

By employing the calculation procedure in (3.1) and (3.2) at each time steps, the co-simulation can be carried on. The detailed co-simulation diagram is shown in Fig. 5.

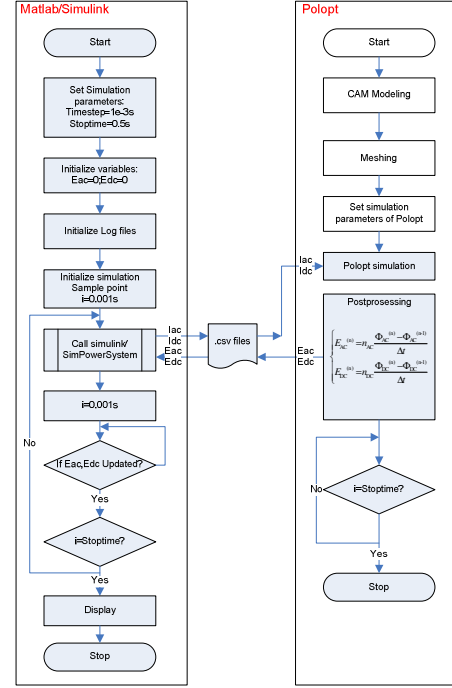

Fig. 5 The detailed co-simulation diagram

IV. APPLICATION EXAMPLES

A. The co-simulation results

The example is a 500kV/50MVA single phase controllable reactor with control system. The circuit diagram of the controllable reactor for the co-simulation is shown in Fig. 6. The breaker will trip the line when fault occurs at the load side, and the resulting overvoltage of the line caused by the load rejection will be suppressed by the controllable reactor, which is simulated by the IEM model.

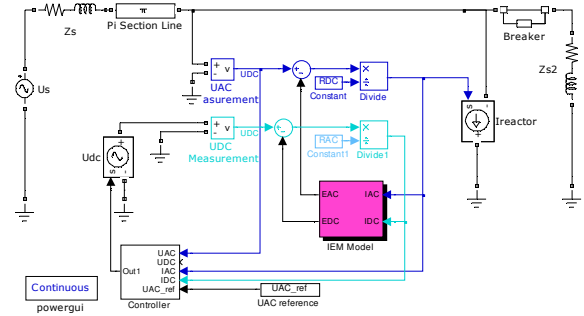

Fig. 6 Circuit diagram of 288kV/50MVA controllable reactor in the transmission grid system

Detailed co-simulation results will be presented in the full paper.

Abstract — This paper presents a steady and transient analysis for magnetic and thermal field of induction machines (IM). The electromagnetic performances, such as magnetic field distribution, winding current and eddy currents flowing in conductor bars, are simulated by using field-circuit coupled method. The losses including of core loss, conducting loss of windings and rotor bars are evaluated during startup and steady operation. Excited by the losses, the transient and steady thermal fields are investigated by using finite volume method (FVM). The axial structural meshing is applied to simulate the temperature rise under ventilation case. The simulated electromagnetic performances and temperature rise are validated by experiment. The thermal field distribution of induction machine at both startup and steady states are discussed.

I. INTRODUCTION

The thermal conditions of induction machine (IM) are one of the main factors that limit the lifetime and the reliability of IM. Thermal analysis is very important for electrical machine designing, manufacturing, fault diagnosis and detection. One of the most effective methods to estimate the IM heating process is with the help of an equivalent thermal circuit, in which an IM is simulated as a system of heat sources that are interconnected to each other and connected to the environment by means of thermal conductivities [1]. A transient 2-D thermal analysis of switched reluctance motor by Finite Element Method (FEM) has been presented in [2], in which some thermal parameters are obtained by measurement.

The electromagnetic losses play a very important role as the sources of the temperature rise of electrical machines. Precise electromagnetic analysis of induction machines is necessary during steady and startup operation. FEM coupled with drive circuit is a powerful method to calculate the electromagnetic field distribution and the electromagnetic losses.

In this paper, the time-step field-circuit coupled method is applied to analysis of the electromagnetic field and current distribution of IM during startup and steady operation. The transient and steady thermal field is calculated by FVM after determination of the conduction and the convective heat transfer coefficients.

II. ELECTROMAGNETIC FIELD ANALYSIS OF IM

A two-dimensional (2D) FEM is applied for the IM, where the magnetic vector potential has only the z -component.

The Maxwell's equations applied to IM can be expressed as

$$\nabla \cdot (\nu \nabla A) - \sigma \frac{\partial A}{\partial t} + \frac{d_f N_f}{S_f a p} i_f + \frac{d_f a \sigma}{N_f l} u_{bar} = 0 \quad (1)$$

where A is the component of magnetic vector potential in the z axis, ν is the reluctivity of materials. i_f is the winding current, S_f is the total cross-sectional area of the region occupied by this winding in the solution domain, p is the symmetry multiplier which is defined as the ratio of the original full cross-sectional area to the solution area, d_f is the polarity to represent forward path or return path, a is the number of parallel branches, and N_f is the total conductor number. u_{bar} is the voltage difference between the terminals of solid conductor, and l is the model depth in the z axis.

The branch equations of the stranded windings and solid conductors are coupled with field equations. The loop method is applied to describe the circuit equations of the stranded windings, the solid conductors and the external circuits. The currents flowing in stranded winding and solid conductors are regarded as branch currents which may be expressed as a function of loop currents according to KCL. In loop method, the variables are chosen as loop current.

From above the field-circuit coupled equation can be established. The magnetic vector potentials of the nodes and the loop currents are chosen as unknowns.

The air gap of IM is re-meshed at each time step and the electromagnetic torque is calculated by using the Maxwell stress tensor. The angular speed and the rotor displacement at each time interval can be determined.

Core loss is evaluated by a traditional loss calculation approach. Because the current density is not uniform over the cross-section of the rotor bar, the loss on the rotor bar is expressed as the volume integration of current density of rotor bars.

III. THERMAL FIELD ANALYSIS USING FVM

Considering the computational accuracy and complexity of thermal field, the thermal model of IM such as end cover, end winding, end ring, bearing and shaft, etc., should be simplified. Fig. 1 illustrates the axial simplified models of IM.

Fig. 1. Axial model of induction motor

The heat conductivity and convective heat transfer coefficients are determined by ventilation calculation and the bearing losses are evaluated. Those will be presented in detail in full paper.

In cross-section of the IM, the same triangular meshes are used in both electromagnetic FEM and thermal FVM. The structure grid is constructed in axial direction and an equivalent thermal circuit is applied to calculate the axial temperature distribution.

In FVM, the discrete equation is an integration of the conservation heat transfer equation over each control volume. In this paper, cell-centered method is used. For triangular mesh, the control volume is regarded as the element, also called the cell. The discrete temperature equation associated with one cell is expressed as

$$a_o T_o = \sum_{i=1}^3 a_i T_i + b_o \quad (2)$$

where, a_o and a_i are the convection and diffusion coefficients of a cell center and its adjacent points. b_o is the source associated with electromagnetic losses. T_o and T_i are temperatures of this cell center and its adjacent points. The boundary condition will be presented in full paper.

IV. STEADY AND TRANSIENT ANALYSIS OF ELECTROMAGNETIC-THERMAL FIELDS FOR IM

The simulation code of steady and transient coupled magnetic and thermal fields for IM is carried out. Due to the different time constants between the electromagnetic and the thermal systems, during every predefined time interval which including several time steps in electromagnetic computation, the thermal analysis is executed once.

A 3-phase four-pole asynchronous generator, a kind of IM, is used to evaluate the developed simulation code. The rated output power is 750 kW, the output voltage is 690 V and the frequency is 50 Hz. The finite element mesh is shown in Fig. 2. Fig. 3 pictures the current flowing in one rotor bar. The magnetic field distribution at startup operation is illustrated in Fig. 4 and the steady losses are shown in Fig. 5. Fig. 6 (a) and (b) show the temperature rise distributions at both startup and steady operations.

The axial temperature rise distribution is pictured in Fig. 7. The simulated temperature rise of stator winding, 106.4°C, is much closed to experimental result, 104.2°C, at steady operation. More simulation results and evaluation of developed code will be presented in full paper.

V. CONCLUSION

This paper develops a simulation code of electromagnetic-thermal field for IM. The transient electromagnetic losses are

calculated by FEM and temperature distribution is computed by FVM and equivalent thermal circuit. The simulation temperature rise of stator winding is verified by experimental ones. The temperature rise of the rotor bars is great than that of other parts at startup operation. At steady operation, the stator windings possess the greatest temperature rise. The detailed discussion will be presented in full paper.

Abstract — This paper deals with a coupled analysis method of electromagnetic-structural-acoustic coupled fields for flat panel speaker driven by giant magnetostrictive materials (GMM) transducer using finite element method (FEM). This method is applied to predict the sound pressure level (SPL) of flat panel speaker at audio frequency. The validity of the analysis method is verified by the measurement of a prototype.

I. INTRODUCTION

Giant Magnetostrictive Materials came to attract attention because of great magnetostriction, strong force, high response speed and so on [1]. Recently, the flat panel speaker system driven by this smart material based transducer has been released. Whereas other standard speaker systems with enclosure create acoustic field, which only spread forward, one of the obvious advantages of speaker system like this is creation of 360-degree acoustic field by vibrating a rigid panel with a GMM transducer. However, by vibrating a rigid panel as principle of operation, it is difficult to optimize the SPL at audio frequency range. The SPL relies on the vibration of rigid panel occurred by GMM transducer, it is necessary to grasp not only the vibration of GMM transducer and rigid panel but also acoustical phenomenon at a time.

In this paper, we present the numerical analysis method of electromagnetic-structural-acoustically coupled system at frequency domain employing FEM. Moreover, the validity of the analysis method is verified through the comparison with the measurement of a prototype.

II. THEORY

A. Magnetic field analysis

The governing equation of the magnetic field can be indicated in frequency domain as follows

$$\text{rot}(\dot{\nu} \text{rot } \dot{A}) = \dot{J}_0 + \dot{J}_e = \dot{J}_0 - \sigma(j\omega \dot{A} + \text{grad } \dot{\phi}) \quad (1)$$

where $\dot{\nu}$ is the magnetic reluctivity, \dot{J}_0 is the exciting current density, \dot{J}_e is the eddy current density, σ is the electric conductivity, ω is the angular frequency, \dot{A} is the magnetic vector potential and $\dot{\phi}$ is the electric scalar potential. Dot ($\dot{\cdot}$) means complex number.

B. Structure analysis

For the modeling of vibration of GMM transducer and panel, the following equation of motion is used.

$$\nabla \cdot (\mathbf{T}_{mech} + \mathbf{T}_M) + \mathbf{b}_{mech} = \rho \frac{d^2 \mathbf{u}}{dt^2} \quad (2)$$

Where \mathbf{T}_{mech} is the stress tensor induced by deformation, \mathbf{T}_M is the Maxwell stress tensor, \mathbf{b}_{mech} is the mechanical body force, ρ is the mass density and \mathbf{u} is the displacement vector. Since GMM are magnetizable magnetic materials, \mathbf{T}_M can be described as [2]

$$\mathbf{T}_M = \mathbf{H} \otimes \mathbf{B} - \frac{\mu_0}{2} (\mathbf{H} \cdot \mathbf{H}) \mathbf{I} \quad (3)$$

where \mathbf{H} is the magnetic field intensity, \mathbf{B} is the magnetic flux density, the operator \otimes is the dynamic tensor product, μ_0 is the permeability matrix of vacuum and \mathbf{I} is the unit matrix.

C. Constitutive equations of GMM [3]

Although the constitutive equations that describe the phenomenon of magnetostriction are nonlinear formulation, they can be approximated to linear system under small changes of electromagnetic and mechanical quantities. The linearized constitutive equations of GMM can be expressed in the d -type form as follow

$$\mathbf{S} = \mathbf{s}^H \mathbf{T}_{mech} + \mathbf{d}^T \mathbf{H} \quad (4)$$

$$\mathbf{B} = \mathbf{d}^T \mathbf{T}_{mech} + \boldsymbol{\mu}^T \mathbf{H} \quad (5)$$

where, \mathbf{S} is the strain tensor, \mathbf{s}^H is the compliance matrix, \mathbf{d} is the magneto-mechanical coupling coefficient, $\boldsymbol{\mu}$ is the permeability and the superscript 't' indicates the transpose of the matrix. The superscript H and T mean that the value inside the matrix reflects condition under constant.

D. Acoustic field analysis

In this analysis, to deal with the structure-acoustic coupled field, the Eulerian approach [4] is used that the governing equation can be written as a wave equation in terms of pressure. In this case, the governing equation of the acoustic field can be indicated using Helmholtz equation as

$$\nabla \cdot \left(-\frac{1}{\rho_0} \nabla \mathbf{P} \right) - \frac{\omega^2 \mathbf{P}}{\rho_0 c^2} = 0 \quad (6)$$

where ρ_0 is the fluid density, \mathbf{P} is the pressure, c is the speed of sound and ω is the angular frequency.

III. ANALYSIS MODEL AND CONDITIONS

A. Analysis Model

The structure of GMM transducer is shown in Fig. 1. The transducer mainly consists of two GMM rods (TDK, PMT-1, $\phi 5$ -mm and 14-mm length), permanent magnet (Ferrite, 0.4T, supplying 18kA/m bias magnetic field to GMM rods) and

wound coil of 700 turns for driving. As a rigid panel, $\phi 200$ -mm and 1.5-mm thickness aluminum panel is used. Because these structures are axial symmetric, the analysis is conducted using 2-D axial symmetric model. Fig. 2 shows the entire analyzed model including air domain for SPL calculation. The air domain extends to one meter around panel and perfectly matched layer (PML) is constructed around the outside of the fluid domain for avoiding the reflection of sound pressure.

The input voltage is 1 V, in the frequency range from 400 Hz to 20 kHz. The discretization is listed in Table I.

Fig. 1. Structure of GMM actuator.

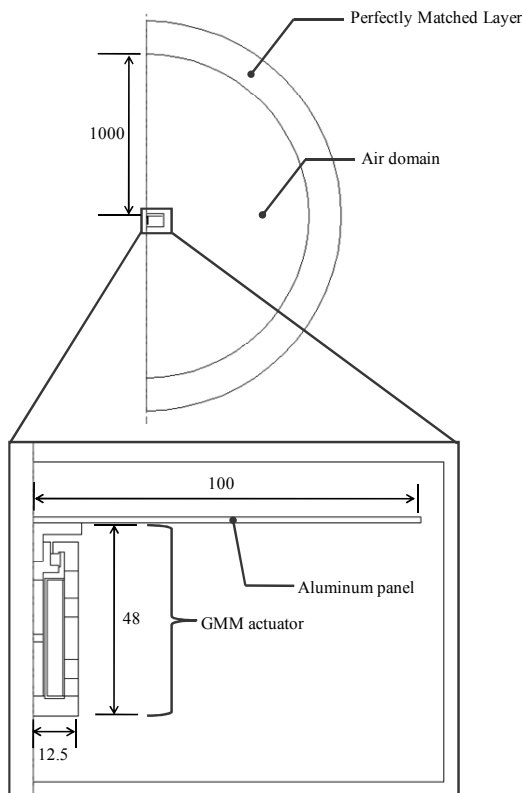

Fig. 2. Analyzed model.

DISCRETIZATION AND CPU TIME

Number of elements	402, 943
Number of nodes	201, 893
CPU time (hours)	2.5

Used computer: Xeon (3.0 GHz)

IV. VERIFICATION BY MEASUREMENT

The SPL measurement of flat panel speaker driven by GMM transducer is conducted in an anechoic room. The input AC voltage for driving the speaker is 1 V (peak-to-peak), and the frequency range is swept from 400 Hz to 20 kHz as well as analyzed conditions. Fig. 3 shows the SPL comparison positions between analysis and measurement. Fig. 4 shows the comparison results between analysis and measurement at above positions. As can be seen, analyzed results agree well with the measured ones.

Abstract—Due to increasing levels of the fault currents, Fault Current Limiters (FCLs) are expected to play an important role in protection of future power grids. Inductive saturable FCL are particularly interesting due to their inherent reaction on the fault. Many different configurations have been proposed in literature. Being difficult or impossible to create accurate analytical models of some FCL configurations, the development of finite element (FE) FCL models is required. This paper presents 3D transient FE model of two configurations of inductive FCL: so called open-core and three-leg FCLs. The model has been validated by comparing simulation results with lab measurements. Results show very good agreement. The model is valuable tool for design, optimization and verification of inductive FCLs.

I. INTRODUCTION

Fault Current Limiters (FCLs) are expected to play an important role in the protection of future power grids. They are capable of preventing the fault currents from reaching too high levels and, therefore, reducing the mechanical and thermal stress of all power system components.

The FCLs can be classified on passive, solid-state and hybrid FCLs [1]. Passive FCLs are particularly interesting due to their merit to inherently react on the fault. Inductive FCLs based on the core saturation is type of the passive FCLs. They comprise magnetic cores and windings. Different configurations of inductive FCL are proposed in literature [1]-[4]. It is difficult, or in some cases impossible, to derive accurate analytical model of different FCL designs.

The goal of this paper is to introduce the 3D transient finite element (FE) model of the inductive FCL. The model presents a valuable tool for verification and optimization of the inductive FCL. The operation of the designed FCL can be verified precisely, with the possibility to vary all design parameters. The experiment with both FCL configurations, three-leg [2] and open-core [3], is done in lab in order to provide reference data for verification of the models. The simulation results of both 2D and 3D FCL models are presented. The 2D model is not sufficiently good for modeling of the FCL. The 3D simulation results show good matching with the experimental results.

II. PRINCIPLE OF OPERATION OF INDUCTIVE FCL

A. Three-Leg Core FCL Configuration

A single core is used per phase, with three vertical legs [2], see in Fig.1(a). Each outer leg contains one ac and

one dc winding. Dc windings provide circular dc flux flow, saturating the outer legs. Upon the fault inception, outer legs are alternately de-saturated, increasing in that way the impedance of the ac windings. The ac flux closes its path through the left (in another half cycle right leg) and the middle core legs.

Fig. 1: FCLs used in the experiment

B. Open-Core FCL Configuration

FCL comprises single core per-phase with one ac and one dc winding [3], see in Fig.1(b). The dc winding is connected to a dc current source and saturates the core. The ac winding is connected in series with line. During a fault, core remains saturated and the inductance of the ac winding is very low. In a fault stage, left and right legs of the core are alternately de-saturated by the fault current, imposing large impedance into the line.

Detailed explanations of both configuration will be given in the full paper.

III. MATHEMATICAL BACKGROUND OF THE MODEL

The developed mathematical model consists of a partial differential equation for the magnetic field in the structure of the FCL, coupled with an ordinary differential equation for the current in the ac coil. Both are coupled by the magnetically induced voltage in the ac coil. We introduce the so-called coil winding function t , in such a way that the applied current density in the coils can be written as:

$$J_e = \frac{N_w I(t)}{S} t, \quad (1)$$

where $I(t)$, N_w and S are the applied current, the number of coil turns and the cross-sectional area, respectively. The magnetic field equation in the magnetic vector potential A can then be written as [5]:

$$\sigma \frac{dA}{dt} + \nabla \times \mu_0^{-1} \mu_r^{-1} (\nabla \times A) = J_e \quad (2)$$

The circuit relation for the current in the ac coil is an algebraic relation that ensures that at all times the sum of resistive and induced voltage V_{ind} is equal to the externally applied voltage:

$$(R_{load} + R_{ac}) I + V_{ind} = V_e \quad (3)$$

In this relation V_{ind} is computed as the following integral over the volume of the ac coil:

$$V_{ind} = \frac{N_w}{S} \int_{\Omega_{ac}} E t d\Omega \quad (4)$$

The fault is modeled by allowing $R_{load}(t)$ to suddenly drop to a very low value at a particular time instance. The Comsol Multiphysics package [6] offers an easy to use interface to implement this field-circuit coupled model.

IV. SIMULATION AND EXPERIMENTAL RESULTS

In this section the representative numerical and experimental results are presented. Fig.2 shows the close match between the 3D model and the experimental results for the open-core FCL, indicating that the 3D model can indeed be used to predict the behavior of the FCL. If a 2D model is used, the results are considerably different from those obtained in the experiment (see in Fig.2).

Fig. 2: Simulation and experimental current waveforms for open-core FCL

Fig.3 presents simulation and experimental results for the three-leg core FCL. They are derived for two cases: FCL without a gap in the middle leg and with the 3.5mm gap length. The shown results are for 2D FE model. In the case when there is no gap, results match very well. However, difference between results appears if the gap is inserted in the middle leg, see in Fig.3(b).

The results of the 3D model will be presented in the final paper. Just as in the case of the open-core FCL model, it is expected that 3D results will show much better matching with the experimental one.

(a) Without gap

(b) With 3.5mm gap

Fig. 3: Simulation and experimental current waveforms for the three-leg core FCL

V. WHAT WILL BE PRESENTED IN THE FINAL PAPER

All the sections will be further developed. The presented experiments will be described in detail and additional simulation results for both FCLs will be depicted. The results will clearly show the operation principles of both FCL configurations.

VI. CONCLUSION

FE modeling is required for accurate design of inductive saturable FCL. Although 2D model considerably saves simulation time, it cannot provide sufficiently accurate results.

Derived 3D model presents a valuable tool for design, optimization and verification of inductive FCL. 3D FE model was verified for two FCL configurations: open-core and three-leg core FCLs. Simulation results from 3D model match very well those from the lab experiments.

Hybrid Analytical-FEM Method for Microwave Heating Analysis in a Single Mode Cavity

D. B. Oliveira and E. J. Silva

Department of Electrical Engineering, Federal University of Minas Gerais
Av. Antônio Carlos, 6627, 31270-901, Belo Horizonte – MG – Brazil

Abstract — In this paper an approach to solve the thermal-electromagnetic problem of microwave heating a thin load inside a single mode applicator is presented. A direct problem solving methodology that takes into account the temperature dependence of the electrical permittivity is very time-consuming. By using a hybrid analytical finite element method we can speed up the determination of the electromagnetic field. Also the hybrid method provides an easy way of tuning the cavity coupling. To validate the approach the heating of a thin ceramic cylinder inside a WR-340 single mode cavity is presented.

I. INTRODUCTION

The single mode cavity is an applicator very common for processing small and low loss samples through microwave heating, Fig. 1.

Fig. 1 – Description of single mode cavity.

The determination of the electromagnetic fields inside the cavity using the standard finite element method, even if the electrical permittivity is independent of the temperature, is a difficult task [1]. The iris presence makes the modal composition of the electromagnetic fields very complex leading to a very slow convergence rate to obtain an accepted solution. Also the FEM global matrix is usually ill-conditioning making the inversion very hard. Hence, the electromagnetic solution is very time consuming.

This work presents a methodology to solve the thermal electromagnetic problem in the single mode cavity. To overcome the drawbacks above a hybrid analytical finite element method is used in the computation of the electromagnetic fields. The analytical technique is based on the scattering matrix theory.

As a by product of this method, a tuning technique that allows the iris aperture and the end short to move during the heating process is obtained. It allows analyzing efficient working conditions of the highly resonant cavity.

The thermal problem is solved using the standart FEM in time domain with Crank-Nicolson time discretization.

II. METHODOLOGY

A. Electromagnetic Problem

Fig. 2 shows three planes z_1 , z_2 e z_3 through which is assumed to propagate only TE_{10} modes. It is a valid assumption if evanescent modes excited by the load and the iris have negligible amplitudes there.

Fig. 2 – Top view of the applicator and the propagating modes.

Using the scattering matrix theory the ceramic sample region is modeled by the following matrix system

$$\begin{bmatrix} \bar{E}_1 \\ \bar{R}_3 \end{bmatrix} = \begin{bmatrix} r_c^l e^{-j2k_{10}z_l} & t_c^r \\ t_c^l & r_c^r e^{+j2k_{10}z_l} \end{bmatrix} \begin{bmatrix} \bar{T} \\ \bar{E}_3 \end{bmatrix} \quad (1)$$

where k_{10} is the propagation constant of TE_{10} mode, r_c and t_c are respectively the reflection and transmission coefficients of the load. The superscripts l and r mean that these coefficients are calculated considering the TE_{10} incident mode propagating in $+\hat{z}$ and $-\hat{z}$ direction. This distinction must be done since the temperature dependence of the permittivity makes the ceramic a non-symmetric load.

These coefficients are calculated numerically using the FEM [2]. Note that to calculate these coefficients we have to solve two simple problems as shown in Fig. 3.

Two other relations are needed for expressing analytically the modes amplitudes in the cavity. One to define the reflection coefficient (γ) of the structure composed by waveguide, load and short and another to relate the modes E_3 and R_3 .

$$E_1 = \gamma T \quad \text{and} \quad E_3 = -e^{+2jk_{10}z_w} R_3 \quad (2)$$

From (1) and (2) we can write the amplitudes of the modes R, T and E_3 and of the coefficient γ by analytical expressions

$$\gamma = r_c^l e^{-j2k_{10}z_l} + \frac{t_c^r t_c^l}{\left(\frac{-1}{e^{-j2k_{10}z_w}} - r_c^r e^{+j2k_{10}z_l} \right)} \quad (3)$$

$$R = r_1 E_0 + \frac{t_1^2 \gamma E_0}{1 - r_1 \gamma} \quad \text{and} \quad T = \frac{t_1 E_0}{1 - r_1 \gamma} \quad (4)$$

$$E_3 = \frac{t_c^l T}{\begin{pmatrix} -1 \\ e^{-j2k_{10}z_w} - r_c^r e^{+j2k_{10}z_t} \end{pmatrix}} \quad (5)$$

The coefficients r_1 and t_1 are the reflection and transmission coefficients of the iris [3].

Fig. 3 – Reflection and transmission coefficients for TE₁₀ incidence, (a) from left and (b) from right.

As next step the length z_w and the iris aperture d are determined by what is called tuning process.

Finally, the electric field solution in the load region $z_2 \leq z \leq z_3$ can be found. It is done by multiplying the field distribution in Fig. 3(a) and Fig. 3(b) by T and E_3 respectively and then summing the distributions.

B. Coupled Problem

The source of heat due to the microwave is given by the power density absorption in the material

$$p = \frac{1}{2} \omega \epsilon_0 \epsilon_r''(T) |E|^2 \quad (6)$$

The complex electrical permittivity of the ceramic (mullite) changes with the temperature according to Fig. 4.

Fig. 4 – Mullite relative electrical permittivity.

In the simulation process the thermal problem is solved during some time steps until the temperature is sufficient to produce significant change in the permittivity. If significant changes are detected the heat source is updated by computing a new electromagnetic field distribution.

C. Tuning Technique

Most papers, tuning the cavity means to adjust the plunger position. In [4], the authors proposed an experimental device where an adjustable iris aperture is used for optimal coupling. This idea is modeled numerically in this work.

In the tuning process we search the aperture value and the plunger position that minimize the energy of the R mode every time the electromagnetic problem is solved.

This tuning technique is easily implemented by the methodology presented in this paper. In a standard finite element method we would have to re-mesh the problem every time that the plunger position or iris aperture changes.

III. RESULTS

To validate our approach we analyze the microwave heating of a mullite ceramic sample inside the heater. It is a rod of radius 0.01m.

The Fig. 5 shows the temperature distribution on the external surface of the rod. The total processing time was 1800s. In this case the electromagnetic problem was solved 58 times. The time step was 6s and the electrical permittivity was corrected when the real part or the imaginary part changed more than 5% in relation to the last value.

Although we have to solve two electromagnetic problems they are much simpler than the original one. By using a mesh parameter $h_{\max} = \lambda/25$, the tetrahedral mesh used in the hybrid method has 13727 elements while the original problem requires 90854 elements. This is due to the difference in the length of the domains. Also the mesh is more uniform in hybrid method since the iris is not present once it is taken into account in the analytical part.

Note that since the two electromagnetic problems in the hybrid method are independent we can use parallel multithreading processing in multi-core computer to determine the electric field. Another improvement can be obtained by optimizing the number of times the power density need to be re-calculated [5].

Fig. 5 – Temperature distribution on the external surface.

Distributed Models for Air-Core Ethernet Transformers

Isaak D. Mayergoyz¹, David Bowen¹, Charles Krafft²

¹ECE Department and UMIACS, University of Maryland, College Park, Maryland 20742, USA

²Laboratory for Physical Sciences, College Park, Maryland 20740, USA

Abstract— Ethernet transformers are widely used for isolation in computer networks in the high frequency range (0.1 MHz – 1GHz). It turns out that it is the cross-winding capacitance that supports the flat pass band of these transformers above 50MHz. Size reduction for fabrication of these transformers motivates the development of a capacitance coupled air-core device. In this paper, novel models of air-core Ethernet transformers that take into account the distributed nature of cross-winding and intra-winding capacitances will be discussed. Differential-mode signal transfer characteristics will be computed for different transformer parameters. The computation of cross-winding capacitance will be discussed as well along with the symmetry considerations which appreciably simplify its computation.

Ethernet transformers are widely used as interfaces between communication networks and computers. For this reason, these transformers are designed to suppress common-mode signals (noise), induced as a results of electromagnetic interference, and at the same time pass through with minimal distortion differential-mode signals, which carry transmitted information. To achieve this performance, the primary and secondary windings have the same turn numbers and are wound together (in bifilar manner) around ferrite cores [1]-[3]. This bifilar winding arrangement is done on purpose to minimize leakage inductances of these windings in order to get flat transfer characteristics of these transformers in the desired high frequency range (0.1 MHz – 1GHz). The close proximity of the primary and secondary windings results in the appreciable cross-winding capacitance. This cross-winding capacitance is beneficial to the Ethernet transformers bandwidth. However, this capacitance also serves as a channel for common-mode signals. To suppress this channel, the midpoints of the primary and secondary windings are grounded.

It is known (and has been confirmed in our experimental research) that magnetic permeability of ferrite cores appreciably and rapidly degrades at frequencies above 1MHz. This clearly suggests that the differential-mode signal pass band of Ethernet transformers for frequencies above 50 MHz is by and large supported by the cross-winding capacitance. This has prompted the idea that the air-core designs of Ethernet transformers must be possible. These designs are compatible with the existing silicon fabrication technologies and may result in planar miniaturized structures of Ethernet transformers.

Figure 1. Transfer Characteristics of Distributed transformer model: varying α' .

Figure 2. Transfer characteristics of distributed transformer model: varying β .

In the talk, novel distributed models of air-core Ethernet transformers will be discussed. These models take into account the distributed nature of cross-winding and intra-winding capacitances. Mathematically, these models are described by boundary value problems for specific differential equations. It turns out that separate distributed models are needed for differential-mode and common-mode signals. The main distinction between these models lies in the boundary conditions which are used for differential-mode and common-mode signals. The main goal of the analysis is the calculation

of the transfer characteristics of air-core transformers. These transfer characteristics depend on five variables (R, R_L, C, C' , and l) which can be combined into three parameters (α, α', β) (see below). In other words, these transfer characteristics can be fully encoded in terms of α, α' and β . Extensive numerical computations of transfer characteristics of air-core Ethernet transformers will be presented in the talk. An example of such computations is given in Figures 1 and 2. In these figures, the differential-mode signal transfer characteristics of Ethernet transformers are computed for different values of three parameters

$$\alpha = RC, \quad (1)$$

$$\alpha' = \frac{RC'}{l^2}, \quad (2)$$

$$\text{and } \beta = \frac{R}{R_L}. \quad (3)$$

Here, R is the resistance of the primary (or secondary) winding, C and C' are cross-winding and inter-winding capacitances, respectively, R_L is a load resistance, while l is

the length of each winding. It is apparent from Figures 1 and 2 that various designs of air-core Ethernet transformers encoded by the same values of α, α' , and β result in the same (and acceptable) differential-mode transfer characteristics. It is apparent that the values of cross-winding and intra-winding capacitances determine properties of Ethernet transformers. For this reason, the computation of these capacitances will be discussed in the talk along with the symmetry considerations which appreciably simplify the computation of these capacitances. These symmetry considerations allow one to reduce the calculation of capacitances of line conductors placed on dielectric substrate to the calculation of capacitances of the same conductors in free space.

Abstract—This paper presents the model of an electromechanical energy scavenging device whose energy conversion is due to the motion of a permanent magnet inside a magnetic circuit. Magnet acceleration is created by tyre deformation during car motion along the road. Small dimensions (less than one cubic centimeter) and relatively high power output (more than one milliwatt), requires an accurate modeling of the energy conversion device. A nonlinear magnetic modeling is carried out and its outcomes are coupled to a dynamic model developed inside the Simulink environment. A good agreement is found in the comparison between theoretical model and experiments.

I. INTRODUCTION

A recent concept being implemented to power circuits is using energy scavenging or energy harvesting. This makes use of energy diffused in the system to be collected by some energy conversion devices like solar cells, piezoelectric generators, or others like electromechanical structures. These devices take energy from diffuse sources, convert it to electricity, and, by means of a proper electronic signal conditioning, use it to supply isolated users, for instance remote wireless controlled sensors.

Among the main difficulties of the design phase of this class of devices, there is the need to reach high values of power density cell and very high global efficiency of the whole process since the diffuse power which primarily feeds the scavenger is usually low. This fact calls for an accurate simulation of the integrated energy scavenger component made up of converter and electronic circuit.

In the following, the design process of an electromechanical energy scavenger, aimed at taking power from tyre deformation during the movement of a car, is described. The main design constraints are related to the volume occupied by the converter which should be less than 1 cm³, by power which should be more than 1 mW in average over one wheel revolution and by voltage which should not be lower than 1.3 V and not exceeding 4 V.

II. SCAVENGER MODEL

An accurate model of the energy scavenger requires the study of different phenomena, in particular:

- magnetic circuit and interaction with magnet movement, taking into account nonlinearities of materials;
- interaction with external electric load and definition of a scavenger equivalent circuit;

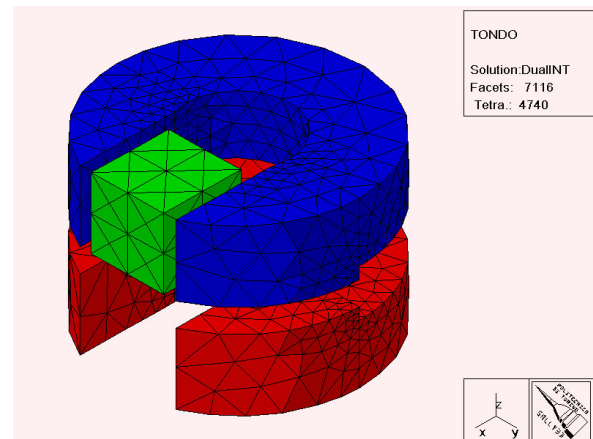

Fig. 1. Magnetic circuit of the energy scavenger without coils wound on cores

- dynamic simulation of the moving mass as a response from external acceleration;
- definition of the energy dissipations present in the system like dry friction and pneumatic forces arising from mass motion.

A. Magnetic simulation

The magnetic system is made by two ferromagnetic cores, with two coils wound on them, and by a brick shaped moving permanent magnet traveling between them. Ferromagnetic cores are made by Soft Magnetic Composite (SMC) material. The reasons for this choice are: the time-varying flux conditions and thus the need to reduce eddy currents and losses and the good machinability of the material that allows to obtain complex three dimensional core shapes. Magnetic analysis of the structure (reported in Fig. 1), should give as results: the magnetic flux linked with the coils and the forces acting on the magnet as function of the coordinate of the magnet z .

The nonlinear magnetic analysis is performed by a hybrid magneto-static code based on the coupling of a cell method volume discretization technique with a Green function integral approach [1]. Due to its mesh-less treatment of air, the code gives accurate results in term of force values computed by means of integration of the Maxwell stress tensor [2] and this fact is here very important since reluctance forces, caused

by ferromagnetic salient poles, largely influence the dynamic behavior of the moving mass.

B. Circuit model

The lumped parameter model of the converter is used to interface it with the external load and is made by an electromotive-force generator depending on magnet velocity $e = e(\dot{z})$ being z magnet position, by the ohmic resistance and by the inductance of the winding. The second parameter is varying because of core saturation and so the value of inductance is sampled at different magnet positions obtaining then a $L = L(z)$.

C. Dynamic simulation

The dynamic model is developed in Matlab/Simulink environment by means of a block-oriented approach that allows to interconnect both mechanical and electrical subsystems [3]. It takes into account external forces acting on the moving permanent magnet due to radial, longitudinal and transversal accelerations imposed by the tyre dynamic.

For the experimental comparison the electromechanical energy scavenging device is tested on a shaker. Thus, each mechanical or electrical subsystem coupled to the magnet is modelled in a relative system reference in order to transmit direct or reactive forces proportional to the displacement or velocity of the structure containing the moving magnet. The considered mechanical interactions on the moving magnet are adhesion or friction phenomena (dependent on the relative magnet velocity) inside the vertical box-runner. At both ends of the magnet stroke, rubbery bumpers are designed to protect magnet impacts. Their mechanical effect is a typical dead-band of the elastic-dissipative characteristic. Their lumped properties are assumed on a Kelvin-Voight model. Due to the finite volume of air inside the magnet box-runner, also pneumatic forces arising from the relative magnet motion are taken into account. Their effects are modelled with an equivalent lumped series of spring and damper.

The electromechanical coupling consists of a conservative elastic magnetic force due to reluctance effects and a dissipative proportional to the relative velocity between magnet and coils. Their nonlinear properties are mapped in function of the relative magnet position and velocity. For the experimental comparison on the shaker, a simple adapted resistive load circuit is adopted.

D. Comparison with experiments

In Fig. 2 the electromechanical energy scavenging prototype is shown. For the experimental tests on shaker or for tyre applications, the device is consolidated with potting fluid. The reported comparison between experimental data and simulations of Fig. 3 presents the voltage dynamic behaviour between the resistive load during impulsive testes related to tyre excitations. The second-order dynamic behaviour of the magnet has typical dissipative effects due to friction effects coupled to the desired power flow generated by the electromechanical energy scavenging device. A good agreement between model

Fig. 2. Magnetic circuit of the energy scavenging prototype.

Fig. 3. Experimental and simulated voltage during impulsive test.

predictions and experimental outcomes is evinced. In the full paper a complete test of the energy conversion device under realistic tyre acceleration profiles will be presented.

ACKNOWLEDGMENT

The authors would like to thank Dr. Federico Mancosu from Pirelli for his enthusiasm and driving force in the project and Dr. Riccardo Crosa of Hoganas Italia Srl, for supplying Somaloy SMC material for prototype construction.

Abstract – An alternative possibility of highly accurate control of position is suggested, realized by a simple device with a cylindrical dilatation element that works on the principle of thermoelasticity produced by induction heating. The paper describes the device, presents its complete mathematical model in common with the methodology of its numerical solution, and also the algorithm of the control process. The theoretical analysis is illustrated by a typical example, whose results are discussed.

I. INTRODUCTION

Control of position can be realized on several different principles. We can mention, for example, sophisticated mechanical or hydraulic systems with 3D kinematic structures, devices with pneumatic elements, and also elements working on principle of magnetoelasticity. In the above cases, the accuracy of control usually reaches $10^{-5} - 10^{-4}$ m.

For a unidirectional control (e.g., tuning of the laser head for laser cutting or welding or regulation of position of elements in some optical systems) working with accuracy on the order of $10^{-6} - 10^{-3}$ m, the authors suggest an alternative methodology based on the principle of thermoelasticity produced by induction heating. The corresponding device works with a cylindrical element, whose longitudinal dilatation is controlled by the appropriate time evolution of the field current.

The papers in the domain are rather rare. Some applications based on thermoelasticity produced by induction heating (with a very limited possibility of control) were described in [1] and [2]. A time-variable magnetic field produced by harmonic current carrying field coil induces eddy currents in the dilatation element. These currents generate in it the Joule (and when the dilatation element is ferromagnetic, also hysteresis) losses that produce heat and, consequently, thermoelastic strains and stresses resulting in the corresponding displacements. The task is characterized by the interaction of three physical fields (electromagnetic field, temperature field, and field of thermoelastic displacements) influencing one another.

II. FORMULATION OF THE PROBLEM

The basic arrangement of the device (that may be considered axisymmetric) is depicted in Fig. 1. The dilatation element **2** made of a suitable metal is inserted into a harmonic current-carrying coil **3** fixed in frame **4**. The whole system is placed in a Teflon insulating shell **1**. The device is clamped by its bottom part **5** (Teflon front) in basement **6** that is supposed to be perfectly stiff. The time-variable magnetic field generated by field coil **3** induces in the dilatation element **2** eddy

currents that produce heat and consequent geometrical changes (mainly in its longitudinal direction z) of the thermoelastic origin.

Fig. 1. The basic arrangement of the device
1 – Teflon shell, 2 – dilatation element, 3 – field coil, 4 – fixing frame,
5 – Teflon front, 6 – stiff wall

Now it is necessary to reach a prescribed dilatation u_d of element **2** in the shortest time possible, while the temperature of the system must remain within the allowed range. The situation is indicated in Fig. 2.

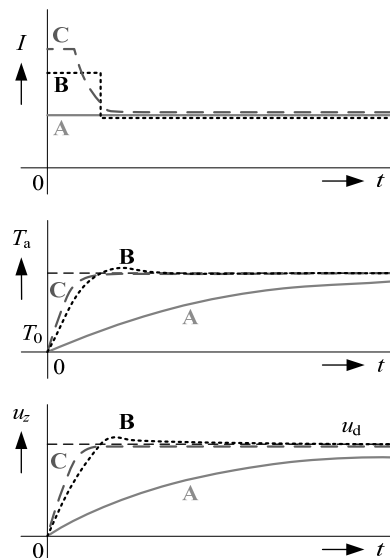

Fig. 2. Possible time evolutions of amplitudes of the field current I and corresponding time evolutions of the average temperature T_a of the dilatation element **2** and its dilatation u_z

The upper part of Fig. 2 contains three different time evolutions of the amplitude I of the field current (that is supposed to be controlled using the pulse-width modulation). The central and lower parts then show the corresponding time evolutions of the average temperatures T_a of the dilatation element (its initial temperature being T_0) and displacement u_z in the direction of the z axis. For current **A** the time of reaching the prescribed dilatation u_d is unacceptably long. A step change of the field current (line **B**) is more favorable, but still the time of reaching the steady state could be substantially shorter. Further shortening of this time can be achieved by using higher current for the first period of the process that is later decreased continuously to its steady-state value (line **C**). The main feature of the steady state is the balance between the heat produced in the system and heat loss due to convection and radiation.

The aims of the paper are:

- to optimize the envelope of the field current with respect to maximum possible shortening of the time of reaching the required dilatation u_d and
- to propose an approximate algorithm that would allow a very fast (on-line) and sufficiently accurate computation of this multiply coupled problem.

III. FUNDAMENTAL MODEL AND ITS SOLUTION

The task represents a nonstationary multiply coupled problem, combined with the optimization of the time evolution of the envelope of the field current. The computations were realized by a combination of the professional code Comsol Multiphysics and a lot of own procedures and scripts. The algorithm consists of the following items:

- Computation of the steady-state dilatation $u_{z,t \rightarrow \infty}$ as a function of the applied field current density $|\mathbf{J}|$ (for the methodology, mathematical model, boundary conditions, and other particulars, see [2]).
- Approximation of this function by a polynomial $f(|\mathbf{J}|)$ of a reasonable order using the least square method. The steady state field current density $|\mathbf{J}_d|$ necessary for dilatation u_d then follows from the solution of equation $f(|\mathbf{J}_d|) = u_d$.
- The model of dilatation is supposed to have the form $\ddot{u}_z = g(u_z, \dot{u}_z, f(|\mathbf{J}|))$ (but even more complicated forms with higher derivatives bring about no serious problems), where $|\mathbf{J}|$ is defined as $|\mathbf{J}| = J_{\max}$ for $t \in (0, \tau)$ and $|\mathbf{J}| = J_d + (J_{\max} - J_d)e^{-\lambda(t-\tau)}$ for $t > \tau$ (corresponding to line **C** in Fig. 2 left denoted by **3**). For a selected value of J_{\max} the quantities τ and λ are subject to optimization.
- The objective function respects the demand on the minimum time necessary for obtaining the dilatation u_d .
- The optimization of parameters τ and λ is carried out using the Nelder-Mead nonlinear simplex method.

IV. ILLUSTRATIVE EXAMPLE

The algorithm was tested on several arrangements. The computation of function $u_{z,t \rightarrow \infty}(|\mathbf{J}|)$ for any particular arrangement takes several hours. But once the results are available, the approximate determination of the envelope $|\mathbf{J}|$ for any required dilatation u_d takes only several seconds.

Figure 3 shows, for example, two graphs obtained for the device in Fig. 1 with zinc dilatation element. The dependence $u_{z,t \rightarrow \infty}(|\mathbf{J}|)$ was approximated by a polynomial of the second order and the model of dilatation had the form $\ddot{u}_z = \alpha(u_z + f(|\mathbf{J}|))$. The upper part of Fig. 3 depicts the time evolution of the current density optimized in accordance with the above algorithm. The lower part contains the corresponding time evolution of the dilatation u_z obtained by the solution of the coupled problem in Comsol (tens of minutes) and by the approximate method proposed by the authors (tens of seconds).

Fig. 3. Optimized time evolution of the field current density $|\mathbf{J}|$ for the arrangement in Fig. 1 (upper part) and time evolution of the corresponding dilatation u_z obtained by the complete calculation (Comsol) and by approximate algorithm suggested by the authors

mohammed@fiu.edu

Abstract— This paper proposes a physics based high frequency transformer model. The model can be used for setting edge rates, selecting switching algorithms, predicting over voltages at terminals, and predicting transformer harmonic behavior. The model is constructed by connecting the conventional power frequency transformer model in parallel with a frequency dependent branch (FDB). The FDB represents the transformer's high frequency behavior over wide frequency range while the power frequency model represents the transformer at low frequency. The model inductances, resistances, and capacitances were obtained by finite element (FE) analysis. The self and mutual capacitances of each conductor were calculated by electrostatic FE analysis. The order of capacitances is reduced by using a reduction technique. The transformer frequency response was obtained by coupling the transformer time harmonic FE model and external circuit simulations. The frequency response was then fitted with rational function approximation. The rational functions are then realized with RLC networks to form the FDB. The model simulation results show the ability of the developed model to predict transformer high frequency behavior during the design and development stage.

I. INTRODUCTION

Modeling of power transformer is challenging especially at high frequencies. In this case, numerical models become complicated and require various levels of details in order to include many effects such as core saturation, hysteresis, ferroresonance, and insulation issues in addition to geometric, and construction features. FE modeling can include all of these effects and provide an efficient way for analysis, simulation, and optimization for transformers. In this paper, the FE analysis has been coupled to driving electric circuit simulations in order to include the operating conditions of the transformer with the real power supply and load connections.

High-frequency modeling is essential in the design stage of transformers to study impulse voltage and switching surge distribution. It is also necessary for winding integrity and insulation diagnosis and most often frequency effects for high-fidelity models in bandwidths up to 10 MHz are required for condition monitoring purposes [1]. The study of the high-frequency part of the spectra is necessary due to the resulting stray capacitances shunting the series inductances and dominating the response.

In this paper, a high frequency model of transformers is developed by connecting a high frequency branch in parallel with the power frequency transformer model. The high frequency branch enables the presentation of the series and parallel resonance from mid to high frequency caused by winding-to-winding and winding to ground stray

capacitance. The Low and high frequency parameters of the windings were obtained from the FE solutions on a turn-to-turn basis. The model is then reduced to a lower order by using a reduction technique. The transformer frequency response was then obtained from coupled circuit-time harmonic FE analysis. The frequency response is curve fitted using vector fitting (VF). Vector Fitting is a robust numerical method for rational approximation in the frequency domain.

The proposed high frequency model and was used to demonstrate the primary current harmonic behavior and terminal overvoltage when the transformer is connected through a long cable to the power source with spikes in the current waveforms are present. Therefore, the model presented here can be used for evaluating electromagnetic interference issues for product development.

II. THE HIGH FREQUENCY FE MODEL

Simulations were carried out on a 60-Hz single-phase, shell type transformer with sandwich coils. The primary and the secondary windings were represented by rectangles of corresponding materials in the FE domain. The magnetic core is an isotropic non-linear magnetic material defined by analytic saturation curve. The FE model contains 11254 second order elements with 22541 nodes.

The transformer magnetic field is governed by the following nonlinear partial differential equations:

$$\vec{\nabla} \times ((\nu) \vec{\nabla} \times \vec{A}) = \vec{J} \quad (1)$$

$$\nabla \cdot \sigma \left(\frac{\partial \vec{A}}{\partial t} + \nabla V \right) = 0 \quad (2)$$

Where all the symbols have their usual meaning.

The current in the circuit domain is governed by:

$$[E_m] = [R_m][I_m] + [L_m] \frac{d}{dt} [I_m] + [C_m^{-1}] \int [I_m] dt + [\gamma_m] \quad (3)$$

Where, E_m , I_m , R_m , L_m , C_m^{-1} , and γ_m represent the vector of voltage sources in each electric mesh m, the vector of the mesh currents, the resistances matrix, inductances matrix, the matrix of the reciprocal of the capacitance, and the matrix of the non-linear voltage drop, respectively.

A. Capacitance Calculation

The transformer capacitance matrix is obtained from an FE electrostatic analysis by energy principles. It is assumed, in this paper, that both the electric permittivity of the materials and the electric field energy are constant with the frequency and, therefore, the value of the transformer capacitances are a function of geometry rather than the

frequency. The model considers three types of stray capacitances, winding to ground, winding to winding, and turn-to-turn capacitances.

A distributed parameter winding circuit is formed using the high frequency parameters obtained from the FE analysis. To reduce the computational burden, the model capacitances order needs to be reduced. We move the capacitance connected to internal nodes to the external nodes. In this technique, all the nodes other than terminal nodes are eliminated.

Fig. 1 the transformer mesh details

B. Resistance and Inductance Calculation

The transformer inductance and resistance values will change with a change supply frequency. The transformer resistances increase with an increase in the supply frequency. The inductances value decrease with the supply frequency increase. This change in the transformer parameters is due to the skin and proximity effects. The size of the mesh elements used is selected in coordination with the skin depth. Fig.1 shows the mesh details used to calculate the transformer frequency response. When the supply frequency changes from 60-Hz to 50-kHz, the transformer resistance increase by 300%, while the primary inductance decreased by 50%

III. VECTOR FITTING

The transformer admittance $Y(s)$ frequency response is obtained from harmonic coupled circuit- FE analysis by varying the primary voltage source frequency while the secondary is short circuited. The frequency response is curve fitted using vector fitting (VF). VF takes as input a column of $Y(s)$ and approximates all of its n elements simultaneously using an identical set of N poles. Each element, Y_j , in $Y(s)$ becomes [2]:

$$Y_j(s) \approx Y_{fitj}(s) = \sum_{i=1}^N \frac{c_{ji}}{s - a_i} + d_i + se_i \quad j=1, \dots, n \quad (1)$$

Where c_{ji} and a_i denote the residues and the poles, respectively. The terms d_i and e_i may be specified as zero, if desired. The poles and residues are real or complex conjugate, whereas d_i and e_i are real. The rational functions can then be represented by the electrical network shown in Fig.2.

Fig. 2 Frequency dependent branch equivalent circuit

IV. IMPLEMENTATION AND SIMULATION RESULTS

The developed high frequency physical phase variable model of the transformer is tested with constant frequency inverter and cable to study the effect of different switching frequencies. The high frequency transformer primary current profile is shown in Fig. 3. It can be seen that the proposed HF model can reflect the spikes due to the PWM excitation. The pulsations in the waveforms are the result of PWM action while spikes are the result of high PWM switching speeds. The number of spikes within the current waveforms is increased with an increase in switching frequency. This is obvious as the spikes appear at every transition of PWM supply. These results are difficult to predict without the proposed model. Further details on the simulation and laboratory testing results will be presented in the full paper.

Fig. 3 Primary current profile at different switching frequencies

V. CONCLUSION

A new technique is described in this paper to obtain a high frequency phase variable transformer model from coupled circuit-FE analysis. The model has both frequency dependence and distributed effects. The model allows the analysis of high and low frequency phenomena simultaneously. The model takes into account the electromagnetic field effects which cause the change in the transformer frequency behavior. Thus this model can represent the transformer under non-sinusoidal operating condition. The model can be used for setting edge rates, selecting switching algorithms and predicting overvoltages at terminals. The study can be utilized to evaluate various transformer designs, diagnose the incompatibilities of the transformer with other components, and insulation issues.

Abstract—This paper develops a particular 2D FEM model for iron loss analysis in permanent magnet machines during rotor speed oscillations. Hysteresis and saturation effects in solid rotor iron parts are considered and rotor skew is accounted by using a particular special air-gap element combined with standard 2D finite elements. Internal and surface permanent magnet rotor topologies are compared. The results obtained have been validated by measurements of rotor speed damping, consisting an important phenomenon of the respective drive.

Index Terms—Analytical solutions, finite element method, permanent magnets, rotor skew, speed oscillations.

I. INTRODUCTION

Permanent magnet (PM) motors are widely used in variable speed drive applications, due to their inherent advantages of high efficiency, high reliability and robustness [1]. However, the small damping effects of the rotor constitute an important constraint requiring adequate control techniques in order to avoid speed oscillations [2]. The present paper develops particular methodologies enabling to evaluate iron loss [3], [4] and the respective damping during oscillatory operation through convenient 2D finite element analysis. The method has been applied in order to compare damping effects of surface (SPM) and internal permanent magnet (IPM) rotor configurations.

II. FORMULATION

In order to enable a flexible time discretization and rotor skew consideration, the air gap of the machine has been represented by analytical solutions combined with standard 2D FEM techniques for stator and rotor simulation [1]. Such a methodology involves a particular coupling of the two methods across the boundary, obtained as follows:

A. 2D Hybrid FEM-Macroelement Formulation

In the air-gap of electrical machines, the magnetic field distribution is governed by Laplace equation as the magnetic permeability is constant and there are no current sources. The proposed technique involves shape functions α_i determination based on the general solution of Laplace equation in terms of the vector potential in two dimensional cylindrical coordinate system.

Generally the system of equations to be solved can be written in matrix form:

$$[S] [A] = [F] \quad (1)$$

where $[S]$ is the stiffness matrix, A is the matrix of unknown vector potential nodal values and $[F]$ the source matrix.

The standard finite element stiffness matrix is band while the nodes surrounding the air-gap (macroelement part) form locally a full coefficient sub-matrix with terms of the form:

$$s_{ij}^g = \frac{1}{\mu_0} \int_{\Gamma_g} \alpha_i \frac{\partial \alpha_j}{\partial n} d\Gamma_g \quad (2)$$

Such a technique enables consideration of rotor skew by convenient constitution of the respective integrals as well as flexible representation of the rotor rotation.

B. Coupled Electromagnetic-Mechanical Problem

The coupled mechanical-electromagnetic problem of rotor speed oscillations can be solved [5], by conveniently combining the above mentioned formulation for the field analysis with the one governing the rotor motion, expressed as follows:

$$T_{el} - T_m = J \frac{d^2\theta}{dt} + D \frac{d\theta}{dt} + k\theta \quad (3)$$

For this reason a step by step time discretization is employed. The relative movement of the rotor to the stator, in a time-transient analysis can be modeled by applying variable time step techniques and considering the relative geometry variation with rotor rotation. In a first step the 2D FE problem is solved and the electromagnetic torque is evaluated. Then, electromagnetic torque value, and the value of the rotor angle is obtained, providing feedback to the FE model. The problem is solved for the new rotor position and the new current values. The flowchart of the described algorithm is depicted in Fig. 1.

Fig. 1. Flowchart of the implemented algorithm

The time step is continuously adapted to the variation of electromagnetic quantities as the mechanical time constants are considerably greater.

III. RESULTS AND DISCUSSION

The proposed methodology has been applied in order to compare the damping effectiveness of rotor oscillations in case

of two different rotor configurations, SPM and IPM, respectively. The eddy current losses distributions for the SPM machine under maximum oscillation speed for two rotor positions are given in Fig. 2. Figure 3 shows the same results in case of IPM rotor configuration. The respective iron loss density and eddy current density distributions in the radial direction are presented in Figs. 4 and 5. These figures equally show the respective iron loss density and eddy current density distributions in the respective cases involving rotor skew. The total iron loss values for the different rotor configurations are tabulated in table I, illustrating that the IPM configuration provides six times greater damping than the SPM one. It may be noted that the calculated damping effects are in good agreement with the respective mechanical time constants derived by the measured current and speed oscillations shown in Fig. 6.

E-mail lijian613@gmail.com

Abstract— This paper describes modeling and analysis of canned induction motor for coolant pump used in nuclear reactor. The electromagnetic field of a canned motor was analyzed by using the time-step finite element method, and the eddy loss was obtained. Equivalent circuit considering can loss was developed and the equation to calculate can loss was derived from theory of conventional motor. Using the loss from electromagnetic analysis as heat source of temperature field, thermal analysis was conducted by using Computational Fluid Dynamics (CFD) analysis. The simulation results show good agreement with experiment data, which indicates that this method has good accuracy and reliability for dealing with thermal behavior of canned motor.

I. INTRODUCTION

The main coolant pump used in system-integrated modular advanced reactor is an axial flow type, and it is constructed vertically because of the space limitation of building of reactor. A 200Kw three phase induction motor was designed and analyzed for application. Three journal bearings and one thrust bearing are used to hold rotor. The materials of bearings are black lead and silicon to endure high temperature and high pressure in reactor. For lubrication and cooling of bearings, pure water is forced to flow through airgap between stator and rotor. Therefore, the stator and rotor are welded by sealed can to prevent them from the lubricating water. The can is made of stainless steel SUS316L, which has resistivity of $74 \mu\Omega\cdot\text{cm}$ and relative permeability of 1.004. Eddy currents will be produced in the can and eddy current loss decreases efficiency of motor.

II. EQUIVALENT CIRCUIT OF CANNED INDUCTION MOTOR CONSIDERING CAN LOSS

In canned induction motors, the airgap is usually wider compared with conventional induction motors because cans are attached to the surfaces of stator and rotor. Eddy currents generated in the can also increases iron loss of the motor. Fig. 1 shows the characteristics of current produced in can. Similar to the currents in rotor bar and end ring of cage, the currents are denoted as I_{canb} and I_{canr} , which are the currents generated in can bars and ring respectively. The length of can bar l_{can} is same as length of core l_s , l_{can} is the total length of can bar and can ring.

The stator can Derived from the calculation of eddy current loss in cage at startup [1], the formulas to calculate eddy current losses in stator can and rotor can are as follows,

$$P_{canbar} = \left(\frac{I_{canb}}{\sqrt{2}} \cdot \frac{1}{4} \right)^2 \frac{\rho_{can} \cdot l_{canbar}}{A_{canbar}} \cdot 4 = I_{canbar}^2 \frac{\rho_{can} \cdot l_{canbar}}{2 \cdot A_{canbar}} \quad (1)$$

$$P_{canring} = \left(\frac{I_{canr}}{\sqrt{2} \cdot \pi \cdot p} \right)^2 \frac{\rho_{can} \cdot \pi \cdot D_{canr}}{A_{canring}} \cdot 2 \\ = I_{canbar}^2 \frac{\rho_{can} \cdot D_{canr}}{\pi \cdot p^2 \cdot A_{canring}} \quad (2)$$

where ρ_{can} is the resistivity of can, p is number of poles, D_{canr} is average diameter of ring and $A_{canring}$ is the cross area of can ring. The can does not have an inductive effect [2], only the resistances of the stator can and rotor can are represented in the equivalent circuit as shown in Fig. 2. Where r_1 is stator winding resistance per phase, x_1 is stator leakage reactance per phase, x_M is the magnetizing reactance per phase, I_1' is rotor current per phase referred to stator, r_2/s is rotor resistance per phase referred to stator, the r_{fe} is the resistance of iron loss, r_{can} is resistance of can, I_{1can} is the current in can referred to stator

Fig. 1. Characteristics of currents in can.

Fig. 2. Equivalent circuits of induction motor considering can loss

III. NUMERICAL SIMULATION

A. Electromagnetic Analysis

Time-step finite element analysis is used to study the performance of motor. Two models with and without can were simulated and compared. One model has cans made of stainless steel and in the other mode, the can is replaced with vacuum. Flux density distribution canned motor is given in Fig. 3. The stator can has a much higher current density than rotor can. Because magnet field traverses through stator can at frequency of f and through rotor at frequency of $s \cdot f$, where f is the frequency of magnetic field and s is slip factor. Due to eddy current effect in can, the peak value of phase current increases from 130A to 194A at same load condition, and the phase is also a little delayed as shown in Fig. 4.

B. Thermal Analysis Using CFD

Figure 5 gives the cooling system of canned induction motor. Because stator core as well as windings is enclosed by the can, the heat caused by core and copper loss was mainly conducted to the shell and stator can. The cooling water flows through airgap and the rotor rotates at a high speed. Conventional thermal analysis can't simulate this phenomenon, thus Computational Fluid Dynamics (CFD) was used to simulate fluid flow and heat transfer. Flow analysis involves solving of the Navier-Stokes equation using numerical tools. Thermal simulation involves solving of energy equations and can simulate distribution patterns of variables like temperature, heat loss/gain, thermal energy etc. The 3-D model of prototype is shown in Fig. 6, and the temperature distribution of stator core and coil at full load is given in Fig. 7. Experiment was also set for load and thermal test as shown in Fig. 8.

Abstract— A method for computer simulation of the radial active magnetic bearing (AMB) dynamic characteristics is presented. An implicit 3D finite element method (FEM) has been involved into the field-circuit model. Lagrange's equations, which contain the electrical and mechanical equations of motion, have been implemented. Some parameters of the AMB have been measured and compared with the calculated ones. Especially, for the moving and current characteristics, the calculation and tests results comparison yields a good agreement.

I. INTRODUCTION

Computer aided design (CAD) of an active magnetic bearing (AMB) can be done in two steps, mostly [1]. The first one includes the field-circuit model, and the second one concern the testing on the selected prototype [2], [6]. Finite element method (FEM) to the field analysis [3], [7] and Lagrange's equations for numerical modeling of the dynamic characteristics can be coupled in an implicit procedure [1]. The magnetic field integral parameters such as flux density distribution, winding inductances, and magnetic forces have been internally calculated with the procedure [4]. Inside this algorithm we have created the AMB dynamics characteristics.

II. THE DRIVE SYSTEM UNDER CONSIDERATION

We have considered the high-speed drive system with tree magnetic bearings. One of them, so-called radial AMB, was analyzed and tested in this work. The rated speed and torque of the motor are $n=40\,000$ RPM and $T_N=0.065$ Nm, respectively. The rotor mass of $m=1.2$ kg is suspended due to magnetic force arisen from both main flux, by the bias current of $I_b=0.8$ A, and additional flux by the control current. For the unstable rotor position, the controller should change all of the excitation currents, so that it is well kept, especially when their rotational speed is close to the critical banding mode [5].

Fig. 1. Magnetically suspended, high speed electric motor.

III. MODELING OF THE AMB DYNAMIC CHARACTERISTICS

To simulate the AMB dynamic characteristics, Lagrange's differential equations should be formulated and solved.

$$\begin{cases} u_x = R_x i_x + L_{dx} \frac{di_x}{dt} + k_{ix} \frac{dx}{dt} \\ u_y = R_y i_y + L_{dy} \frac{di_y}{dt} + k_{iy} \frac{dy}{dt} \end{cases} \quad (1a)$$

$$\begin{cases} F_{ex}(\tilde{I}, x) = m \frac{d^2 x}{dt^2} + k_{sx} x + mg + F_{ox} \\ F_{ey}(\tilde{I}, y) = m \frac{d^2 y}{dt^2} + k_{sy} y + F_{oy} \end{cases} \quad (1b)$$

The voltage and current-balance equations (1a) with u_x , u_y voltages as well as i_x , i_y currents, taken together their stiffness coefficients k_{ix} , k_{iy} , govern electrical behavior of the AMB system. Dynamic inductances L_{dx} , L_{dy} of the coils in the stator electromagnets have been calculated with the field model [4]. The resistances R_x , R_y have been determined previously in the course of the coil design.

Relocations x and y of the bearing shaft center depend on the electromagnetic forces F_{ex} , F_{ey} as well as displacement stiffness coefficients k_{sx} , k_{sy} . They are included in the mechanical equations of motion (1b). The applied forces, which are time dependent functions of the currents I and shaft displacements, have been calculated with the field model.

The transfer function of the bearing shaft can be expressed including the control currents and external forces F_{ox} , F_{oy} in each displacement directions of the rotor [5]. After Laplace's transformation the equations can be expressed:

$$\begin{cases} x(s) = \frac{2k_{ix}}{ms^2 - 2k_{sx}} i_x(s) + \frac{1}{ms^2 - 2k_{sx}} F_{ox}(s) \\ y(s) = \frac{2k_{iy}}{ms^2 - 2k_{sy}} i_y(s) + \frac{1}{ms^2 - 2k_{sy}} F_{oy}(s) \end{cases} \quad (2)$$

Regarding the PID controller, the transformed function of the current, referring the control error e , is given:

$$i(s) = G_{PID}(s)e(s) = \left(\frac{K_d s^2 + K_p s + K_i}{s} \right) e(s) \quad (3)$$

The gain parameters K_p , K_d , K_i are proportional, derivative, and integral coefficients of the PID controller, respectively. The system of equations (1) is often characterized by its input-output (IN-OUT) relationships [5]. An alternative way of their representing is the simplified block diagram (Fig.2) where the control currents are coupled with the shaft displacements.

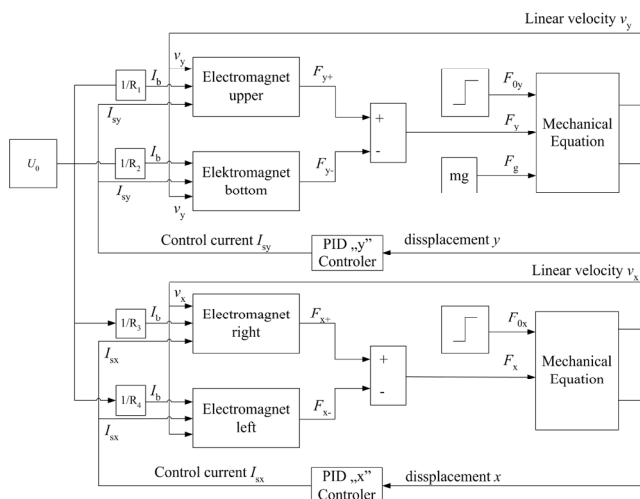

Fig. 2 Block diagram for the analysis of the AMB dynamics.

The blocks „Electromagnet” (Fig.2) have been realized in the FEM solution. After the field analysis, the magnetic forces F_{ex} , F_{ey} and other field parameters were obtained. Determination of the characteristics of the AMB operation has been included in the algorithm implemented in Matlab/Simulink application.

The blocks PID “x” and PID “y” (Fig.2) denote the controllers for two main directions of the shaft displacement. Regarding the algorithm of PID controllers, the functions $i(t)$ for control current are executed inside the block-diagram. As force-position and force-current characteristics are nonlinear, linearization of their segments has been implemented in the controlling procedure.

Fig. 3 Shaft positioning concerning the vertical symmetry axis.

Owing to the field-circuit method, we created characteristics of the shaft positioning and the control currents under non-steady states. The locus of the shaft center and the excitation currents have been measured, as well. One should add that the assumed vertical y -axis is perpendicular to the symmetry axis of the drive.

For the presented example, the shaft center is assumed to be replaced to the initial position: $x=0.3\mu\text{m}$, $y=-100\mu\text{m}$. The shaft locus changes abruptly within length of time $t=4$ ms, (Fig. 3). After $t=15$ ms, the shaft displacement nearly vanish, and we have the steady state.

Fig. 4 Control current vs. time.

The transients of the control currents I_s in the coils have been calculated and compared with the measurement values. The wave of the current corresponding the y -axis is presented in (Fig. 4).

IV. CONCLUSIONS

We have studied transients of the active magnetic bearing (AMB). Many numerical examples have been executed with our field-circuit method, where the variation of the shaft center is governed by the mechanical as well as electrical nonlinear equations with changeable coefficients. Diagrams of the rotor axis locus as well as the control currents in the stator coils have been also created, which is not presented in this short version of the paper.

The control current highly influences the magnetic forces and displacements of the bearing shaft. As the bearing is a structurally unstable object, the fast control system is indispensable for its operating. Some measured waves, at the time of the AMB starting, were compared with the computer simulation results. The experiments have been done for the step response of the bearing, especially. The calculation and measurement errors have opposite signs. Thus, the curves are close each other. The field-circuit method presented in this paper has greatly assisted in computer aided design (CAD) of the magnetic bearings.

Abstract — The internal and external magnetic couplings within a double-star permanent magnet synchronous machine (DS-PMSM), the influence of the switching frequency and of interleaved control are studied. An architecture with external coupling devices allowing to phase-shift the control signals of the two inverters is proposed; it allows reducing the current ripples and the total losses of the converter-machine assembly. Obtaining the same effect within a special machine with no external magnetic coupling is also possible and will be presented in the final paper.

I. INTRODUCTION

Today, the power of electrical systems onboard aircraft increases and minimizing the weight and mass by means of global optimization is critical. Of course, in this field, safety is also a crucial requirement which must be taken into account in the optimization process. One solution is to change the architecture of the energy conversion chain by segmenting the power in the components with a high risk of failure [2]; for example, a multi-star machine can be supplied by several independent three-phase voltage source inverters (VSIs). However, the magnetic couplings between the different stars influence the harmonic content of the current flowing through each winding and this phenomenon needs to be studied.

Previous work concluded that because of these interactions the switching frequency voltage applied across the different sub-machines should be in phase, which brings us back to the behaviour of a single star machine supplied by a single VSI: no benefit in terms of current ripple in the windings and no reduction of the input filter.

This paper analyzes the mechanisms of interaction between the machine and the VSIs. Understanding these phenomena allows us to modify these interactions by means of InterCell Transformers (ICTs) [3]. In a second step, we show that it is even possible to modify the machine so that it incorporates the desired coupling characteristic and allows operation with a 180° phase-shift between the control signals of the two VSIs, thus bringing almost the same advantages as ICTs.

II. DOUBLE-STAR SYNCHRONOUS MACHINE – MODEL SUMMARY

The machine at stake is a double-star synchronous machine with permanent magnet and non-salient poles. In its general

form, the stator consists of two stars shifted by an electric angle γ [Fig. 1].

Fig. 1. Windings of the double-star synchronous machine

The machine is supposed to be unsaturated and the back EMF of the two stars is sinusoidal. The double-star machine has 6 coils, defining an inductance matrix with 36 parameters: 6 inductances and 30 mutual inductances. For reasons of symmetry, only 5 independent parameters are in general needed to define the magnetic couplings of such a machine.

The aim of this paper is to obtain a compensation of the harmonics at the switching frequency between the different subsystems; it is thus necessary to have the same harmonic amplitude, which requires equal duty cycles in corresponding phases. For this reason only the case $\gamma = 0^\circ$ is considered here and we will show that in this case, the machine is characterized by 4 parameters only: L_{11} , M_{12} , M_{13} , and M_{14} . Fig. 2 shows the simplified single-phase equivalent diagram of the double-star synchronous machine.

Fig. 2. Simplified equivalent circuit single-phase of the DS-PMSM

The voltage equation is expressed as follows:

$$\begin{bmatrix} v_1 \\ v_2 \end{bmatrix} = \begin{bmatrix} L_{Cyc} & M_{Cyc} \\ M_{Cyc} & L_{Cyc} \end{bmatrix} \cdot \begin{bmatrix} di_1/dt \\ di_2/dt \end{bmatrix} + \begin{bmatrix} e_{v_1} \\ e_{v_2} \end{bmatrix} \quad (1)$$

$$L_{CYC} = L_{11} - M_{13} = L_{11} - M_{15} \quad (2)$$

$$M_{CYC} = M_{12} - M_{14} = M_{12} - M_{16} \quad (3)$$

III. EXISTING STRUCTURES

The system studied in this paper is shown in Fig. 3. Considering the harmonic content at the input of the *VSI*s, it was first concluded that phase-shifting the control signals of the two *VSI*s by 180° is advantageous, because the input current harmonics of the two *VSI*s cancel out partially. In this case, the phase currents are as shown in Fig. 4.

Fig. 3. Global system (inverters + machine) with internal magnetic coupling

Fig. 4. Phase currents with inverter commands 180 degrees out of phase

Compared to the ideal sinusoidal supply, the relatively high current ripple generates extra conduction losses in the windings and higher stator and rotor losses. If the two *VSI*s are in phase, which means they operate as a single *VSI*, the current waveforms become those of Fig. 5. It can directly be seen that the current ripple is lower in this case, and a deeper study comes to the conclusion that the total losses in the machine are reduced very significantly with the *VSI*s in phase. By the way, this is in agreement with the conclusions presented in [1].

Fig. 5. Phase currents with inverter commands no shifted.

On the other hand, another study [3] showed that using external *ICT*s (Fig. 6), it is possible to use *VSI*s controlled with a phase-shift of 180 degrees and to obtain simultaneously two benefits that seemed incompatible until then:

- improving the input current *THD*;
- reducing the phase current ripple.

The first benefit is obtained as a well-known consequence of phase-shifting the control signals of the *VSI*s, and the second benefit can be explained as follows. The very strong coupling brought by the *ICT*s imposes quasi-equal currents in corresponding phases of the two inverters and their waveform is the same as if it was fed by a 3-level *VSI*: the current ripple

is at twice the switching frequency and the amplitude is roughly four times smaller than in the case of Fig. 5. Such waveforms will be shown in the final paper.

The price to pay for these important benefits is the addition of new components on the whole system, thus increasing the weight and price.

Fig. 6. Global system (inverters + *DS-PMSM*) with external magnetic coupling

IV. PROPOSED STRUCTURE

The innovation described in this paper allows obtaining the same effect within a machine which is slightly modified to provide the appropriate magnetic couplings without any external component (Fig. 3). Such a machine has been studied with the finite element software *EFCAD* (Fig. 7).

Fig. 7. Example of field map for the determination of magnetic couplings

Fig. 8. Phase currents with internal magnetic couplings (proposed structure)

V. CONCLUSION

As will be shown, such internal couplings allow operation with *VSI*s 180 degrees out of phase thus providing multi-level operation, creation of a higher apparent frequency, reduction of the phase current ripples (Fig. 8) and of the input filter, as well as a significant reduction of the overall losses (inverters + machine).

Abstract—The design of electromagnetic devices submitted to mechanical stress is a growing issue and requires appropriate modeling tools. We propose in this paper to implement a multiscale model for magneto-elastic behavior in a finite element code.

Index Terms—Magneto-elasticity, multiscale modeling, finite element method.

I. INTRODUCTION

Magnetic materials in electrical machines or actuators are submitted to multiaxial mechanical loadings. These stress states significantly modify their magnetic and magnetostrictive behavior [1]. The design of electromagnetic systems consequently requires appropriate modeling tools. A possible choice is the introduction of coupled constitutive laws into finite element modeling. Unfortunately, most of magneto-elastic models are restricted to uniaxial mechanical loadings [2], [3]. A fully multiaxial magneto-elastic model, based on a multiscale energetic approach has been proposed recently [4]. The implementation of this model into a finite element simulation still leads to dissuasive computational times for engineering design applications. We propose in this paper to define a simplified version of the multiscale approach and to implement it into a coupled magneto-mechanical code.

II. LOCAL MAGNETO-ELASTIC CONSTITUTIVE LAW

The local constitutive law is derived from a multiscale approach [4], [5] and gets very close to Armstrong model [6]. The model has been simplified considering fully isotropic materials. The local potential energy W_α of the material is then written as the sum of magneto-static energy and elastic energy.

$$W_\alpha = -\mu_0 \vec{H} \cdot \vec{M}_\alpha - \boldsymbol{\sigma} : \boldsymbol{\varepsilon}_\alpha^\mu \quad (1)$$

$$\vec{M}_\alpha = M_s \vec{\alpha} = M_s \begin{bmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \end{bmatrix},$$

$$\boldsymbol{\varepsilon}_\alpha^\mu = \frac{3}{2} \begin{pmatrix} \lambda_{100}(\alpha_1^2 - \frac{1}{3}) & \lambda_{111}\alpha_1\alpha_2 & \lambda_{111}\alpha_1\alpha_3 \\ \lambda_{111}\alpha_1\alpha_2 & \lambda_{100}(\alpha_2^2 - \frac{1}{3}) & \lambda_{111}\alpha_2\alpha_3 \\ \lambda_{111}\alpha_1\alpha_3 & \lambda_{111}\alpha_2\alpha_3 & \lambda_{100}(\alpha_3^2 - \frac{1}{3}) \end{pmatrix} \quad (2)$$

\vec{H} and \vec{M}_α are the magnetic field and the magnetization. $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}_\alpha^\mu$ are the stress and magnetostriction strain

second order tensors. The unknown of the problem is the local magnetization direction $\vec{\alpha}$. M_s is the saturation magnetization of the material, λ_{100} and λ_{111} its magnetostriction constants. Assuming an isotropic behavior, we will consider $\lambda_{100} = \lambda_{111} = \lambda_s$ (macroscopic saturation magnetostriction of the material). The probability f_α for the magnetization to be in the direction $\vec{\alpha}$ is calculated using a Boltzmann type relation:

$$f_\alpha = \frac{\exp(-A_s \cdot W_\alpha)}{\sum_\alpha \exp(-A_s \cdot W_\alpha)} \quad (3)$$

A_s being a material parameter linked to the initial anisotropic susceptibility χ_o [4]:

$$A_s = \frac{3\chi_o}{\mu_o M_s^2} \quad (4)$$

Once the probability f_α is defined, the macroscopic magnetization \vec{M} and magnetostriction $\boldsymbol{\varepsilon}^\mu$ are obtained thanks to an averaging operation over all possible directions:

$$\vec{M} = \langle \vec{M}_\alpha \rangle = \int_\alpha f_\alpha \vec{M}_\alpha d\alpha \quad (5)$$

$$\boldsymbol{\varepsilon}^\mu = \langle \boldsymbol{\varepsilon}_\alpha^\mu \rangle = \int_\alpha f_\alpha \boldsymbol{\varepsilon}_\alpha^\mu d\alpha \quad (6)$$

III. FINITE ELEMENT IMPLEMENTATION

The static finite element model (FE) is based on classical mechanical and magnetic formulations. Considering the mechanical problem with the decomposition of the total strain $\boldsymbol{\varepsilon}$ into elastic strain $\boldsymbol{\varepsilon}^e(\boldsymbol{\sigma})$ and magnetostriction strain $\boldsymbol{\varepsilon}^\mu(\vec{H}, \boldsymbol{\sigma})$ ($\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^\mu$), the mechanical formulation contains an additional term $F^\mu(\vec{H}, \boldsymbol{\sigma})$, corresponding to an equivalent force due to the magneto-elastic coupling. After discretization with nodal elements, this term is expressed with:

$$F^\mu(\vec{H}, \boldsymbol{\sigma}) = \int_\Omega \nabla^s [C] \boldsymbol{\varepsilon}^\mu(\vec{H}, \boldsymbol{\sigma}) d\Omega \quad (7)$$

∇^s is the symmetrical gradient of the shape functions, $[C]$ the usual stiffness tensor, Ω the study domain. $\boldsymbol{\varepsilon}^\mu(\vec{H}, \boldsymbol{\sigma})$ is the magnetostriction strain obtained with the multiscale model (MSM). Similarly, the magnetic scalar potential (Φ with $\vec{H} = -\text{grad}\Phi$) formulation contains an additional term equivalent to a magnetic charge. The magnetic flux

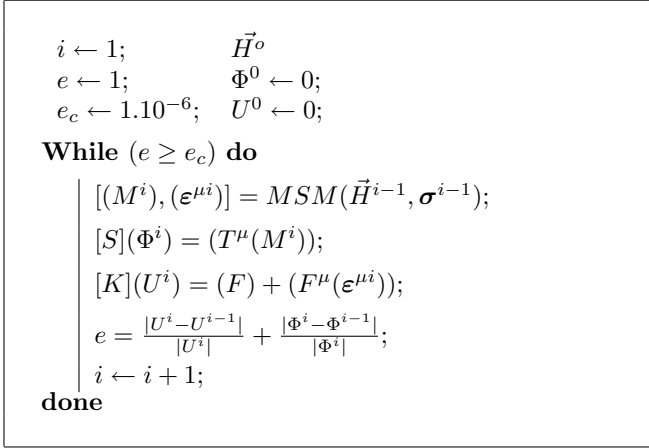

Fig. 1. Fixed-point algorithm; i represents the iteration number, MSM corresponds to the multiscale model.

density \vec{B} is defined from the magnetization \vec{M} ($\vec{B} = \mu_0(\vec{H} + \vec{M})$). Maxwell's flux conservation is written:

$$\text{div}(\text{grad}\Phi) = \text{div}(\vec{M}(\vec{H}, \sigma)) \quad (8)$$

where Φ corresponds to the magnetic scalar potential, and $M(\vec{H}, \sigma)$ to the magnetization obtained with the MSM. Thus, the coupling term in the magnetic formulation is finally obtained:

$$T^\mu(\vec{H}, \sigma) = \int_{\Omega} \nabla^m M(\vec{H}, \sigma) d\Omega \quad (9)$$

with ∇^m the gradient of the shape functions. The coupled system is then defined by:

$$\begin{cases} [S](\Phi) = (T^\mu(\vec{H}, \sigma)) \\ [K](U) = (F) + (F^\mu(\vec{H}, \sigma)) \end{cases} \quad (10)$$

with S and K respectively the magnetic and mechanical stiffness matrices, U the displacement field and F the external forces. Due to the non linearity of the problem introduced by the MSM model, an iterative algorithm based on the fixed point method is chosen for the resolution (Fig. 1). Values of magnetization and magnetostriction strain are updated using the MSM model at each step i for each element of the mesh, until the error criterion e falls down e_c .

IV. APPLICATION TO A SIMPLE STRUCTURE

In order to validate the finite element implementation, the first study concerns a rectangular FeCo sample placed in an uniform magnetic field and with uniform applied stress (here compression). For such a homogeneous configuration, the analytical MSM model provides the magnetization and the magnetostriction strain directly, allowing the comparison with the FE results (Fig. 2 and 3).

Considering these figures, the effect of the stress and of the magnetic field on the magnetic and mechanical behavior are obvious. Moreover, these results validate the implementation in the FE simulation.

Fig. 2. Magnetization as a function of applied field and stress

Fig. 3. Magneto-elastic strain as a function of applied field and stress

V. CONCLUSION

In this paper, the implementation of a multiscale magneto-elastic model in a finite element analysis has been detailed. This implementation is validated considering an iron-cobalt rectangular sample submitted to a homogeneous magneto-mechanical loading. The interest of this modeling tool concerns structural analysis for the design of electromagnetic devices. An illustration of a coupled calculation on the rotor structure of an electrical machine will be presented in the final paper.

Novel Design Method of a Single-phase Induction Motor considering Magnetic Balance

Myoung-Hyun Choi and Byung-Taek Kim, *IEEE, member*
 Dept. of Electrical Eng., Kunsan National University
 San68, myrongsong, 573-701, Korea
 cancmh@kunsan.ac.kr

Abstract — In this paper a design condition for magnetically balanced operation in a single phase induction motor is induced in analytic forms. In addition, a condition for minimal stator copper loss is also induced under the balance conditions. Using these conditions, an induction motor is designed by a proper optimization algorithm, and its loss characteristics are investigated. The validity of the proposed method is verified from the results.

I. INTRODUCTION

Single-phase induction motors (SPIMs) are used in various applications such as household applications, tooling machines and industry applications [1]. SPIMs are driven with a ‘single’ phase voltage source; therefore it is split to both a main and an auxiliary winding in order to develop start-up torque. However, the magneto-motive forces (MMFs) produced by both the windings of a SPIM are generally in a magnetically unbalanced state, thereby resulting in a backward field which deteriorates performances such as efficiency, vibration and noise etc. If the backward field can be artificially removed, the magnetic field of the motor gets in balanced state, improving efficiency [2]. In this paper, a new design method for the perfect balanced operation and the minimal copper loss is suggested.

II. OPTIMAL DESIGN OF A SINGLE-PHASE INDUCTION MOTOR

A. Conditions for the Balanced Operation

For a SPIM with a main winding in arbitrary angle ξ with respect to an auxiliary winding, magneto-motive forces (MMF) produced by both windings are shown in Fig. 1(a). To get a balanced state, the MMFs should satisfy

$$\mathbf{F}_m = -a\mathbf{F}_a e^{j\xi}. \quad (1)$$

The SPIM equivalent circuit considering the angle ξ in Fig. 1(a) can be deduced from its classical circuit model [3], [4] and shown in Fig. 1(b). Since a MMF is a product of the current and turn number of each winding, (1) is changed with

$$\mathbf{I}_m = -a\mathbf{I}_a e^{j\xi} \quad (2)$$

, where a is the effective turns ratio. By calculating the currents of the circuit of Fig. 1(b) and using (2), the balance conditions are induced as follows;

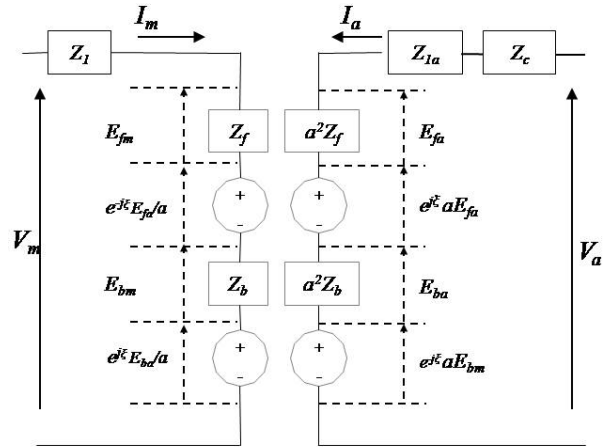

$$R_{1a} = f_1(a, \xi, R_1, \mathbf{Z}_f) \quad (3)$$

$$X_c = f_2(a, \xi, R_1, X_1, X_{1a}, \mathbf{Z}_f) \quad (4)$$

, where \mathbf{Z}_f is the forward impedance of a rotor circuit. The function f_1 and f_2 will be given in the full paper.

(a) Diagram of magnetic forces

(b) Equivalent circuit of a SPIM

Fig. 1. A single-phase induction motor

B. Conditions for the Minimal Copper Loss

Provided that the balance condition of (2) is satisfied, the conditions for minimal stator copper loss can be also induced as follows; Let the slot area for each winding be S_m , S_a and their total area be S_{tot} . The copper loss in a stator winding is given by (5), where n_m and n_a are each turn number, and l_c is stack length.

$$\begin{aligned}
W_{CS} &= R_1 I_m^2 + R_{1a} I_a^2 = I_a^2 (R_1 a^2 + R_{1a}) \\
&= I_a^2 \frac{L_c}{\sigma} a n_m n_a S_{tot} / \left(\left(S_m - \frac{S_{tot}}{2} \right)^2 + \left(\frac{S_{tot}}{2} \right)^2 \right)
\end{aligned} \quad (5)$$

By differentiating (5) a condition for minimal copper loss can be obtained by (6).

$$R_{1a} = a^2 R_1 \quad (6)$$

C. Optimal Design Strategy

By using the proposed design method, a given commercial SPIM for an instance is optimized. The optimization algorithm in Fig. 2 is applied to improve the given previous model. The turn number of each winding and the spatial angle ξ are selected as design variables. The total slot area of the designed model is same as that of the previous model. With variance of the design variables, all the combinations satisfying (3), (4) and (6) are founded and the best one is finally determined as shown in Fig. 2. The designed motor is compared with the previous one in Fig. 3 in which the determined angle ξ is 77.1° , not in quadrature.

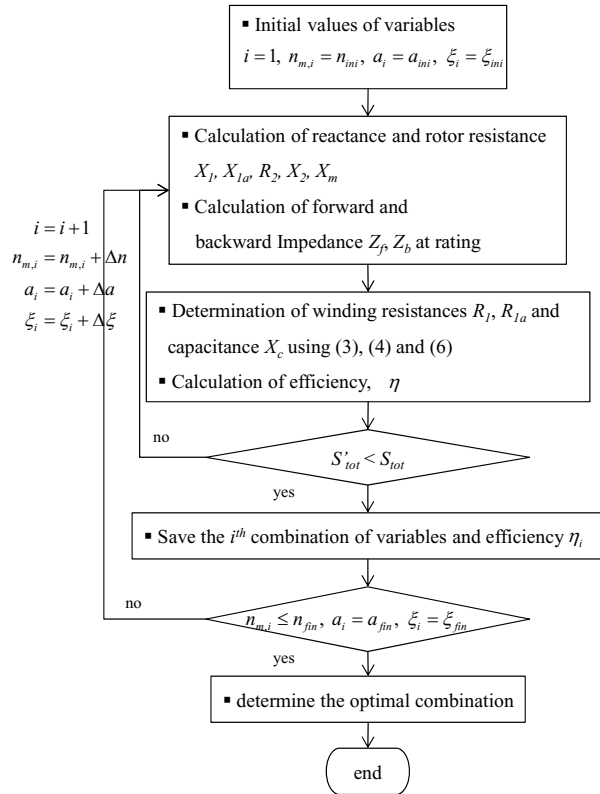

Fig. 2. Optimal design algorithm

Figs. 4-6 show the analysis results performed by the time-stepped FEA for the previous and optimized motors. From current waveforms in Fig. 4, it is noted that magnitudes of both MMFs become similar through the proposed design, getting into more balanced state. Magnetically balanced states lead to decrease of the torque ripple and ohmic losses in rotor

as shown in Fig. 5. The efficiency is improved by 0.8% at a rated load (110W) as shown in Fig. 6.

Fig. 3. Comparison of winding distribution

Fig. 4. Comparison of current

Fig. 5. Comparison of torque and ohmic loss in rotor

Abstract — A method for finite-element analysis of a rolling-rotor electrical machine was developed. The conventional moving-band technique for modelling motion was replaced by an element structure of radial bands in the air gap. This finite-element scheme allows a large distortion of the elements at the contact point of stator and rotor without suffering of problems in the convergence of numerical solution or the accuracy of results.

I. INTRODUCTION

Fig. 1 presents the operation principle of a rolling-rotor machine. The machine has no bearings, and the rotor rolls along the stator bore. A winding in stator produces a magnetic field and force F_{em} that causes the rotary motion and maintains the contact between the stator and rotor. The support forces on the contact line balance the electromagnetic force. The friction between the bodies has to be large enough to prevent slipping.

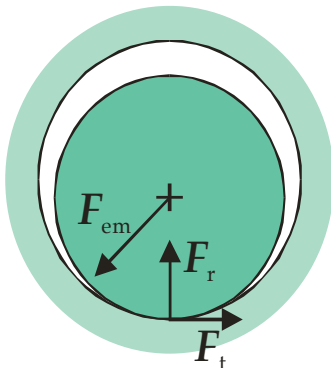

Fig. 1. Operating principle of the rolling-rotor machine.

The torque per volume ratio of a conventional radial-flux electrical machine remains small as the magnetic stress for the torque is proportional to the product of the radial flux density and circumferential flux density that is typically small. In the rolling-rotor case, the torque arm acts from the contact point of the rotor and stator, and the magnetic stress for the torque is proportional to the radial flux density squared. A large local force density can be obtained for torque production.

The contact line on the stator bore may move at a relatively large speed but the rotation speed of the rotor remains small. Thus, the potential applications of rolling-rotor machines are in low-speed high-torque drives. A rolling-rotor machine was first described by a Russian engineer A. I. Moskowitin in 1944 [1]. Later on, these machines have been studied by Viviani [2] and Kaminski&Wrotek [3], among others.

If finite-element analysis (FEA) and the commonly used moving-band technique [4] are applied for the rolling motion, problems arise related to the quality of the finite elements in the air gap. The elements become distorted, especially, close to the contact point. Refining the mesh may bring some relief but this easily leads to very large numbers of finite elements and long simulation times. Further more, as a rotor eccentricity is present, the finite-element mesh has to be constructed for the whole cross-section of the motor. There is no symmetry that could be used to reduce the solution region. Other possible ways of modelling the rolling motion within FEA could be the technique of overlapping meshes [5] or a hybrid method of FEM and BEM [6].

The aim of the present study is to develop the means to design and analyse rolling-rotor machines. The method should be computationally efficient and reliable enough to be used for structural optimisation of these machines. A small prototype of this machine was built and tested for the validation of the methods of analyses and for verifying the torque production ability of this type of a machine.

II. MODELLING MOTION AND TORQUE

The rotor of a rolling-rotor machine is typically a homogeneous cylinder made of electrical steel sheets. If the core losses of the rotor are neglected, more freedom is obtained for modelling the motion. The rotor can be just pushed against the stator at the successive time steps in such a manner that the contact point moves exactly as in the rolling motion but the rotor does not rotate. If using this semi-rolling approach, adjusting the finite-element mesh in the air-gap becomes easier.

To model the semi-rolling motion and avoid dense finite-element meshes, the circumferential element bands in the air gap were replaced by radial bands (Fig. 2a). The idea is to keep the thickness of a radial band relatively constant from the rotor to the stator. When the rotor approaches the stator, such an element band is gradually reduced to two elements, which cover an almost rectangular area (Fig. 2b). When the motion proceeds, the rectangle is gradually reduces to almost a line segment, however, still including the two elements. A right-angled triangular element seems to allow large distortions. Using this approach for a 2D time-discretised analysis, the process can be performed without convergence problems even if the length-to-thickness ratios larger than 1000 are allowed for the air-gap elements at the contact point.

The torque was computed from the air gap using the method developed by Coulomb [7]. No special treatment was used for the distorted elements close to the contact point.

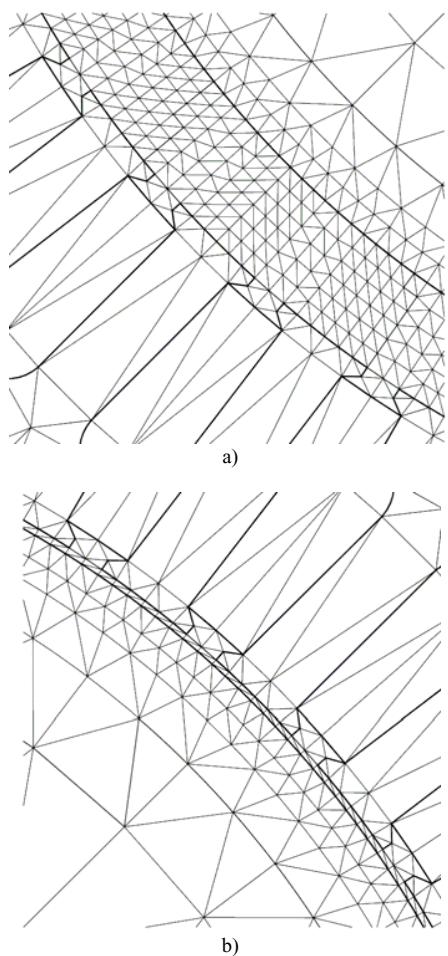

Fig. 2. Second-order isoparametric elements are used. Regions where the rotor and stator are a) relatively far from each other and b) close to each other.

III. RESULTS

Fig. 3 shows the geometry and magnetic field of the prototype rolling-rotor machine equipped with a five-phase stator winding, when the first phase is excited by a dc current. The definition of the load angle is also shown. Table I gives the main dimensions of the machine.

Fig. 3. Geometry of the rolling-rotor prototype motor. The eccentricity is 99% of the average air gap. The load angle δ defines the phase of the excitation with respect to the rotor position.

TABLE I
DIMENSIONS OF THE ROLLING-ROTOR MACHINE STUDIED

Outer diameter of the stator [mm]	160
Inner diameter of the stator [mm]	115
Outer diameter of the rotor [mm]	112
Inner diameter of the rotor [mm]	85
Core length [mm]	100

Fig. 4 shows the power versus load-angle curve of the machine, when the rotor is rolling and the phases are excited successively one by one with current pulses of amplitude 7 A.

Fig. 4. The shaft power versus load angle for the rolling-rotor machine.

IV. CONCLUSION

Using the methods described above, it is possible to model cases with full stator-rotor contact, i.e. 100% eccentricity. No convergence problems were encountered when analysing machines supplied from current sources. When voltage-fed machines with full contact were studied, the time-stepping process was not completely reliable suffering from problems in convergence every now and then.

The operation characteristics computed and measured for the prototype machine, i.e. the validation of the method of analysis is presented in the full paper.

Abstract — This paper presents an application of a vector Hysteresis model to the prediction of the inrush current due the arbitrary initial excitation of a transformer after a fault.

The approach proposed seems promising in order to predict the optimal time to close the circuit after the fault.

I. INTRODUCTION

Inrush currents are high value transient currents generated when a magnetic core is driven into saturation during initial excitation. They have many undesirable effects, such as damage or reduction of life of the transformer, opening of the power circuit by means of protective relays, and this fact can strongly reduce the quality and the continuity of the power systems, especially in the case of uninterruptible power supplies. The effects of inrush currents can be mitigated by using suitable late-closing relays, over-size fuses, or other passive components. Although reduction in inrush currents magnitudes has been achieved with this hardware, active controls, such as controlled closing ones, seem to be promising in order to reduce the complexity and the cost of the power system. An open question is about their complexity, that means how much must they have memory of the power system parameters, in order to ensure the desired degree of reliability and robustness of the protection system. Usually the control strategies are based on the prediction of the residual magnetic flux acting in the transformer in order to avoid a transient overshoot in the current, by selecting the closing time correspondent to the given residual flux [1], [2], [3],[4], [5]. The evaluation of the residual flux with accuracy is a very difficult and complex problem to solve, for the two following reasons: the effects of the eddy currents in the laminated cores is in general considerable; the hysteresis in the magnetic materials must be taken into account.

In this paper we approach the general problem of the prediction of the optimal closing time in a single-phase transformer, introducing a model of hysteresis in the transient during the transformer initial excitation.

II. NUMERICAL MODELLING

In this first approach to the problem, we postulate that magnetic hysteresis as a rate-independent phenomena and that the magnetic induction is uniform in the cross section of the magnetic core of the transformer. So, in the following, the eddy current effect will be neglected. The experiments reported in the extended version of the paper in order to help the discussion about the numerical modeling approached will be addressed to cases in which the eddy current effect seems to be negligible *a priori*. This paper is mainly focused to the introduction of vector models of static magnetic hysteresis in the simulation of inrush currents in order to discuss the improvement in accuracy achieved. The modelling of magnetic Hysteresis used is based on the rule of a phenomenological vector hysteresis operator recently defined

in the H -space. The vector hysteresis operator is defined by means of a convex surface, called critical surface, which is the locus of the values of H where there is discontinuity of the magnetization and a Barkhausen-like jump. This jump is represented in the model by the fact that the unit magnetization is frozen in the direction that it had just before it entered the critical surface for fields inside the critical surface, it remains constant until it is internal to the critical surface, and is then suddenly oriented along the direction normal to the critical surface when the applied vector field it exits the critical surface. These rules allow the model to intrinsically obey to the saturation and the static loss property [6], [7], [8]. The vector model of hysteresis above has been implemented as circuital block in the equivalent network of the transformer at industrial frequency (See Fig.1). The magnetic and electric equilibrium equations have been solved in time domain via a suitable finite difference scheme.

Fig. 1 – Equivalent circuit used for the simulation of the inrush of the no-load transformer.

III. PRELIMINARY RESULTS

In this section are reported preliminary data about the numerical simulations presented in the full paper.

The figures below refer to the initial excitation of a single-phase transformer respectively after a short circuit fault (see Fig.2) and an open circuit fault (see Fig. 3). Simulations of the example are made either by using the virgin curve or the complete hysteresis path. In Fig. 4 are reported the experimental data.

Fig. 2 – Voltage and current vs time (a)(b), and magnetization path (c) in the core of the transformer calculated for a single phase short-circuit.

Fig. 3 - Voltage and current vs time (a)(b), and magnetization path (c) in the core of the transformer calculated for an open-circuit fault.

Fig. 4 – Experimental data recorded for the example of fig. 3.

Abstract — A 2D Transient FE model is used to evaluate a new excitation signal in the estimation of synchronous generator equivalent circuit parameters. Traditionally, step, dc flux decay, sinusoidal perturbations have been used for obtaining off-line data, which are then used to estimate the machine parameters. This paper presents the results of applying a Gaussian Modulated Pulse Signal into the d - q axes of the machine. The FE simulation results are used to estimate the equivalent circuit parameters with genetic algorithms, and the resulting parameters are then validated by applying a sudden three-phase short-circuit to a 7 kVA, 220V, 60 Hz, four-pole synchronous generator.

I. INTRODUCTION

Equivalent circuits of electrical machines are a lumped representation of its complex electromagnetic behavior. They have been used since several decades ago for predicting the performance of synchronous generators, induction motors and transformers; their main advantages are their simplicity and acceptable accuracy. Lumped models are represented by a set of nonlinear ordinary differential equations; its parameters have traditionally been obtained by standard methods: standstill and online tests. Standstill tests are attractive because by applying a small perturbation signal along each magnetic axis, the complete set of parameters can be estimated, and furthermore it avoids a possible damage to the generator. Step voltage, dc flux decay and frequency response are the perturbations commonly employed; recently new signals have been explored [1]. A Finite Element (FE) model offers the ability of evaluating new excitations signals, which can be of interest to manufacturers of large generators. In this paper, the Gaussian Modulated Signal Pulse (GMSP) excitation is investigated, a two-dimensional FE model is used to simulate the test. The data obtained is then used to estimate the machine parameters by using a Genetic Algorithm (GA) and they are fine tuned by using a deterministic method. To evaluate the estimated parameters from FE data, the model is compared with a real sudden short circuit of a 7 kVA, 220V, and 60 Hz salient pole generator.

II. MACHINE MODEL

The electromagnetic behavior of synchronous machines is governed by the time-domain diffusion equation.

$$\frac{\partial}{\partial x} \left(\nu \frac{\partial A}{\partial x} \right) + \frac{\partial}{\partial y} \left(\nu \frac{\partial A}{\partial y} \right) + \sigma E - \sigma \frac{\partial A}{\partial t} = 0 \quad (1)$$

where σ is the electric conductivity, E is the electric field intensity and ν is the magnetic reluctivity.

To couple the field and circuit equations fed by an external voltage source, it is necessary to consider the winding currents as one degree of freedom and solve simultaneously with (1), as it can be expressed by following set of equations [2]-[3]:

$$SA + N \frac{dA}{dt} - PI = 0 \quad (2)$$

$$Q \frac{dA}{dt} + RI + L \frac{dI}{dt} = V \quad (3)$$

where S is the stiffness matrix, N represents eddy current regions, P represents machine windings, Q are induced voltages, R are dc resistances, L are end-winding inductances and V are source voltages.

The synchronous generator, even though is of a salient-pole type, it has solid poles where eddy currents are present. The GMSP is applied to the d or q axes while the alternator is at standstill with the field winding in short-circuit. This kind of excitation has been applied to transient electromagnetic wave propagation and it is given by [4]:

$$v(t) = V_m e^{-\frac{(t-T_{delay})^2}{A}} \sin(\omega(t - T_{delay})) \quad (4)$$

where V_m is the amplitude of the signal, ω is the operational frequency, t is time, A and T_{delay} are the shape parameters.

The vector potential distribution while the machine is at the d -axis position is illustrated in Fig. 1, it can be seen the effect of the field produced by the eddy currents.

Figure 1. D -axis field distribution with the GMSP excitation at $t=0.15$ s.

III. PARAMETER ESTIMATION AND MODEL VALIDATION

The set of state-equations are derived using the electric equivalent circuit of the machine. One-damper winding is selected for both axes, and the equations for the d -axis are:

$$\dot{\mathbf{I}}_d = \omega_0 \mathbf{X}_d^{-1} \mathbf{V}_d - \omega_0 \mathbf{X}_d^{-1} \mathbf{R}_d \mathbf{I}_d \quad (5)$$

where \mathbf{I}_d , \mathbf{R}_d , \mathbf{V}_d and \mathbf{X}_d are vector of d -axis currents, resistance matrix, voltage vector and d -axis reactance matrix, respectively, ω_0 is the rated angular speed.

The q -axis state-space equations are,

$$\dot{\mathbf{I}}_q = \omega_0 \mathbf{X}_q^{-1} \mathbf{V}_q - \omega_0 \mathbf{X}_q^{-1} \mathbf{R}_q \mathbf{I}_q \quad (6)$$

where \mathbf{I}_q , \mathbf{R}_q , \mathbf{V}_q and \mathbf{X}_q stand for q -axis current vector, resistance matrix, voltage vector and q -axis reactance matrix, respectively.

The estimation of the fundamental parameters for each equivalent circuit was made using the least squares approach where the objective function can be expressed as:

$$\min J(\theta) = \frac{1}{2} \sum_{i=1}^N (y_i - \hat{y}_i)^2 \quad (7)$$

where $J(\theta)$ is the objective function, y_i is the set of experimental data, \hat{y}_i is the set of estimated responses from the proposed mathematical model, N is the number of the experimental points and θ is the parameter vector.

In this paper, a genetic algorithm was used to solve (7). A GA is a stochastic method that employs probabilistic and non-local search heuristics that simulate natural evolution, which works on the chromosomes [5]. The final results were determined using a deterministic algorithm (Gauss-Newton). The obtained set of parameters are shown in Table I. Fig. 2 illustrates the comparison of FE model and equivalent circuit for the d -axis current, where a good accuracy can be seen.

To validate the estimated set of parameters from FE data, a sudden three-phase short-circuit was applied to the generator which has special instrumentation features. The non-linear model of the synchronous machine under short-circuit conditions is represented by (8).

$$\dot{\mathbf{x}} = \mathbf{A} \mathbf{x} + \mathbf{F}(\mathbf{x}) + \mathbf{B} \mathbf{z} \quad (8)$$

where \mathbf{x} denotes the flux linkage state-variables, \mathbf{F} is a function of nonlinear terms, \mathbf{A} is the system matrix, \mathbf{B} is the input vector and \mathbf{z} is the input variable vector.

Fig. 3 shows the comparison of the lumped model against experimental data for the field current in the short-circuit fault. It can be seen that field current is reproduced with an acceptable accuracy. The line currents are also reproduced accurately. In the full paper version more validation results will be given.

TABLE I
ESTIMATED PARAMETERS FOR THE GENERATOR

Parameter	Value (pu)	Parameter	Value (pu)
X_{md}	1.44018595	X_{mq}	1.28136182
X_a	0.19250433	X_{kd}	0.23907052
X_f	0.27719480	r_{kd}	0.14906767
X_{kd}	0.01671623	r_a	0.05251969
r_{kd}	0.16033241	r_f	0.01304253

Fig. 2. Comparison of model and FE model for the d -axis current with a 6V GMSP amplitude.

Fig. 3. Field current in the sudden three-phase short-circuit.

IV. CONCLUSION

The 2D FE ability as a data source for parameter estimation using the Gaussian Modulated Signal Pulse was demonstrated. A Genetic Algorithm was used to obtain the parameters which were then employed in a non-linear time-stepping lumped model to simulate the sudden three-phase short-circuit where good results were achieved.

Abstract — This paper presents a new efficient method for finite-elements identification of the equivalent circuit inductances of doubly-fed induction machines (DFIM). The method can be easily integrated in a computer aided optimization design of DFIM, since it allows good precision combined with a fast magnetostatic analysis. The magnetizing inductance estimation is performed by a FFT of the spatial distribution of magnetic field measured in the air gap. The variable reluctance effect produced by the double slotting of the machine yokes is taken into account as well as magnetic saturation effect. An analysis of results precision versus mesh size is presented as well.

I. INTRODUCTION

During the design process of an electrical machine, Finite Elements Analysis (FEA) is widely used for precision increase of performance prediction. FEA offers the possibility to perform a simulation of experimental tests of an electrical machine. This can be considered as a validation step of the final structure, performed at the end of the design process. However, FEA can also be used for intermediate performances validations of the electrical machine structure during the iterative optimal design process. In this case the selected numerical analysis should optimize the balance between precision and time cost. Analytical design models of DFIM can be used in combination with FEA in order to increase the design optimization precision. The detailed method presented in [1], is illustrated by Fig.1.

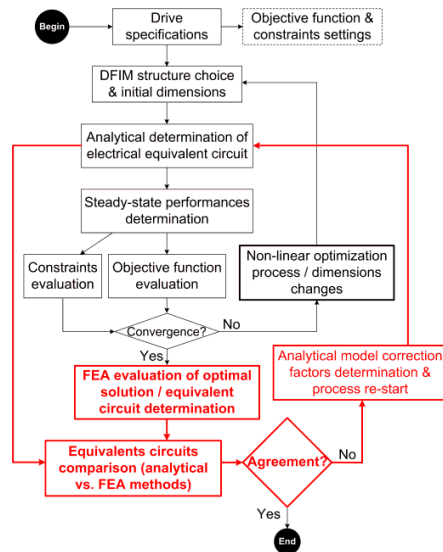

Fig.1 : Optimal DFIM design process in combination with a correction process thank to FEA.

In a first step a non-linear optimization process is used to find the optimal dimensions of the DFIM for a given

specification. The design models treated by the numerical optimization program are fully analytical based. In a second step the optimal dimensional solution is considered for FEA. In this process the goal is to determine the equivalent circuit parameters (inductances) by use of FEA and compare them with the ones determined by analytical methods. In case of unacceptable differences between analytical and FEA methods, correction factors are computed and inserted in the analytical models to improve their accuracy. The process last until the analytical model provides the same results as FEA method. These correction iterations should be as efficient as possible in terms of time cost (design time minimization) and precision.

This paper presents an efficient method to determine the DFIM equivalent circuit inductance with FEA, in order to be easily implemented in the correction process described above.

II. MAGNETOSTATIC ANALYSIS FOR EQUIVALENT CIRCUIT IDENTIFICATION

A. Cyclic inductances identification

For cyclic inductances determination by magnetostatics methods one has to take into account the slotting effect. Indeed, for different relative angular positions of the rotor with respect to the stator, the cyclic inductances may result to be different because of variable reluctance. The presented solution consists in performing several magnetostatic flux computations for n different relative angular positions and by considering the mean value of the measured magnetic flux. In the case of a three-phase balanced sinusoidal supply, one considers the time instant where one phase is supplied by a current with an amplitude value I and where the other two phases are supplied by a current with an amplitude $-I/2$. When magnetic saturation is taken into account, the peak current value must be selected in order to produce the specified maximal magnetic induction level. The rotor or stator cyclic inductance L_s or L_r are derived from the measured magnetic fluxes Ψ for each relative angular position θ , as showed in (1).

$$L_{(s,r)} = \frac{\sum_{\theta=1}^n \Psi_{\theta(s,r)}}{n \cdot I_{(s,r)}} \quad (1)$$

n is the number of relative angular positions. L_s and L_r' are defined in (2), and $L_{\sigma s}$, $L_{\sigma r}$ and L_m are presented in Fig. 2.

$$\begin{aligned} L_s &= L_m + L_{\sigma s} \\ L_r' &= L_m + L_{\sigma r} \end{aligned} \quad (2)$$

Fig.2 : Steady-state equivalent circuit of a DFIM.

Notice that $L_r' = L_r a^2$, where a is the stator to rotor voltage ratio defines as:

$$a = \frac{N_s \cdot k_{ws(h=1)}}{N_r \cdot k_{wr(h=1)}} \quad (3)$$

Where N_s and N_r are the number of turns in series per phase of the stator and the rotor windings respectively. Factors $k_{ws(h=1)}$ and $k_{wr(h=1)}$ are the stator and rotor winding factors with respect to the first spatial harmonic h .

B. Magnetizing inductance identification

Since the early 20th century the magnetizing inductance was defined as the one representing the induced voltage by the fundamental space harmonic of the magnetic flux in the air gap [2]. Since then this definition has not changed as it can be noticed by the analytical formulations in [3]. Therefore, the best way to determine such inductance by finite elements is to measure the air-gap radial magnetic field and perform a *FFT* in order to get the amplitude of its fundamental harmonic. Figure 3 shows the result of such a procedure, for a small DFIM with 48 stator slots and 36 rotor slots presented in Fig.4.

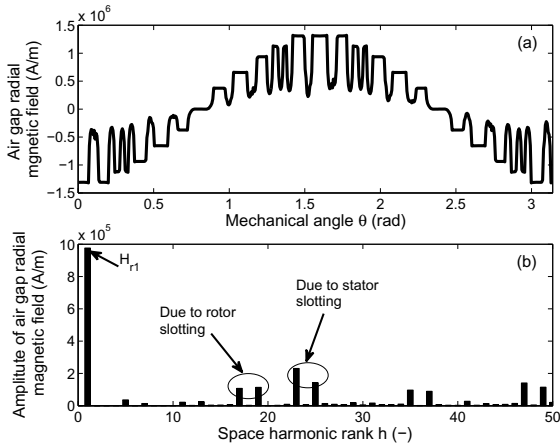

Fig.3 : (a) Radial magnetic field in the air-gap; (b) Harmonics spectrum amplitude of radial magnetic field in the air-gap.

Knowing the fundamental space harmonic amplitude of the radial magnetic field H_{r1} it is possible to derive the associates flux amplitude (4).

$$\hat{\psi}_m = \frac{2}{\pi} \mu_0 H_{r1} \frac{\pi DL}{2p} N_s k_{ws(h=1)} = \mu_0 H_{r1} \frac{DL}{2p} N_s k_{ws(h=1)} \quad (4)$$

D , L and p are the stator bore diameter, the axial length and the poles pair number whereas μ_0 is the vacuum magnetic permeability. Therefore the magnetizing inductance is determined as follows:

$$L_m = \frac{\hat{\psi}_m}{I_s} \quad (5)$$

Notice that the result is correct for any relative position between stator and rotor. The space harmonics of higher order cannot be used to compute the differential leakage inductances because of slotting effects (not rotating at the right speed).

Fig.4 Geometry and induction distribution of the considered DFIM.

C. Leakage inductances & mesh size sensitivity analysis

The leakages inductances are derived by subtraction from (2). However the subtraction between two similar numbers could lead to precision errors. Table I shows that the leakage inductance value (showed for stator) is stable for different elements number n_e in the considered domain. Notice that n_e used for L_s estimation must be equal to n_e used to estimate L_m to avoid unacceptable errors in the leakage inductance value.

 TABLE I
EQUIVALENT CIRCUIT IDENTIFICATION SENSIBILITY VS. NUMBER OF ELEMENTS

Circuit element	$n_e = 5497$	$n_e = 7409$	$n_e = 11129$	$n_e = 14849$
L_s (mH)	3.67317	3.75544	3.79632	3.81714
L_m (mH)	3.65310	3.7350	3.77550	3.7970
L_{gs} (mH)	0.020074	0.020439	0.020818	0.020142

III. CONCLUSION

The presented method is efficient in terms of computing time and precision. The result sensibility against the chosen finite elements number demonstrates the stability of this method and makes it suitable for an implementation in a optimization design environment.

Abstract—Permanent magnet (PM) machines with concentrated fractional-pitch stator windings are interesting because of their cost-effectiveness. However, in machines with fractional-pitch windings, the eddy-current losses, specifically in solid back-iron of the rotor are considerable and depend strongly on the combination of number of teeth and number of poles. This paper presents a comparison between analytically calculated eddy current losses and the loss calculation by Finite Element (FE) method. The software COMSOL is used for FE calculations. The model is applied to calculate the losses in the solid back-iron of the linear PM generator of the Archimedes Wave Swing (AWS) for different combinations of numbers of poles and numbers of teeth.

Index Terms—eddy currents, permanent-magnet machines, back-iron, fractional-pitch concentrated windings, finite element model.

I. INTRODUCTION

Permanent magnet (PM) machines with concentrated fractional-pitch stator windings are increasingly used because of their cost-effectiveness. The objective of this paper is to compare and bring out differences between an analytical model and a finite element model for calculation of eddy-current losses in the solid back-iron of these machines. If there is sufficient agreement between the results of each method, validation for the analytical method can be proved. The machine used for modeling is the linear PM generator of the Archimedes Wave Swing (AWS)*. Details about AWS are available in [1].

Currently, a PM machine with distributed full-pitch stator windings is applied. It has one slot per pole per phase as illustrated in Fig. 1. The winding is a two-layer winding, which makes it rather expensive. This is where fractional pitch concentrated windings come into picture.

*This work was supported in part by a Marie Curie Early Stage Research Training Fellowship of the European Community's Sixth Framework Programme under contract number MRTN-CT-2004-505166, the WAVETRAIN program.

PM generators with concentrated fractional pitch windings may be much cheaper because they have simple windings around one tooth which can be wound automatically and hence economically.

Fig 1: A Full pitch distributed winding (currently used in AWS)

Fig 2: A fractional pitch concentrated winding

However, the magnetic field of fractional pitch concentrated windings has more space harmonics, including sub-harmonics (harmonics with a wave length larger than twice the pole pitch). This leads to additional eddy-current losses in the magnets and the back-iron, which is made of solid steel to make a cheap and strong construction. If these losses are high, the magnets may become so hot that they demagnetize. The contribution of this paper comes from validation of the analytical model used for calculation of these losses [5] by modeling the machines with different pole-teeth combination in a FE program.

II. TOPOLOGIES SELECTED

The combinations of number of poles and teeth affect the eddy current losses that occur in the solid conductive parts of the machine [5]. This section gives an overview of the type of winding arrangement selected and the combinations of poles and teeth used for analysis. The pole-teeth combinations are

selected in such a way that winding factor is comparable to that of a full pitch distributed winding. The table below shows the winding types considered for analysis

TABLE I
WINDING TYPES CONSIDERED

	WINDING TYPES CONSIDERED
I	Full pitch with 1 slot per pole per phase
II	Fractional pitch with 3 teeth with 3 coils per 2 poles
III	Fractional pitch with 3 teeth with 3 coils per 4 poles
IV	Fractional pitch with 9 teeth with 9 coils per 8 poles
V	Fractional pitch with 9 teeth with 9 coils per 10 poles
VI	Fractional pitch with 12 teeth with 12 coils per 10 poles
VII	Fractional pitch with 12 teeth with 12 coils per 14 poles
VIII	Fractional pitch with 6 teeth with 3 coils per 4 poles
IX	Fractional pitch with 6 teeth with 3 coils per 8 poles
X	Fractional pitch with 12 teeth with 6 coils per 10 poles
XI	Fractional pitch with 12 teeth with 6 coils per 14 poles

III. ANALYTICAL CALCULATIONS

The method for calculation of eddy current losses is fully described in [5]. The Method consists of the following steps:

- a) First of all, using Ampere's law, we estimate the flux density distribution in air gap.
- b) We decompose this flux density waveform into Fourier components.
- c) Then using relative position of rotor, we evaluate the space harmonics of this flux density waveform.
- d) Eddy Current losses can then be calculated from this data.

A three layer model [6-7] for calculation of eddy current losses was selected. The eddy-current losses per square meter of surface area P_A are given by

$$P_A = \frac{\hat{B}_0^2 v^2 \delta}{4\rho_{Fe}}$$

where

\hat{B}_0 is the amplitude of the flux density wave

v is the speed of the flux density wave

ρ_{Fe} is the resistivity of iron

δ is the skin depth

IV. FINITE ELEMENT CALCULATION

A model for FE calculations has been prepared in COMSOL and the results will be included later in the full

paper.

Fig 3: Flux Density Plot for a geometry

The results will include FE modeling of eddy current losses in the machine with motion included.

V. CONCLUSIONS

The following conclusions may be drawn from the paper:

- a) The analytical results for the eddy current loss model have been presented.
- b) The paper presents a comparison between analytical method and a Finite Element method to estimate eddy current losses.
- c) Validity of the analytical method and the error range has been estimated.
- d) Reasons for differences between FE results and analytical calculations have been summarized.

Abstract — Velocity induced eddy currents appear in the ferromagnetic core of an XY-actuator when the mover, equipped with permanent magnets responsible for the generation of the magnetic field of the primary circuit, moves over its working plan. The effect produces a damping force on the mover that affects its dynamics. Furthermore, the magnetic field in the air-gap is modified owing to the secondary magnetic field produced by the induced eddy currents. The induction of electrical current is investigated for different armature core materials, i.e. solid steel and a grain-insulated soft magnetic composite (SMC). The figures show a reduction the velocity-induced eddy current by the use of a SMC core instead of a steel core.

I. INTRODUCTION

The XY-actuator in study comprehends a ferromagnetic slotless core on the top of which two sets of planar windings are placed. The former are orthogonal with respect to each other and have four sections each. The mover is the moving part of the actuator, and holds two high energy product permanent magnets and a back iron that are above the working plane of the actuator across the air-gap, Fig. 1 [1].

Fig. 1. Perspective view of the actuator and its parts.

II. FEATURES OF THE XY-ACTUATOR

The movement over its working plane, with two degrees of freedom, occurs when the coils of the armature phases located under the permanent magnets are properly fed with currents. The actuator relies also on a 3D distribution of the magnetic flux density in its magnetic circuit [1]. Owing to the velocity of the mover that moves the excitation field over the armature core, an electromotive force is produced on that core. As a result, currents are induced in the ferromagnetic core. These currents and their distribution depend on the resistivity and on

the permeability of the core material. One effect of such induced currents will be a breaking force acting on the car to oppose its movement. Additionally, the core will be heated by them. These two aspects can determine the performance of the actuator. The reduction of the velocity-induced currents as described and their effects can be obtained by employing an isotropic grain-insulated composite magnetic material as material core. Hence, a soft magnetic composite, i.e. Somaloy 500, is considered [3]. For comparison, two different slab-type cores are tested: one made of AISI 1020 steel, and other of Somaloy 500, Table I.

TABLE I
PARAMETERS OF THE ARMATURE CORES UNDER TEST [2]

Quantity	AISI 1020	Somaloy 500
Maximum relative permeability	3,800	500
Resistivity ($\mu\Omega\text{m}$)	0.1862	40.03823
Density (g/cm^3)	7.85	7.3356

III. VELOCITY-INDUCED EDDY CURRENT

The motion of the mover over the top face of the armature core causes the appearance of magnetically induced eddy currents in that core. Besides heat, the effect produces a second planar force that opposes the movement of the mover. The equation that sets the density of the induced eddy current, \vec{J} , may be given by (1) [3].

$$\vec{J} = \sigma (\vec{E} + \vec{v} \times \mu_0 \vec{H}) \quad (1)$$

In (1) σ is the electrical conductivity of the armature core, \vec{E} is the electric field, \vec{v} is the velocity of the mover with respect to the armature core, μ_0 is the permeability of the air and \vec{H} is the excitation magnetic field produced by the permanent magnets. In order to reduce those currents and, at the same time, maintain the benefit of the 3D distribution of the magnetic field, the use of an isotropic grain-insulated such as soft magnetic composite is taken into account.

A dynamic analysis carried out by means of a finite element analysis allowed to compute the distribution of the density of the induced current, J , in the core, as a function of the velocity of the mover. The region under the mover analyzed is where the structure has the largest concentration of magnetic flux density and can be visualized in the fig. 2.

Table II shows the results gathered from the numerical analysis for the velocity-induced current under the same air-gap flux distribution for both cores employed one at a time. That current is considered through the cross section of the

armature core defined in between the projected centers of permanent magnets and the thickness of the slab core.

Fig. 2. View of the area monitored to show the electrical current density.

TABLE II
COMPUTED VELOCITY-INDUCED ELECTRICAL CURRENT

Mover velocity (m/s)	Computed induced current (A)	
	AISI 1020	Somaloy 500
0.05	1.61004	0.07837
0.10	2.37128	0.11274
0.15	3.24823	0.16762

Another important detail is that the depth the induced currents penetrate the core are affected by the frequency of flux variation, the electrical conductivity and the magnetic permeability of the material. It decreases when the frequency increases, or the magnetic permeability increases, or when the electrical conductivity rises.

These results are computed a velocity of 15m/s for the mover. Figure 4 shows the results for the two different materials [1]. The values presented in the fig. 3 are RMS figures for the electrical current density.

It is important to observe two important aspects. It is possible to see that the current density is much larger when the AISI 1020 is used in the armature core; that happens once its electrical resistivity is lower than the one for the Somaloy 500. Another aspect that deserves comment is that, due the higher magnetic permeability of the AISI 1020 steel, the closer to the air-gap, the larger the concentration of induced current in the core; however, when Somaloy 500 is used the current is less concentrated in the region close to the top of the armature core. That is explained by the skin effect.

IV. CONCLUSION

For the sake of a comparative study, AISI 1020 steel and Somaloy 500 were separately employed in the armature core of an XY-actuator. Although both allow a quite similar static propulsion force, the braking force resulting from velocity-induced eddy currents is smaller in the XY-actuator with

Somaloy 500. That is explained by a larger resistivity of that core material. An overall friction coefficient that takes into account the mechanical friction and the electromagnetic braking force produced by the velocity-induced eddy currents is proposed and shows coherent figures. Moreover, the SMC, as an isotropic material, favours a 3D flux density distribution which the XY-actuator relies on.

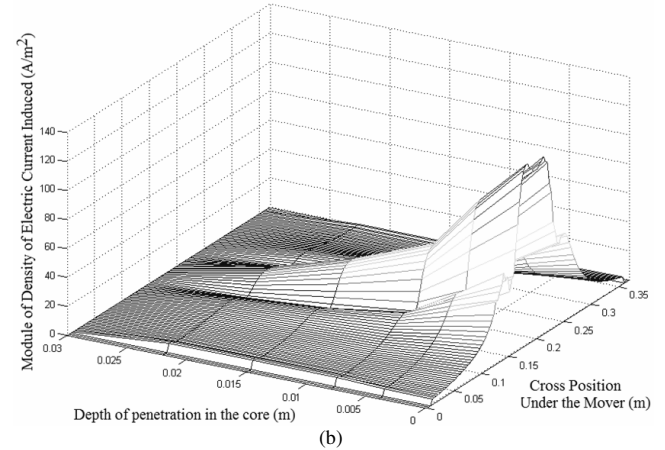

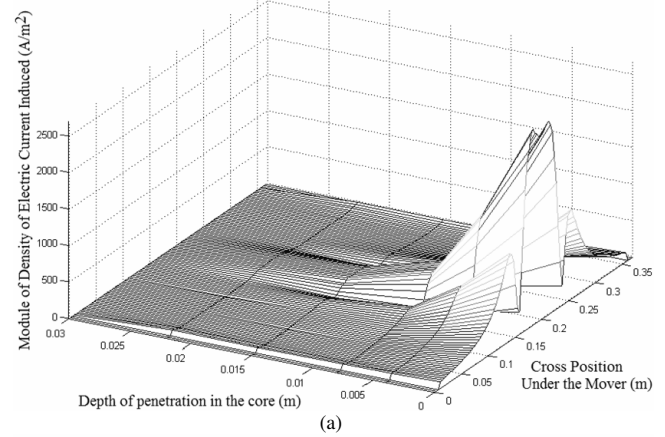

Fig. 3. Distribution of the induced current density in the armature core composed when the mover is movement with velocity of 0.15m/s with core material: (a) AISI 1020 and (b) Somaloy 500.

Abstract- This paper presents least squares support vector machine (LS-SVM) neural networks as a new tool to develop the model of the Switched Reluctance Starter/Generator (SRS/G). The basic premise of LS-SVM regression is that it forms a very efficient mapping structure for the nonlinear phase flux linkage and torque characteristics of SRS/G. The LS-SVM models are comprised of magnetization data with rotor position and phase current as input, and the corresponding flux linkage and torque as output. A LS-SVM current-flux-linkage-position model and a LS-SVM torque model are then used to simulate the dynamic performance of SRS/G, and the accuracy of the model is tested via comparison to the measurements of steady state waveforms. Both the simulation and experimental test results for a 0.55kW 6/4 SRS/G system on a digital platform at the starting and generating modes are also presented along with useful guidelines for electric starter/generator implementation.

I. INTRODUCTION

The simply structure, low cost, and the absence of windings and permanent magnets on the rotor of a switched reluctance machine (SRM) makes it a viable candidate for various general purpose adjustable speed and operation in harsh environments as a generator. The development of a SRS/G system demands a good computer simulation model to reduce the expensive and time consuming experimental stage. This paper presents Least Squares Support Vector Machine (LS-SVM) as a new tool to develop the flux linkage current position and torque current position characteristics of the SRS/G. The sampled data sets obtained from experimental SRS/G by measurement and calculation via co-energy method, are comprised of magnetization data with position and current as inputs and the corresponding flux linkage and torque as outputs. Compared with the models based on artificial neural networks (ANN) methods, the proposed model has better capability of generalization and better convergent speed. The accuracy of the model is tested via comparison to the laboratory measurements of the machine's steady state current waveforms and torque-speed characteristics.

II. MATHEMATICAL MODEL OF SRS/G

This section firstly describes the basic operation principle of SRS/G and then gives an indirect method of obtaining the flux linkage and torque by experimental test calculation. The schematic diagram of the experimental setup to obtain the instantaneous voltage and instantaneous current for flux linkage determination is shown in Fig.1. The flux linkage versus different rotor positions and phase current, obtained are shown in Fig.2(a). Then, the static torque-current-position

characteristic can be calculated by derivative of co-energy via the principle of virtual displacement, which is shown in Fig.2(b).

Fig.1 Experimental setup to obtain flux linkage of SRS/G

Fig.2 Flux linkage and torque characteristics of SRS/G: (a) flux linkage; (b) torque

III. MODELING FOR SRS/G BASED ON LS-SVM

This section presents least square support vector machine (LS-SVM) as a new toll to develop the model of flux linkage-current-position and torque-current-position models for the SRS/G.

A. Least Square Support Vector Machine

The discriminant function of LS-SVM classifier is constructed by solving the following minimization problem:

$$\min J = \frac{1}{2} \langle w \cdot w \rangle + \frac{1}{2} \gamma \sum_{i=1}^n e_i^2 \quad (1)$$

$$\text{s.t. } y_i = \langle w \cdot \phi(x) \rangle + b + e_i, \quad i=1, \dots, n \quad (2)$$

where γ is the regularization factor and e_i is the difference between the output y_i and $f(x_i)$. Using Lagrange function, the estimation function becomes:

$$f(x) = \sum_{i=1}^n \alpha_i K(x, x_i) + b \quad (3)$$

B. Application of LS-SVM for SRS/G modeling

The LS-SVM approximates the nonlinear function using the equation (3). The Gaussian radial basis function (RBF) kernel is

$$K(x, x_i) = \exp\left(-\|x - x_i\|^2 / 2\delta^2\right) \quad (4)$$

The LS-SVM has adapted for calculation of the flux linkage and torque of SRS/G. For the LS-SVM, the inputs are rotor position θ and current i , and the output are flux linkage

ψ and torque T . The LS-SVM model used for calculating the phase flux linkage and torque are shown in Fig.3.

Fig.3 LS-SVM models for calculation flux linkage and torque

In this paper, the measurement flux linkage data and calculation torque data were used to generate sample data for training the LS-SVM and the data were shown in Fig.2. After the training is completed, the LS-SVM models of flux linkage and torque surface versus the rotor position and phase current are shown in Fig.4. The comparison of simulation results by ANN and LS-SVM models are shown in table I.

Fig.4 LS-SVM models of flux linkage and torque characteristics: (a) flux linkage; (b) torque

TABLE I COMPARISON OF SIMULATION RESULTS BY ANN AND LS-SVM MODEL FOR FLUX LINKAGE

Number of sample data	Modeling methods and parameters	$\varepsilon_{mae}/\text{Wb}$	$\varepsilon_{rms}/\text{Wb}$	CPU/s
248	ANN($\varepsilon=0.001, \delta=0.4$)	0.0487	0.0258	23.66
	LS-SVM($\varepsilon=10000, \delta=0.4$)	0.0085	0.0046	2.38
496	ANN($\varepsilon=0.001, \delta=0.4$)	0.0102	0.0076	58.37
	LS-SVM($\varepsilon=10000, \delta=0.4$)	0.0013	0.00045	4.12

V. SIMULATION AND EXPERIMENTAL RESULTS

In order to validate the accuracy of this model, this section uses machine variable waveforms and several characteristic curves predicted by the model for comparison with the actual machine data. Fig.5 shows the schematic diagram of the systematic simulation. The simulation algorithm includes an LS-SVM current-dependent inverse flux linkage model $i(\psi, \theta)$ to estimate current from flux linkage and rotor position, and an LS-SVM torque model $T(i, \theta)$ to estimate the torque from phase current and rotor position.

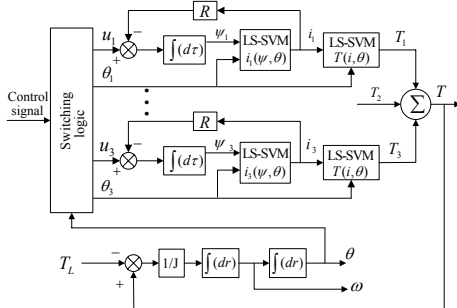

Fig.5 Schematic diagram of the systematic simulation

1) *Steady state waveforms*: Fig.6 shows a comparison of measured current and simulated phase current at the starting mode. Fig.7 shows a comparison of measured current and

simulated phase current when the machine was operated at the generating mode.

2) *Average torque versus speed*: Accurate prediction of the average torque versus speed characteristics of the SRM is crucial. Measurements were taken for dc voltages of 90V and 150 V at speeds ranging from 600 to 1200 r/min. Fig.8 depicts torque-speed data at the two dc voltages. The maximum deviation between the simulated and measured curves is lower than 10%.

Fig.7 Measured and simulated results at the generating mode with 1100rpm and 100V: (a) phase current; (b) energy conversion loop

Fig.8 Average torque versus speed

VII. CONCLUSION

This paper has presented a new idea and the procedure to use least squares support vector machine (LS-SVM) networks to model SRS/G. The LS-SVM models are comprised of magnetization data with rotor position and phase current as input, and the corresponding flux linkage and torque as output. Compared with the models based on artificial neural networks (ANN) methods, the proposed model has better capability of generalization and better convergent speed. Using the LS-SVM current model and LS-SVM torque model, a dynamic performance model for 6/4 SRS/G is constructed. The simulation and experimental results are presented to verify the effectiveness of the proposed modeling method. In addition, the experimental results are shown to demonstrate that the proposed method can be ideal for practical implementation of SRS/G system.

Abstract — This paper discusses an accurate magnetic field analysis that elasto-plastic deformation in the magnetic core by using the finite-element method (FEM) to estimate motor characteristics. This analysis method consists of the following steps: 1) measurement of the magnetic characteristics of electrical steel sheets in a state where plastic strain and elastic stress are added; 2) calculation of strain distribution and stress distribution using structural analysis; 3) preprocessing of the magnetic field analysis, which generates the FEM mesh taking account of the changes of the magnetic properties in each of the core elements corresponding to strain and stress distribution; and 4) magnetic field analysis using the data measured in step 1) and the FEM mesh generated in step 3). As an example, a result of a permanent magnet motor's cogging torque calculation is shown, focusing on elasto-plastic deformation due to stamping electrical steel sheets when the stator core of motor is manufactured

As a result, the cogging torque waveform was shown to differ depending on the strain and stress in the magnetic core when the electric steel sheets of motor core are stamped by metal mold.

I. INTRODUCTION

The permanent-magnet synchronous motor (PM motor) is widely used in industrial drives, automotive applications, and traction machines for elevators due to its high performance. The electric steel sheets of PM motor are often stamped by metal mold in order to raise the productivity. On the other hand, the magnetic characteristics of electrical steel sheets in the strain and stress condition due to stamping are known to be inferior to those in the normal condition [1], but few examinations have reported on the relationship between stress and motor characteristics; up until now, quantitative analysis of the cogging torque or the torque ripple arising from strain has not been seen.

In this paper, we discuss an accurate finite-element analysis for estimating motor characteristics, focusing on elasto-plastic deformation in the magnetic core. First, we measured the magnetic characteristics of a single sheet specimen under a strain and stress condition, and using these data we conducted a magnetic field analysis concerning the distribution of the magnetic characteristics resulting from strain and stress. As an example, we showed a result of the cogging torque calculation of a PM motor, examining strain and stress in the electrical steel sheets when the stator core of motor is manufactured.

II. DEVELOPED COMBINED SYSTEM OF STRUCTURAL ANALYSIS AND MAGNETIC FIELD ANALYSIS

Taking strain and stress distribution into account, we developed a combined system of structural analysis and magnetic field analysis. Fig. 1 shows the flow of the developed motor analysis system. This method consists of the following four steps:

- 1) measurement of the magnetic characteristics of the electrical steel sheets in the condition where strain and stress is added;
- 2) calculation of strain and stress distribution using structural analysis when the electric steel sheets of motor core are stamped by metal mold;
- 3) preprocessing of the magnetic field analysis, in which the finite-element method (FEM) mesh is changing the properties of each mesh in the stator core corresponding to the strain and stress distribution;
- 4) magnetic field analysis using the measured data obtained in step 1) and the FEM mesh generated in step 3).

Several expressions of stress value can be used in the stress-mapping process of this system, e.g., principal stress, which means the vector value, or the von Mises stress, which expresses the stress in each element as a scalar value. In this paper we use the von Mises stress.

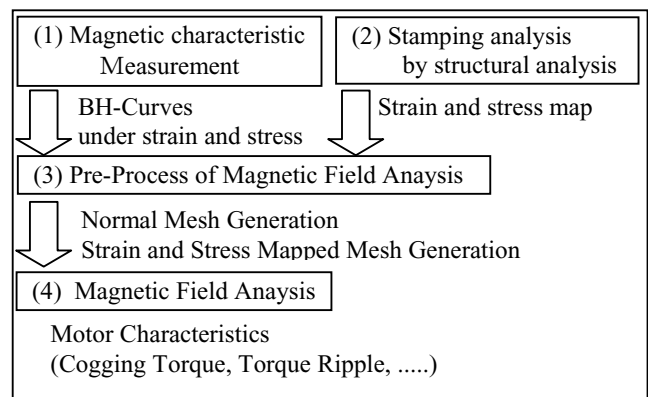

Fig. 1 Flow of motor characteristic analysis considering strain and stress distribution in stator core

III. MEASUREMENT OF MAGNETIC CHARACTERISTICS UNDER ELASTO - PLASTIC STRAIN AND STRESSED CONDITION

In order to add a uniform strain distribution to electric steel sheets, we prepared the tensile test piece in Fig 2. And a single sheet test pieces is produced by wire cut after the tensile test. A single sheet test pieces is add an elasto-strain of 0% and 5% by the tensile test. Fig. 3 and 4 show the example of the measured data. Fig. 3 shows BH-Curve versus applied strain, Fig. 4 shows relative permeability versus applied stress at magnetic flux density 1.0 T. The core grade of the magnetic steel sheet is 35A230 (JIS C 2552), and the measured frequency is 50 (1/s). These figures show that the BH-Curve and relative permeability under a strain and stressed condition is inferior to the normal (unstrain and unstress) condition; in particular, the characteristics under compressive are worse rather than those under tensile stress. For a combined analysis, we need to measure more data for different magnetic flux densities.

Fig. 3 Measured results of BH-Curve of magnetic steel with strain.

Fig. 4 Measured results of the relative permeability of magnetic steel with applied stress.

IV. SPECIFICATION OF ANALYSIS MODEL AND CALCULATION RESULTS

In this paper, we tried to estimate the cogging torque resulting from strain and stress, when the stator core is stamped by metal mold. The verification model is shown in Fig.5. We examine the PM motor having 8 poles and 12 sator slots.

Firstly, we calculate the strain and stress distribution of the motor core due to stamping using structural analysis. The calculated result is shown in Fig.6. The figure indicates that the stress of the motor core is growing in the edge of core. Secondly, the FEM mesh for the magnetic field analysis was generated using the result of structural analysis i.e., the properties of each of the core elements were changed according to the distributed elastic strain and plastic stress

value. The calculated results of cogging torque by magnetic field anaysis are shown in Fig. 7. This figure indicate the cogging torque with strained and stressed core due to stamping is greater than that with the normal (unstrain and unstress) core.

Fig.5 Verification model

Fig.6 Calculation result of contour map of stress distribution in stator teeth

Fig. 7 Calculation Results of Cogging Torque

V. CONCLUSION

In this paper, we proposed an accurate finite-element analysis for estimating motor characteristics, focusing on elasto-plastic deformation in the magnetic core. Taking strain and stress distribution into account, we developed a combined system of structural analysis and magnetic field analysis. And, we then measured the magnetic characteristics of the electrical steel sheets under a strain and stressed condition. Using this method, we tried to estimate the cogging torque of a PM motor resulting from strain and stress generated in the stator core at stamping. As a result, we showed that the cogging torque waveform differed depending on the strain and stress in the stator core when electric steel sheets of motor core are stamped by metal mold.

Calculation of Radial Forces in Cage Induction Motors at Start – the Effect of Rotor Differential

David G. Dorrell

School University of Technology Sydney, Broadway, Sydney, Australia
ddorrell@eng.uts.edu.au

Abstract— In this paper the radial forces in an induction motor are calculated using finite element analysis. These radial forces (or unbalanced magnetic pull - UMP) are generated when the rotor is eccentric. The work illustrates the importance of higher winding harmonics and rotor differential leakage in the starting UMP. Examples of a 6 pole machine with 26 and 40 bar rotors show that increasing the bar number and air-gap length will reduce the UMP.

I. INTRODUCTION – CAUSES OF RADIAL FORCE

Radial forces, or unbalance magnetic pull (UMP) is caused by the concentration of air-gap flux so that it is asymmetrical. If the rotor is eccentric (not centered) then the flux will be concentrated around where the air-gap is narrowest. In terms of mathematical breakdown it was shown in [1] that in a cylindrical machine this concentration can be represented by flux waves with pole-pair numbers differing by one. There is much literature that focuses on the calculation of UMP, both in terms of analytical calculation and finite element analysis [2][3][4]. The standard approximation considers only the radial air-gap flux to produce normal stress where

$$\sigma = \frac{b_n^2}{2\mu_0} \quad (1)$$

However Binns and Dye [5] suggested that, while the tangential components are small, there is still up to a 10 % UMP component due to the tangential stress. More accurately, the shear and tangential stresses are

$$\sigma = \frac{b_n^2 - b_t^2}{2\mu_0} \text{ and } \gamma = \frac{b_n b_t}{\mu_0} \quad (2)$$

where b_t is the tangential air-gap flux density. Dorrell [6] has shown that there is up to 10 % variation of UMP due to the tangential components using finite element analysis (FEA). These can be used to calculate the UMP in orthogonal directions using stress integrals around the air-gap:

$$F_d = L \int_0^{2\pi r} (\sigma \cos(ky) - \gamma \sin(ky)) dy \quad (3)$$

$$F_q = L \int_0^{2\pi r} (\sigma \sin(ky) + \gamma \cos(ky)) dy \quad (4)$$

This assumes that y is the tangential direction, x is the radial direction, b_t is positive in the counter-clockwise direction and b_n is positive when flowing out in the radial direction; k is the inverse of the mean air-gap radius while L is the axial core length. In this paper a finite element analysis is carried out and (1) is implemented (first terms of (3) and (4) integrals) in a step-wise fashion since it is a valid approximation.

The literature contains little about UMP in cage induction motors when starting. Dorrell gave some results for a 10-pole machine at low voltage [7]. This is an analytical simulation and dates from 1994 when FEA of this problem was difficult. This simulation includes higher winding harmonic flux waves

but did not include the rotor differential flux waves in the UMP calculation. The machine had 90 stator slots (18 slots per pole-pair – which is the same as the 6-pole machines investigated here) and 80 rotor bars (which is 16 rotor bars per pole-pair, which is a very popular bar number per pole-pair; this compares to 8.67 bars per pole-pair for a 6-pole 26-bar rotor machine and 13.33 bars per pole-pair for a 6-pole 40-bar machine – these arrangements are investigated here).

Different types of eccentricity need to be addressed. Static eccentricity is where the rotor rotates on its own axis but is off-centre from the stator bore. This can be caused by misplaced bearings or alignment. Dynamic eccentricity is where the rotor is not rotating about the rotor centre but is rotating on the stator bore centre. This could be caused by a bent shaft. Obviously static and dynamic eccentricity can exist together and Burakov and Arkkio [2] studied eccentricity (with FEA analysis) in general terms of a rotating eccentricity which does not correspond to rotor speed. However, this only really becomes relevant at higher speed and rated load. This was illustrated by Dorrell [8]. At low speed the air-gap is dominated by the higher winding harmonic flux waves (which are undamped by the rotor because the bar number is usually close the harmonic number) and also the rotor differential flux waves (which increase with slip and tend to saturate the tooth tips of the stator and the rotor surface).

Fig. 1 Flux plots for 26 bar and 40 bar rotor at 75 % eccentricity.

II. 6-POLE MOTOR ARRANGEMENT

Some induction machines have marked differences from normal power drive machines. High-voltage submersible machines exist with hydrodynamic bearings for underwater operation. One of the properties of the hydrodynamic bearings is that there is a large degree of inherent rotor eccentricity compared to standard drive motors which means the air-gap has to be larger. In this paper an initial 26 bar rotor (air-gap of 1.7 mm) is studied – this had excessive UMP; while a further 40 bar rotor is studied with an increased 2 mm air-gap. This will give lower UMP because, for a given rotor movement, the per-unit eccentricity is less and UMP is more a function of the per-unit eccentricity.

Fig. 1 gives the UMP simulations for these machines when the rotors are up to 75 % eccentricity (1.5 mm for 40 bar rotor and 1.275 mm for 26 bar rotor). The aim of this work is to identify the UMP that will cause hard pull-over of the rotor against the stator. At start there is no differentiation between static and dynamic eccentricity. The 40 bar and 26 bar machines were studied under locked rotor conditions using magneto-static FEA (with the current in the rotor calculated using an analytical calculation tool) and an analytical algorithm [1]. It is possible to develop full transient time-stepped FEA models [2]; these are very time consuming both in terms of development and run. While magneto-static FEA should be used with prudence for an induction machine. The analytical calculation tool calculates a good value for the rotor current vector, even under locked and saturated conditions, which makes it suitable for carrying forward for use as the rotor current vector in a magneto-static FEA. In addition, the rotor damping currents of the main 6-pole MMF-sourced flux waves will be limited because the main 6-pole flux wave is small at start.

The initial results, which compare the FEA, analytical algorithm and a typical rotor deflection line for rotor with hydrodynamic bearings, are summarized in Fig. 2 with the 26 bar rotor having much higher UMP. The reasons for the different UMP characteristics are due to the increase in rotor bars, which will increase the damping of the lower pole number air-gap flux waves [7] and also decrease in rotor differential waves (which dominate the flux waves – this has not been reported in the literature before), and the increase in air-gap length. In Fig. 3, it can be seen that for both the 26 bar and 40 machines there are harmonics due to the stator winding at 15, 21, 51 and 57. For the 26 bar machine there are substantial harmonics due to rotor differential at 23, 29, 49 and 55. This is also further modulation of the first slot passing frequencies and differential to give 25 (51-26) and 31 (57-26). For the 40 bar machine there are first rotor differentials are 37 and 43 harmonics while there is first modulation of the slot passing frequencies at 11 (51-40) and 17 (57-40). There are several other harmonics for the machines which may be due to further modulations or possibly from numerical variance. When the rotor becomes eccentric additional flux waves either side of the main flux waves appear.

Further air-gap flux waves can be analyzed which illustrate the flux variation over speed and voltage. This shows the air-gap flux to be very variable in terms of harmonic make-up and hence the UMP is difficult to calculate, susceptible to continual variation and a function of core saturation. Hence there is variation between the FEA and analytical method from [1] in Fig. 2.

III. CONCLUSIONS

This paper assesses the UMP in a 6-pole induction motor with either 26 and 40 bar rotors with rotor eccentricity. It illustrates that at start the air-gap flux is dominated by the higher flux waves including the rotor differential waves. Hence increasing the bar number will decrease the UMP. This paper presents some new information on UMP in cage induction machines that has not appeared in the literature.

Fig. 2. UMP calculation for 26 bar and 40 bar rotors at start including half-voltage calculations – 26 bar rotor liable to rotor pull over since UMP higher.

Fig. 3. Flux wave harmonics in air-gap for 26 and 40 bar rotors (centered) – from FEA at full voltage – the 6-pole main winding is harmonic 3.

Eddy-current Losses and Temperature Rise in the Form-wound Stator Winding of an Inverter-fed Cage Induction Motor

M.J. Islam, H.V. Khang, A-K. Repo, A. Arkkio

 E-mail: huynh.khang@tkk.fi

Abstract— Temperature rise of the form-wound multi-conductor stator winding of a 1250-kW cage induction motor was analyzed resulting from the eddy currents in the winding. The eddy current was modeled using time-discretized finite-element analysis (FEA). The resistive losses in each of the conductor obtained from the FEA are used as input for thermal modeling. The distance from the air gap to the topmost bar in the stator has a significant effect on the eddy-current loss as well as temperature rise in the winding. An acceptable distance for winding design was recommended. By using magnetic slot wedges the eddy-current losses can be reduced.

I. INTRODUCTION

The eddy-current losses increase with the high-frequency harmonics of power supply. The loss determination has an important role in both design and use stages. The heating sources in a motor come from the losses. The consideration of the temperature rise is necessary to check whether the motor design is suitable or not. Numerical methods have been used to compute the losses, and then analyze the temperature rise in the electrical machines in recent years [1-2]. The time-stepping finite element analysis (FEA) is required to estimate the losses due to high-order harmonic fields [3].

In this paper, the eddy-current losses in a multi-conductor stator winding of an inverter-fed cage induction machine are modeled. Secondly, the thermal analysis is performed on the basis of the average loss density of each stator bar. The installment of the magnetic wedges at the slot opening is a simple way to reduce the temperature rise.

II. EDDY-CURRENT LOSSES IN STATOR WINDINGS

The two-dimensional (2-D) electromagnetic model is used to model the eddy currents in a cage induction machine [3]. The electromagnetic field in the multi-conductor winding is

$$\nabla \times (\nu \nabla \times A) + \sigma \frac{\partial A}{\partial t} - \left(\frac{1}{l} \sum_{j=1}^{Q_b} \sigma \eta_j u_j \right) e_z = 0 \quad (1)$$

where ν , σ – reluctivity and conductivity of conductor, A – magnetic vector potential, l – effective length of stator, Q_b – number of bars in stator winding, u_j – the potential difference of stator bar j , η_j is defined as follows

$$\eta_j = \begin{cases} 1 & \text{if the point belongs to stator bar } j \\ 0 & \text{otherwise} \end{cases}$$

A separate voltage equation is considered for the bar. This voltage equation strongly couples the field and circuit equation of the phase. The equations are discretised in time using backward Euler method. These equations are solved using Newton-Raphson method.

The stator resistive loss P_t includes the resistive loss of stator bar P_{sb} and the end-winding resistive loss P_{ew} . The eddy-current loss P_{eddy} is the difference between the total resistive loss and DC resistive loss.

$$P_t = P_{sb} + P_{ew} \quad (2)$$

$$P_{sb} = \frac{Q_l}{\sigma} \sum_{j=1}^{Q_b} \int_{\Omega} n_j J^2 d\Omega \quad (3)$$

$$P_{ew} = \sum_{j=1}^m R_e i_j^2 \quad (4)$$

$$P_{eddy} = P_t - \sum_{j=1}^m R_s i_j^2 \quad (5)$$

J – current density, i_j – phase current in stator bar j , Q_s – number of symmetry sectors. R_s and R_e are one phase DC resistances of the end-winding region and stator bar.

III. THERMAL ANALYSIS OF STATOR WINDING

The heat conduction of the solid conductor bars in the stator winding at the steady state obeys Gauss' law [4].

$$-\nabla \cdot (\lambda \nabla T) = p_{\text{loss}} \quad (6)$$

where p_{loss} – power loss density, λ – thermal conductivity.

A 2-D finite element model is built to consider the heat flow in the stator slot. The temperature T over a solution domain solved from (6) shows the thermal distribution in the stator winding. The heating sources are the average resistive losses in each conductor of the stator winding.

IV. RESULTS

A PWM inverter fed three-phase cage induction motor 690V, 1250 kW is used to consider the eddy-current losses and thermal distribution in the stator winding. The simulations are performed according to the distances from air gap to the conductor h_{sb} (the radial positions of the stator bar) in the

case of with and without the magnetic slot wedges installed at the slot opening. The stator bars are systematically transposed to reduce the effect of the circulating currents.

A. Eddy-current losses

The AC resistive losses decrease dramatically when the radial position h_{sb} is increased from 0.8 to 11.8 mm as shown in Fig. 1. This variation mainly comes from the dependence of eddy-current losses on h_{sb} in Fig. 2.

Fig. 1. AC and DC stator resistive losses at different radial positions.

The eddy-current losses in the stator slots can be reduced by installing the magnetic wedges at the slot opening. The thickness of magnetic slot wedges is varied from 0.5 to 5 mm when h_{sb} is increased from 0.8 to 5.8 mm. The thickness of wedges 5 mm is kept constant when h_{sb} is larger than 5.8 mm.

Fig. 2. Eddy-current losses at different radial positions.

B. Temperature rise

The temperature-rise analysis is performed by using public domain software FEMM [4]. The volume heat generation is calculated from the average AC resistive-loss density in each stator bar. The temperature-rise distributions in the stator slot without and with the magnetic wedge are shown in Fig. 3.

Fig. 4 shows the maximum and average temperature rise in the stator slot according to the radial position of stator bars. The design of the stator winding is reasonable when the difference between the maximum and average temperature rise is smaller than 10 K. The presence of magnetic wedges helps reducing the maximum temperature rise or this

difference. The radial position has to be larger than 5.8 mm or larger 4.8 mm in case of without or with the magnetic slot wedges installed.

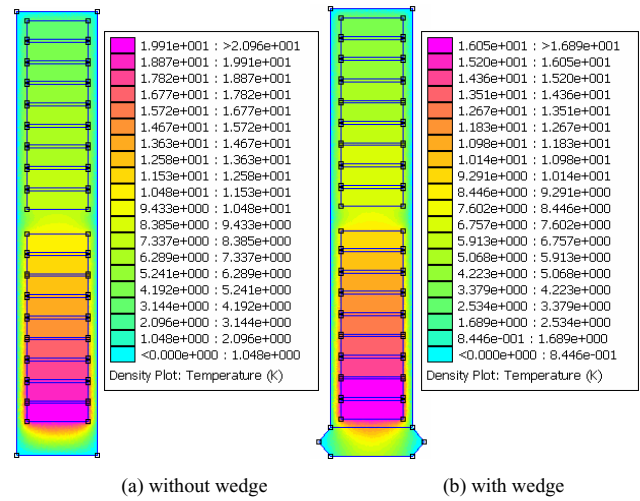

Fig. 3. Temperature-rise distribution in the stator slot at $h_{sb} = 5.8$ mm.

Fig. 4. The maximum and average temperature rise in the stator slot.

V. CONCLUSIONS

The eddy-current losses strongly depend on the distance from air gap to the stator bars. The magnetic wedges installed at the slot opening make it possible to reduce the eddy-current losses or heating dissipation in the stator windings. The goodness of winding design for an inverter-fed large induction machines can be pre-examined via a coupled electromagnetic and temperature-rise analysis.

Semi-Analytical Solution of Cogging Torque in SMPMM

F. DUBAS and C. ESPANET

ENISYS Department, FEMTO-ST Institute, CNRS UMR 6174, F90010 Belfort, France

E-mail: FDubas@gmail.com

Abstract — In this abstract, the authors present a cogging torque determination by a new two-dimensional (2-D) semi-analytical solution of the magnetic field taking into account the slotting effect in surface mounted permanent-magnet (PM) motors (SMPMM). The cogging torque waveforms is compared with the finite element analysis (FEA) for radial and parallel magnetized PMs. The analytical results are in very good agreement with those obtained by the FEA, considering both amplitude and waveform.

I. INTRODUCTION

In a PM Brushless motor which consists of the magnet poles and slotted stator core, there exists the cogging torque. It can be the sources of speed pulsation, vibration, and acoustic noise...[1]. As electromagnetic forces result from the interaction between the rotor and the stator through the no-load magnetic field in the air-gap, an accurate prediction of the instantaneous local magnetic field taking into account the slotting effect is essential. In [2], Zhu *et al.* presents and compares six alternate analytical models for cogging torque prediction. In this paper, the authors propose another alternative approach for cogging torque evaluation by using the results of a new 2-D semi-analytical solution [3], which determines the no-load magnetic field distribution in the air-gap taking account into the slotting effect. The cogging torque waveforms predicted by this new approach of the slotting effect (and calculated for both radial and parallel magnetization) have been compared with the FEA [4]. The semi-analytical results are in very good agreement with those obtained by the FEA, considering both amplitude and waveform.

II. A 2-D NEW SEMI-ANALYTICAL SOLUTION [3]

A. Problem Description and Assumptions

Fig. 1 shows the geometric representation of the multi-pole SMPMM for the new 2-D semi-analytical solution used to study the effect of the stator slotting. The main parameters of this geometry are: the radius of the stator yoke surface, R_{sy} , the radius of the stator surface, R_s , the radius of the PMs surface, R_m , the radius of the rotor yoke surface, R_r , the mechanical angle of PMs, θ_m , the mechanical angle of a stator slot-opening, θ_o , the mechanical angle of a stator tooth-pitch, θ_t , and the mechanical angle of a pole-pitch, θ_p .

The authors make the following assumptions which are usual in many models of the literature: i) End-effects are neglected; ii) The stator and rotor back-iron is infinitely permeable (i.e., the magnetic saturation is neglected); iii) The electrical conductivity of the PMs is assumed to be null to

Fig. 1. Cross section of one pole pitch of the multi-pole SMPMM.

calculate the no-load magnetic vector potential (i.e., no resolution of Diffusion's equations); iv) The PMs are assumed to be nonoriented (with no particular direction of magnetization), isotropic, and having a linear demagnetization characteristic (rare earth magnets); v) Radial slot faces on the stator.

B. No-load Vector Potential Determination

The new semi-analytical solution is based on 2-D analysis in polar coordinates, and involves the solution of Laplace's equations in the air-gap (i.e., concentric region) and in the slots on the stator (i.e., non-concentric regions) and the solution of Poisson's equations in the PMs (i.e., concentric region) [see Fig. 1] with constant magnetic permeabilities. The no-load magnetic field solutions with the slotting effect are obtained by using the Fourier's series and the method of separating variables. However, it now caters for i) internal rotor motor topology; ii) radial and parallel magnetization; iii) curvature effect; iv) depth of the slots.

The no-load flux density, in each region, has been compared to the FEA calculations, and the agreement was quite satisfying (considering both amplitude and waveform). The no-load vector potential can be expressed in the PMs, i.e., in Region 1, by

$$A_{z1} = B_{rm} \cdot R_m \cdot f_{z1n}(E_{1n}, G_{1n}, r, \theta_s), \quad (1)$$

in the air-gap, i.e., in Region 2, by

$$A_{z2} = B_{rm} \cdot R_m \cdot f_{z2n}(E_{2n} \sim H_{2n}, r, \theta_s), \quad (2)$$

in the slots on the stator, i.e., Regions i , by

$$A_{zi} = B_{rm} \cdot R_s \cdot f_{ziv}(F_{iv}, r, \theta_s), \quad (3)$$

where B_{rm} is the remanent flux density of PMs; r and θ_s are respectively the radial position and the mechanical angular

position of the stator; f_{z1n} , f_{z2n} and f_{ziv} are the functions in Fourier's series which depend respectively on the integration constants E_{1n} & G_{1n} in Region 1, $E_{2n} \sim H_{2n}$ in Region 2, and F_{iv} in Regions i . In these equations, n and v represent respectively the spatial and the slotting harmonic orders.

The integration constants in each region are determined by numerically solving the linear equations (i.e., the Cramer's system) for each Θ_{rs} (with Θ_{rs} the mechanical angular position between the rotor and the stator). The Cramer's system, detailed in [3], for each Θ_{rs} is based on $6 \cdot (n_{max} + 1) + Q_p \cdot (v_{max} + 1)$ equations and unknowns with n_{max} and v_{max} terms in the Fourier's series for the computation of A_{z1} , A_{z2} and A_{zi} .

III. COGGING TORQUE CALCULATION

The cogging torque is calculated by multiplying the Maxwell stress tensor at the stator surface by R_s and integrating it over the stator surface, i.e.,

$$T_C = -\frac{p \cdot R_s \cdot L}{\mu_0} \cdot \int_{-\Theta_p}^{\Theta_p} \frac{\partial A_{z2}}{\partial r} \Big|_{r=R_s} \cdot \frac{\partial A_{z2}}{\partial \Theta_s} \cdot d\Theta_s, \quad (4)$$

where p is the number of pole pairs, μ_0 is the vacuum permeability, and L is the effective axial length of the motor.

By using (2), the cogging torque can be defined by

$$T_C = V_{cyl} \cdot \frac{B_{rm}^2}{\mu_0} \cdot f_T, \quad (5)$$

where $V_{cyl} = \pi \cdot R_s^2 \cdot L$ is the exchange volume of the stator, and

$$f_T = \sum_{n=1,3,5,\dots}^{n_{max}+1} f_{Tn} \cdot (E_{2n} \cdot H_{2n} - F_{2n} \cdot G_{2n}) \quad \forall np, \quad (6a)$$

$$f_{Tn} = 2 \cdot \left(np \cdot \frac{R_m}{R_s} \right)^2. \quad (6b)$$

It can be noted that the harmonic function f_T is equal to zero for the slotless motors equipped with surface mounted PMs and in this case the cogging torque does not exist.

IV. COMPARISON WITH FINITE ELEMENT SIMULATIONS

The cogging torque evaluation has been applied to a SMPMM, whose main characteristics are given in the Table I. Fig. 2 shows the cogging torque waveforms, under a tooth-pitch, with radial and parallel magnetized PMs. The semi-analytical results are in very good agreement with those obtained by the FEA, considering both amplitude and waveform. The new semi-analytical solution takes significantly less computing time than the FEA. In this comparison, the Cramer's system in [3] has 486 elements (i.e., with $n_{max} = 49$ and $v_{max} = 30$) which is much smaller than the FEA having 6,000 surfaces elements for the studied SMPMM.

TABLE I
PARAMETERS OF SURFACE MOUNTED PM MOTOR

Parameters	Values	Unit
Number of pole pairs, p	1	—
Total number of slots, Q_s	12	—
Magnet pole-arc to pole-pitch ratio, $\alpha_p = \Theta_m / \Theta_p$	100	%
Stator slot opening to tooth-pitch ratio, $\zeta_o = \Theta_o / \Theta_t$	33.33	%
Radius of the stator yoke surface, R_{sy}	37	mm
Radius of the stator surface, R_s	20	mm
Radius of the PMs surface, R_m	19	mm
Radius of the rotor yoke surface, R_r	14	mm
Axial length, L	45	mm
Remanent flux density of the PMs, B_{rm}	1.13	T
Relative magnetic permeability of the PMs, μ_{rm}	1.029	—

Fig. 2. Comparison of the cogging torque waveforms calculated numerically by FEA and semi-analytically by 2-D new approach of the slotting effect.

V. CONCLUSION

A new 2-D semi-analytical solution of the magnetic field taking into account the slotting effect has been used to determine the cogging torque in SMPMM. This general approach is mathematically more rigorous than the method based on the Schwarz-Christoffel transformation [5] which gives a 2-D complex permeance functions. Moreover, the semi-analytical solution can be a useful tool for design and optimization of multi-pole SMPMM, for example to minimize the cogging torque.

Interactive Postprocessing Formulations in 3D

Martin Hafner¹, Marc Schöning¹, Marcin Antczak², Andrzej Demenko² and Kay Hameyer¹

¹ - Institute of Electrical Machines – RWTH Aachen University

² - Institute of Electrical Engineering and Electronics – Poznan University of Technology

E-mail: Martin.Hafner@IEM.RWTH-Aachen.de, Marcin.Antczak@doctorate.put.poznan.pl

Abstract—Nowadays, the postprocessing and visualization of finite element solutions is performed by means of static formulations and methods. Dynamic modifications and interactive exploration of 3D solution data are only possible in a very limited way. In this paper, an interactive postprocessing approach is introduced, allowing for a dynamic modification of finite element solutions, a simplified mesh cutting and data exploring as well as new ways of exploring complex solutions.

I. INTRODUCTION

The exploration and interpretation of a large amount of solution data is the most important part of a typical design process when using the finite element approach. Important decisions are made on basis of solution visualizations and next design steps are planned in dependency of the ongoing understanding of the device under research. Therefore, effective postprocessing algorithms handling large amount of finite element data and the usability of such methods in an interactive way allows a faster and optimized design with finite elements. Today, typical visualizations of finite element solutions are static colored representations of a field distribution, which map a computed value to a specific color. Additionally, vector fields can be visualized by colored cones or arrows, indicating the direction of the solution in every element. In this paper, further postprocessing methods and visualization techniques are introduced to enhance the exploration of finite element solutions. These are mainly mathematical modifications of the visualized solutions, simplified placing of cutting geometries like planes or spheres, and dynamic changing of display objects. For all mentioned aspects, examples are given to underline the usage possibilities of the proposed postprocessing formulations.

II. COMPUTER GRAPHICS SOFTWARE

3D finite element analysis (FEA) leads to a large amount of solution data. In general, developers of electrical devices need to analyze the electromagnetic behavior in certain critical machine parts, such as teeth or teeth heads, or identify local magnetic hot spots. An intuitive method for the evaluation of such simulation data is the interactive exploration in virtual reality [1], which provides a direct visual impression of the field characteristic. This ability supports the machine designer to recognize the points of design interest quickly and allows to perform further interactions and operations on the solution data directly. Therefore, in this paper a software methodology is presented to extend [2] by interactive postprocessing abilities.

The graphical package VTK [3] has been applied to visualize (static) 3D finite element solutions. The Visualization Toolkit (VTK) is an open source, platform independent, software library for 3D computer graphics, image processing

and visualization including an interface layer for several interpreted languages, such as Tcl/Tk, Python. The object oriented design of this software is characterized by general, easy to use data structures, whose versatility encourages a modular use of algorithms acting as filter objects. The working principle of VTK is based on visualization pipelines (see fig. 1).

Fig. 1. Visualization pipeline of VTK.

III. APPLICATION

A. Interactive Cutting

Due to performance issues, the solution data of meshes is generally mapped to its surface in 3D visualization, so that mesh geometry and colored solution appear correlated. The corresponding visualization is restricted to the surface mesh of the data object, so that no information of the internal structure is available and cutting methods lead to an opened hollow representation, compare. fig. 2(a). In these situations,

(a) Hollow cutting through a flux density distribution of a PMSM. (b) Interactive cutting of the flux density distribution in a PMSM.

Fig. 2. Different cutting types for the visualization of the flux density distribution.

a cutting filter chain is required, that provides an insight into the electromagnetic behavior within the simulated devices. Since this exploration is data and user depended (direct user interaction), an intuitive cutting method is required which provides an interaction with the model, previewing the cutting surface and the solution.

The necessary filter procedure is shown in fig. 3. First,

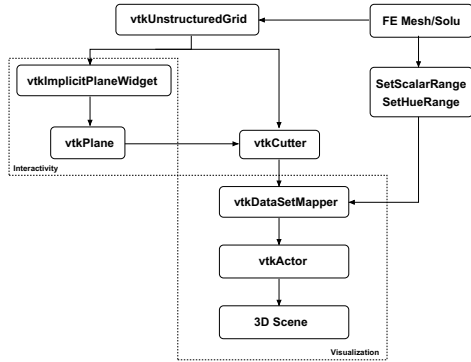

Fig. 3. VTK filter chain for interactive cutting.

the finite element mesh and solution are converted into a `vtkUnstructuredGrid` data set for each material. A `vtkImplicitPlaneWidget`, an interactively placeable infinite plane, is bounded to these grids. The mathematical representation of the cutting surface, in this case a `vtkPlane`, can be obtained from the 3D widget, so that the `vtkCutter` filter can generate a cutting mesh along that surface. The resulting grid is mapped to graphics primitives by the `vtkDataSetMapper`, who also maps the scalar range of the finite element solution to a given color range, specified by `SetHueRange`. The next element of the filter chain is the `vtkActor` representing an entity of the rendering scene. In particular, `vtkActor` combines object properties (color, shading type, etc.), geometric definition, and orientation in the world coordinate system. Since visualization, model interaction and cut-mesh generation are separated objects in the filter chain, other widgets types, such as point-, line-, plane-, sphere- and spline-widgets, can be applied for further purposes.

The cutting plane of fig. 3, can be moved, resized or rotated within the model boundaries and is computed in real time. Fig. 2(b) exemplifies this cutting interaction on a permanent magnet synchronous machine (PMSM) to illustrates the flux density distribution inside.

B. Direct Model Interaction

To improve the interactivity in 3D visualizations of finite element data, possibilities for a direct model interaction are required. The idea of a direct model interaction is to give the users an intuitive direct access to the visualized solution data. By this, any kind of operation, e.g. mathematical integration or multiplication, can be performed on the input, so that the modification of the visualization can directly be observed. Since 3D visualizations are scalable on different display systems (from normal desktop pc up to virtual reality systems like cave style systems [2]), an intuitive model interaction, controllable by various 3D input devices that directly operate in the 3D scenes, is required. To fulfill the mentioned criteria, a software methodology is required, that analyses the actual 3D scene to distinguish between different visualization types like a geometry, a mesh or a scalar or vectorial field solution plot. The methodology needs to returns the corresponding original data sets from the FE meshes and solutions. The generalized VTK filter chain for direct model interaction is

shown in fig. 4. As mentioned before, the finite element mesh

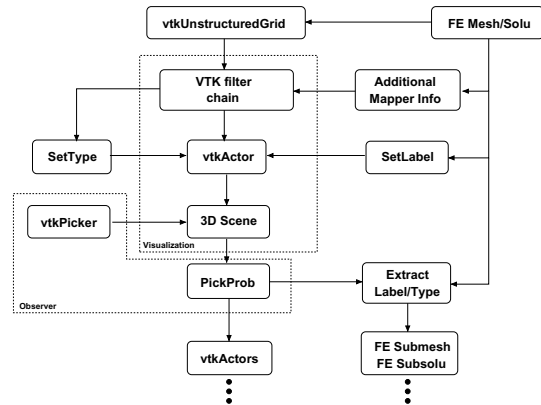

Fig. 4. VTK filter chain for interactive cutting.

and solution are filtered by an arbitrary VTK filter chain and stored in a `vtkActor` placed in a 3D scene, conf. sec. III-A. To identify the `vtkActors` in the further processing, each object gets additional information about the visualization type (`SetType`) and the submesh label identification (`SetLabel`). In the 3D scene, `vtkPicker`, controlled by a 3D input device, can be applied to grab `vtkActor` objects (`PickProb`). Type and label characteristics of the latter class objects can be used to extract the corresponding input data from the FE solution. These data sets are returned to the user interface. The same control pattern enables a direct access to the properties of single visualization objects.

Therewith, a combination of the interactive cutting geometries (cmp. section III-A) with the direct model interaction presented here is possible, to calculate the flux in various positions in an electrical machine for example.

IV. CONCLUSION

Efficient methods for the visualization of finite element solutions are essential for the evaluation of electromagnetic devices under research and development. In present, FE data is illustrated by means of static visualization formulations and methods. In this paper, an interactive postprocessing formulation is introduced, that extends the static process to provide dynamic modifications within the visualization and an intuitive 3D data exploration. Generalized techniques for this postprocessing approach are proposed and described by means of visualization patterns for interactive cutting and direct model interaction. A first application example is given to demonstrate the benefit of the presented 3D postprocessing formulation.

Since interactive visualization enables other illustration facilities, further applications, examples and details will be given in the full paper.

Comprehensive Magnetic Model of Surface Mounted PM Machines Incorporating Saturation Saliency

Yi Wang¹, Jianguo Zhu¹, Youguang Guo¹, Shuhong Wang², Wei Xu¹

¹School of Electrical, Mechanical and Mechatronic Systems, University of Technology
Sydney, NSW 2007, Australia

²Faculty of Electrical Engineering, Xi'an Jiaotong University, Xi'an 710049, China

Abstract— In this paper a comprehensive magnetic model of surface mounted permanent magnet synchronous machine (SPMSM) is proposed considering both the structural and the saturation saliencies to enable the numerical simulation of new rotor position detection algorithms. With an identifiable parameter matrix, a numerical nonlinear inductance model is developed, in which the rotor position and the stator current are taken as two independent variables. Furthermore, the stator current frequency is taken as another variable of the inductances and the inductance variation against the frequency is discussed. After experimentally identifying out all the parameters, a nonlinear mathematic model of SPMSM is built up based on the new magnetic inductance function. Simulation and experiment results are used to verify the proposed nonlinear magnetic model. The performance of proposed model is compared with the linear model provided in SIMULINK library.

I. INTRODUCTION

The permanent magnet (PM) machines, such as permanent magnet synchronous motor (PMSM), have been widely used and a number of techniques for position sensorless and initial rotor position detection have been proposed based on tracking the rotor magnetic saliency. The rotating magnetic saliency inside a PMSM can be classified as structural saliency that mainly comes from the interior structure, and saturation saliency induced by the magnetic saturation effect of the stator core [1]. Most of the existing sensorless control and initial rotor position detection schemes are designed mainly based on the structural saliency incorporated with the saturation saliency for identifying the polarity of magnetic pole. However, these sensorless strategies can only achieve good performance for interior PMSM (IPMSM). They are not suitable for surface mounted PMSM (SPMSM), which has little structural saliency.

Furthermore, the stator current frequency can also influence the values of the winding inductances, which are essential for rotor saliency tracking. The frequency should be counted in as a factor when performing the widely reported high frequency signal injection schemes for sensorless drive.

The conventional PMSM model does not incorporate the saturation saliency. When developing a new scheme for the rotor position detection, it is not possible to numerically simulate the proposed scheme, and the experimental trial and error method has to be employed, which is time-consuming and uncertain.

In this paper, a comprehensive mathematical model of SPMSM is built up considering magnetic saturation saliency

and the influence of the stator current frequency. A numerical nonlinear inductance model is proposed based on the stator currents and rotor position variation with all the parameters experimentally identified. The simulation and experiment results are used to verify the machine model. The comprehensive nonlinear machine model is built up in SIMULINK and this model can be further used to develop, simulate and evaluate the rotor position detection strategies.

II. MAGNETIC MODEL OF SPMSM WITH SALIENCIES

In an SPMSM, the observable total flux linkage λ_t inside the air-gap is contributed by both the stator currents and the permanent magnet on the rotor and it is the link of the stator and the rotor magnetic fields. The three-phase flux linkages λ_{abc} are here defined as the projection of λ_t on the stator reference frame and not only induced from the stator current. Therefore, the inductance of the stator is a function of both the stator currents and the rotor position, which are linear independent [2].

Then a composite function of both the current and rotor position is defined to express the inductance:

$$L(i, \theta) = I(i) \cdot A \cdot C(\theta) \quad (2)$$

where $I(i) = [1 \ i^1 \ i^2 \ \dots \ i^m]$ is obtained from the magnetization curve, indicating that the inductance is a polynomial function of current for a fixed rotor position; $C(\theta) = [1 \ \sin(\theta) \ \cos(\theta) \ \dots \ \sin(n\theta) \ \cos(n\theta)]^T$ is obtained from the Fourier Series expression, indicating that the inductance is a periodic function of rotor position for a fixed stator current; and A is an identifiable parameter matrix with $(m+1) \times (2n+1)$ dimensions.

An experiment platform is carried out on an SPMSM to identify the parameters and test the inductances. During the test, the stator currents are fixed at several different levels from 0 to 6A at which the magnetic circuit is fully saturated. For each current offset, by applying a smaller AC current component the incremental inductance at a particular rotor position is measured. By changing the rotor position with a dividing head, a series of inductance is recorded with a resolution of 6 electrical degrees. Fig. 1 shows the inductance curves at different current offset levels. The magnetic saturation effect can be found and the rotor polarity is

observable when the core is fully saturated with a large current offset.

Fig. 1. Measured self-inductance curves at different current offset levels.

Based on the order of the magnetization curve and the FFT of the tested inductance values at different current offset levels, the dimension of matrix A is set to (7×17) , by setting $m=6$ and $n=8$ to acquire an accurate enough surface regression.

To obtain better regression results, the Least Relative Residual Sum of Square (LRRSS) method is employed.

Fig. 2. Measured and estimated self-inductance at different current offsets.

Fig. 2 is the comparison between the tested and estimated self-inductance of phase A at 0A and 6A current offsets, where $\pm 0.5\%$ error bands are added. It can be found that the relative errors of the inductances are very small and the regressed objective function can be used to describe the variable self-inductance. The same regression method is applied to the mutual-inductance coefficient identification. Then a nonlinear inductance model is built up for this three-phase machine. An accurate inductance matrix can be calculated for given stator currents and rotor position. This model incorporates both the machine structural and the saturation saliencies.

III. INDUCTANCE VARIATION VERSUS FREQUENCY

As shown above, the inductance of the SPMSM is related to the stator current amplitude and the magnet rotor position. On the other hand, the inductance values are also variable with the stator current frequency, which is always varying in the machine drive system. In most of the proposed initial rotor position detection schemes, the injection signal frequency is set at a much higher value in order to keep the rotor at stand still and to amplify the inductance variation.

On the same experiment platform, the inductance tests are carried out on different frequencies. Fig. 3 shows the inductance curve at different current frequencies. The current offset level is set at 6A and the rotor angle varies. It can be found that the self-inductance varies against the current frequency.

Fig. 3. Measured self-inductance curves at different current frequencies.

IV. MACHINE PERFORMANCE

A non-linear SPMSM model is built up in SIMULINK and simulated under open loop operation to compare the performance with the linear PMSM model in SIMULINK library. No-load and loaded tests are simulated with the same machine parameters except the inductance model. The unsaturated inductances are chosen and input into the linear model as the linear part of the magnetization curve. As an example, Fig. 4 shows the speed and torque curves by using the proposed non-linear model and the existing linear model. After adding a load torque on the rotor shaft, there is some ripple on the non-linear model speed and torque output, which results from the non-linear saturated inductances.

Fig. 4. Comparison of speed and torque at no-load and load change

More details about the model and the machine performance prediction using the new model will be presented in the full paper.

eetfchan@polyu.edu.hk

Abstract— The magnet field in a single-sided axial-flux permanent-magnet synchronous generator is analyzed using three-dimensional finite element method (3-D FEM). The flux that flow in radial planes, particularly that crossing the rotor back plates via the ferromagnetic rotor spacer, is accounted for. A time-stepping technique enables the output voltage to be determined to a good accuracy. The computed results have been verified by experiments on a small prototype generator.

I. INTRODUCTION

Two-dimensional analysis is often used for studying the field distribution in an axial-flux permanent-magnet synchronous generator (AFPMSG) [1],[2],[3]. In most the methods the rotor back plates that serve as the yoke are assumed to be physically separate. When the number of poles is large and the radial length of the magnets is large, a two-dimensional (2-D) analytical or finite element analysis gives quite accurate prediction of the machine performance. A 2-D analysis however is valid only when the field region has a uniform cross section, which is not the case with the AFPMSG. The effect of the fringing flux at the inner and outer radii cannot be accounted for. Besides, the end winding leakage is difficult to model accurately. In this paper, a time-stepping, coupled field-circuit, three-dimensional finite element method is used for analyzing an outer-rotor, single-sided, 16-pole, 60-Hz axial-flux permanent-magnet synchronous generator. The computed results have been verified by experiments on an experimental generator.

II. ANALYSIS

The three-dimensional (3-D) finite element transient solver of ANSYS Version 11 SP1 was used as the analysis tool For computation of the no-load magnetic field quantities a static field solution is sufficient. For computation of the generator performance on load, a time-stepping analysis is needed. The time-stepping field-circuit solution procedure is outlined as follows:

- Construct the geometric model of the AFPMSG
- Construct the circuit model of the AFPMSG, coupling with the field region being accomplished by defining appropriate nodes in the winding element and the corresponding field element.
- Construct the sliding surface for time-stepping analysis.
- Select solver, boundary conditions, and size of time-step.
- Execute program to obtain field/circuit solution.

It should be noted however that 3-D FEA is computationally intensive, hence a compromise has to be made with regard to the computational accuracy required and the solution time.

Fig. 1 shows a radial section of the AFPMSG and Fig. 2 shows the geometric model developed for 3-D FEA. The rotor magnet is embedded in the rotor surface and the armature winding is embedded in the stator surface in Fig. 2. Non-essential regions are not modeled in order to reduce the scale of the problem.

Fig. 1 Cross-section of experimental AFPMSG.

Fig. 2 Geometric model of AFPMSG for 3-D FEA.

III. RESULTS

A. Surface Plots of Air Gap Flux Density

In the subsequent discussion x , y and z denote, respectively, the radial, circumferential and axial directions of the AFPMSG. Fig. 2 shows the computed surface plots of the air gap flux density components in the AFPMSG under no load conditions, where circumferential distances 0° and 180° coincide with the interpolar axes. The value of B_x is small under a magnetic pole, but due to fringing flux in the radial directions at the inner and outer radii there are two

conspicuous peaks at $x = 0.055$ m and $x = 0.011$ m (Fig. 2a). At a given radial position, the value of B_y is zero at the pole centre, but it increases progressively towards the interpolar axis (Fig. 2b). Fig. 2c shows that the axial flux density component B_z decreases significantly at the inner and outer radii of the AFPMSG. This is due to fringing and results in reduction in the flux per pole. The use of 3D analysis is therefore justified as this phenomenon results in errors in a 2D analysis.

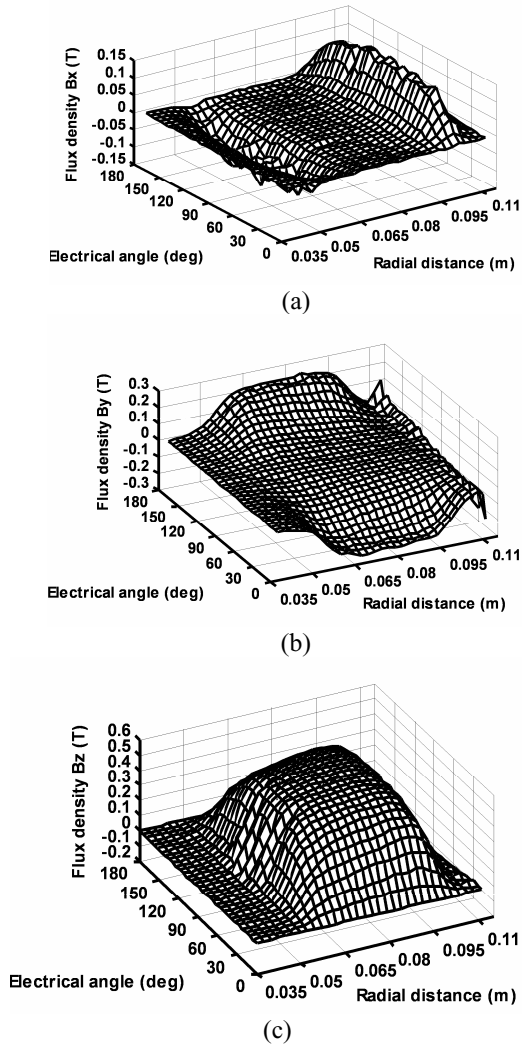

Fig. 3 Surface plots of no-load flux density components at mid-plane of armature winding: (a) radial; (b) circumferential; (c) axial.

B. Effect of Axial Position on Flux Density

Figs. 4 shows the circumferential and radial variations of B_z . The variation of B_z in the circumferential direction affects principally the magnitude and waveform of the generated emf. At $z = 12$ mm (1 mm above the surface of magnet), the B_z waveform is approximately trapezoidal but as z increases the waveform gradually becomes more rounded and become closer to a sinusoid and the magnitude decreases (Fig. 4a). The resultant waveform in the armature winding, however, depends on the axial thickness and radial length of the conductor as different sections of the conductor is cut by a

different value of B_z . As shown in Fig. 4b, the variation of B_z along the radial direction is not symmetrical about the mean radius and the maximum value occurs at a radial position closer to the outer radius. In the ferromagnetic spacer ($0.11\text{m} < x < 0.1135$ m) B_z is negative showing the effect of the spacer on the flux at the outer radius.

Fig. 4 Variation of B_z with axial position in the air gap region: (a) along circumferential direction at mean radius; (b) along radial direction at pole center.

C. Line and Phase Voltage Waveforms

Fig. 5 shows the computed waveforms of the phase and line voltages when the AFPMSG is supplying a resistive load of 1.75Ω per phase at rated speed. It is found that the phase voltages are flat-topped, due mainly to third harmonic contents in the air gap flux density B_z . The line voltages, however, are sinusoidal since a three-phase three-wire star-connected load is being supplied. Convergence of the 3D FEA computations is very fast: in less than 4 steps the computed values are already very close to those at steady state.

There is a slight imbalance in the line voltages and line currents, mainly due to the asymmetry introduced in the geometric winding model for 3D FEA.

Fig. 5 Computed waveforms of line voltages and phase voltages for a load resistance of 1.75Ω per phase.

Abstract—This paper proposes a unified scheme for implementing the fixed-point method (FPM) and the Newton-Raphson method (NRM) in finite-element (FE) analysis of nonlinear magnetic problems. As the NRM and FPM have advantages and disadvantages, the aim is to make both methods available in FE programs and use them in a convenient manner. It is shown in this paper that the FPM can be implemented using the same scheme of the NRM that is commonly applied in FE programs. The idea is simple and straightforward, and can be applied to a wide variety of magnetic problems. As an example, the unified scheme is applied here to a magnetic field problem formulated by the magnetic vector potential. Numerical results for two-dimensional FE simulations of an electrical machine are also presented.

I. INTRODUCTION

Taking into account magnetic nonlinearity is crucial to the investigation and design of electrical devices. The associated difficulties with nonlinearity, however, have restricted the methods that can handle the problem to the Newton-Raphson method (NRM), and less commonly, the fixed-point method (FPM). The NRM has gained monumental popularity, thanks mainly to its high convergence rate and its ability to solve nonlinear functions with several variables [1]. Today, the NRM is extensively applied to solve nonlinear electromagnetic field problems in finite-element (FE) software packages, whereas the FPM is scarcely employed. Popularity, however, can be a somewhat deceiving indicator for measuring success. Most of the NRMs, if not all, use the derivative to find the solution. Therefore, they can easily fail to solve a nonlinear magnetic problem, sometimes even with the simplest B - H curve, such as the normal magnetization curve, not to mention hysteretic field problems.

The FPM can also be applied to solve nonlinear functions with several variables, and because its convergence is not based on finding the derivative, the method is very stable and, hence, proved to be the best candidate to solve complicated nonlinear problems. Recently, the FPM has undergone an excellent improvement in accelerating its convergence, making it even a more attractive choice [2].

Although the FPM is reliable, the method should be regarded as an alternative and not a replacement to the NRM. Researchers and developers of FE software in the area of electrical engineering have become so familiar with the NRM so that they cannot afford to abandon it easily, a credit also goes to the method's quadratic convergence. On the other

hand, the different formulation the FPM imposes is perceived as a barrier towards the method's prevalence. Because most of the existing codes use the NRM formulation, switching to the FPM would obviously require laborious work.

It is therefore expedient to make both the NRM and FPM available in an FE package without augmenting or modifying the entire equations. Accomplishing this desirable situation will be the goal of this paper.

II. SOLUTION OF NONLINEAR EQUATIONS

The purpose of the NRM and FPM is to find the solution of the nonlinear system

$$\mathbf{r}(\mathbf{u}) = \mathbf{0} \quad (1)$$

iteratively in a systematic manner.

An iterative system like (1) can be put as

$$\mathbf{u}^{(k+1)} = \mathbf{g}(\mathbf{u}^{(k)}) \quad (2)$$

where \mathbf{g} is a real function with several variables. The solution of (2), if one exists, is a *fixed-point* vector $\mathbf{u}^* = \mathbf{g}(\mathbf{u}^*)$, which starts at a specified initial iterate $\mathbf{u}^{(0)}$.

The convergence criterion of (2) depends on the contraction mapping principle. A function \mathbf{g} is a contraction at a point \mathbf{u}^* if there exists a constant $0 \leq \beta < 1$ such that

$$\|\mathbf{g}(\mathbf{u}) - \mathbf{g}(\mathbf{u}^*)\| \leq \beta \|\mathbf{u} - \mathbf{u}^*\|. \quad (3)$$

In general, if $\|\mathbf{g}'(\mathbf{u}^*)\| < 1$, then \mathbf{g} is a contraction at \mathbf{u}^* .

The fixed-point iteration is the most basic technique for solving nonlinear equations and is the essence of all other methods. The Newton-Raphson iteration is a special case and consequence of the fixed-point iteration. The goal of the NRM is to construct an efficient iterative scheme that converges rapidly (quadratically) to the solution of (1). Now if (3) is utilized to enforce $\mathbf{g}'(\mathbf{u}^*) = \mathbf{0}$, the following result is obtained from (2) and (3) after simple mathematical manipulations

$$\mathbf{g}(\mathbf{u}^{(k)}) = \mathbf{u}^{(k+1)} = \mathbf{u}^{(k)} - \mathbf{r}'(\mathbf{u}^{(k)})^{-1} \mathbf{r}(\mathbf{u}^{(k)}) \quad (4)$$

which can be also written as

$$\mathbf{u}^{(k+1)} = \mathbf{u}^{(k)} - \mathbf{P}^{-1} \mathbf{r}(\mathbf{u}^{(k)}) \quad (5)$$

where

$$\mathbf{P} = \mathbf{r}'(\mathbf{u}^{(k)}) = \frac{\partial \mathbf{r}}{\partial \mathbf{u}}.$$

Equation (5) represents the *Newton-Raphson* iteration in which the iterates converge quadratically. The Jacobian matrix \mathbf{P} is, however, never explicitly inverted in practical computations. It is more efficient to solve the correction $\Delta \mathbf{u}^{(k+1)}$ from the linear systems of equations as

$$\mathbf{P} \Delta \mathbf{u}^{(k+1)} = -\mathbf{r}(\mathbf{u}^{(k)}) \quad (6)$$

hence

$$\mathbf{u}^{(k+1)} = \mathbf{u}^{(k)} + \Delta \mathbf{u}^{(k+1)}. \quad (7)$$

It is clear that the use of (6) instead of (5) is inevitable and (2) must be therefore modified to unify the scheme of implementing the NRM and FPM. Substituting (7) in (2) results in

$$\Delta \mathbf{u}^{(k+1)} = \mathbf{g}(\mathbf{u}^{(k)}) - \mathbf{u}^{(k)} \quad (8)$$

which ensures that the FPM is also based on solving $\Delta \mathbf{u}$ rather than \mathbf{u} , a straightforward but very useful achievement for solving magnetic field problems.

III. APPLICATION TO MAGNETIC PROBLEMS

The ideas introduced in Section II are general and can be applied to a wide variety of FE problems. The conventional FE formulations of the NRM and FPM are well reported in the literature (see e.g. [1]–[3]). Therefore, only the relevant equations will be shown here without introducing the details. As an example, Maxwell equations will be formulated by the magnetic vector potential \mathbf{A} .

The nonlinear magnetic equation can be put in a convenient way in order to solve it by the NRM as

$$\nabla \times \nu(\nabla \times \mathbf{A}) = \mathbf{J}. \quad (9)$$

For the FPM, the nonlinear magnetic equation is conveniently written as

$$\nabla \times \nu_{\text{FP}}(\nabla \times \mathbf{A}) = \mathbf{J} - \nabla \times \mathbf{M} \quad (10)$$

where \mathbf{J} is the electric current density and ν is the magnetic reluctivity, which is a nonlinear function of \mathbf{B} (or \mathbf{A}). ν_{FP} is a reluctivity-like quantity and is, for now, a positive constant. \mathbf{M} , which is a nonlinear function of \mathbf{B} (or \mathbf{A}), is resulting from enforcing the following constitutive equation

$$\mathbf{H} = \nu_{\text{FP}} \mathbf{B} + \mathbf{M}. \quad (11)$$

Applying the FE method to (9) and (10) results, respectively, in the following two systems of equations

$$\mathbf{S}(\mathbf{a}) \mathbf{a} = \mathbf{f} \quad (12)$$

$$\mathbf{S} \mathbf{a} = \mathbf{f} - \mathbf{q}(\mathbf{a}) \quad (13)$$

where the independent variable \mathbf{a} is a vector of the nodal values of the magnetic vector potential, \mathbf{S} is the assembly matrix, \mathbf{f} is a vector associated with the source \mathbf{J} , and \mathbf{q} is a vector associated with $\nabla \times \mathbf{M}$, which transforms the nonlinearity to the right hand side. (See [1]–[3] for more details about these FE matrices and vectors).

Solving (12) by the NRM, as $\mathbf{S} \mathbf{a} - \mathbf{f} = \mathbf{r} = \mathbf{0}$, leads to

$$\mathbf{P} \Delta \mathbf{a}^{(k+1)} = \mathbf{f}^{(k)} - \mathbf{S} \mathbf{a}^{(k)} \quad (14)$$

where

$$\mathbf{P} = \frac{\partial \mathbf{r}}{\partial \mathbf{a}} = \mathbf{S} + \frac{\partial \mathbf{S}}{\partial \mathbf{a}} \mathbf{a}. \quad (15)$$

On the other hand, solving (13) by the FPM leads to

$$\mathbf{S} \mathbf{a}^{(k+1)} = \mathbf{f}^{(k)} - \mathbf{q}(\mathbf{a}^{(k)}) \quad (16)$$

and since

$$\mathbf{a}^{(k+1)} = \mathbf{a}^{(k)} + \Delta \mathbf{a}^{(k+1)} \quad (17)$$

then (16) can be rewritten as

$$\mathbf{S} \Delta \mathbf{a}^{(k+1)} = \mathbf{f}^{(k)} - \mathbf{q}(\mathbf{a}^{(k)}) - \mathbf{S} \mathbf{a}^{(k)} \quad (18)$$

It is evident that (14) and (18) are analogous in several ways; the main one concerning this paper is that they are both leading to the solution of $\Delta \mathbf{a}$. Therefore, to switch between the NRM and FPM, one only needs to consider the terms of \mathbf{P} and \mathbf{q} when assembling the matrices and vectors within the FE equations. The significance of having a unified scheme for implementing the NRM and FPM will be even more appreciated when dealing with more complex problems, such as rotating electrical machines, for example.

IV. SIMULATION OF ELECTRICAL MACHINES

The developed methods are applied to the modeling of electrical machines using a two-dimensional, time-stepping FE method [3]. The voltage equations of the stator windings and rotor circuits are coupled with the FE equations and solved together, resulting in a strongly coupled system of equations. Therefore, similarly, the stator currents are solved for $\Delta \mathbf{i}$ and the rotor voltages for $\Delta \mathbf{v}$, a consequence that highlights the importance of the proposed scheme. FE simulations were carried out using the NRM and FPM applying the same stopping criterion. To speed up the convergence of the FPM, the locally convergent method was used [2]. Some numerical results carried out for a 380-V, 15-kW induction motor are presented in Table I. The quantities of the motor computed by the NRM and FPM are basically the same and the computation times are close to each other. Although the FPM required more iterates in average, the method was faster because it kept the assembly matrix constant during iteration [2].

TABLE I
NUMERICAL RESULTS OF THE NRM AND FPM

Quantity	NRM	FPM
Terminal current [A]	28.802	28.801
Shaft power [kW]	15.353	15.352
Air-gap flux density [T]	0.937	0.937
Electromagnetic losses [kW]	1.721	1.721
Power factor	0.8739	0.8740
Average number of iterates	5	13
Computation time [sec]	174.32	169.04

Parametric Design Coupled with Dynamic Equation of the BLDC Motor for Electric Vehicle

Young-kyoun Kim, Se-Hyun Rhyu, Jung-Pyo Hong
Korea Electronics Technology Institute
Yatap-Dong, Bundang-Gu, Seongnam-Si, Korea
ensigma@hitel.net

Abstract — The drive-train component of the electric vehicles is frequently using Brushless Permanent Magnet DC (BLDC) motor because that the motor have the advantages of high power density and high efficiency. The BLDC motor, owing to their restrictive field weakening range, is designed to be not as easy for vehicle application. Therefore, this paper presents a design procedure of BLDC motor for electric vehicle. Especially, the study focused to the decision method of the suitable scope of the BLDC motor parameters.

I. INTRODUCTION

Recently, owing to environmental concerns and energy conservation, electric and hybrid vehicles are receiving the significant interest. Hybrid electric vehicles are more interesting than electric vehicles powered only by batteries because they have a limit at cost and size as present technology [1]-[2]. Despite this fact, the electric vehicles (EV) are employed in the urban areas as small electric passenger cars. Because of the reason the advantages of high power density reducing weight and high efficiency giving longer ranges for a given battery size, the drive-train component of EV is frequently using Brushless Permanent Magnet DC motor (BLDC motor) [3].

This paper deals with a parametric design and verification of BLDC motor for an EV propulsion applications. Because that BLDC motor has a restrictive field weakening range, the parametric design of BLDC motor is applied in the design procedure to ensure the required specifications, which are instant rated power and continuous rated power of EV propulsion. The proposed parametric design is accomplished by coupling between the dynamic equation of EV and the voltage equation of BLDC motor.

II. SPECIFICATION OF ELECTRIC VEHICLE PROPULSION

Specifications of the EV, which is small electric passenger car, are as follows;

- EV top speed : 65 kph
- Instant rated power of the traction motor : 25 kW
- Continuous rated power of the traction motor : 10 kW
- EV mass included passengers : 900 kg
- Frontal area of EV : 1.2 m²
- Tire radius of EV : 0.27 m
- Rolling resistance coefficient : 0.013
- Aerodynamic drag coefficient : 0.75

BLDC motor power is required by an acceleration performance of EV. The vehicle acceleration performance is

evaluated by the tractive effort on the level ground, which is consists of two components as follows;

$$\text{Aerodynamic drag force: } F_a = 0.5\rho AC_d v^2 \quad (1)$$

$$\text{Rolling resistance: } F_r = \mu_r mg \quad (2)$$

where ρ is the air mass density 1.205 kg/m³, A is the frontal area of the EV, C_d is aerodynamic drag coefficient, v is the EV speed, μ_r is the rolling resistance coefficient, m is the EV mass. The total tractive effort required to reach the acceleration a is as follows;

$$F_t = ma + F_a + F_r \quad (3)$$

From above equation, the power required by acceleration can be estimated by [3].

$$P_{acc} = \mu_r mgv + 0.625AC_d v^3 + 1.05mv dv/dt \quad (4)$$

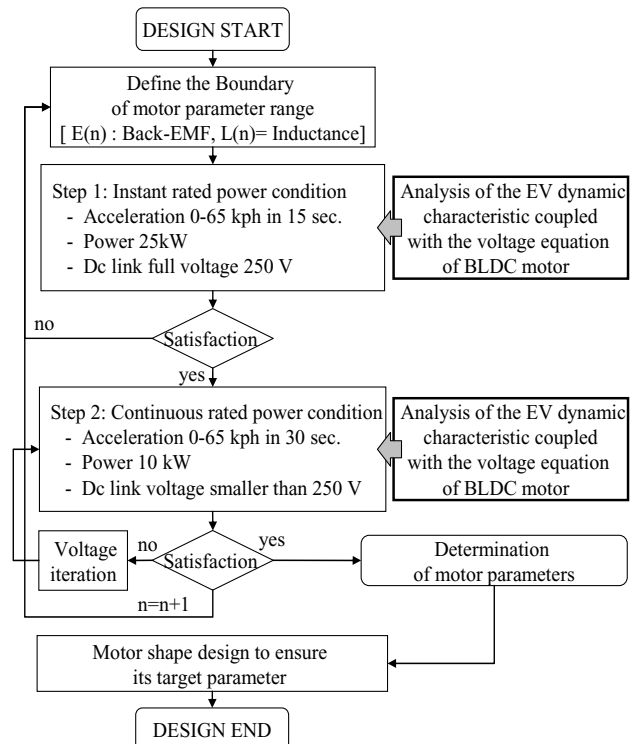

Fig. 1. Proposed parametric design process of BLDC motor

III. PARAMETRIC DESIGN OF TRACTION MOTOR

The important required condition of the traction motor in the EV is the capability for the extended speed range.

The speed and torque of the BLDC motor can be obtained by the voltage equation as follows [4];

$$V_{abc} = i_{abc}R + L \frac{di_{abc}}{dt} - M \frac{di_{abc}}{dt} + E_{abc} \quad (5)$$

$$T = \frac{i_a E_a + i_b E_b - i_c E_c}{\omega_m} \quad (6)$$

From the equation, it is realized that the characteristics of BLDC motor is totally depended on its parameters, such as back EMF, inductance, and resistance. Therefore, in order to design the BLDC motor, it is very important to decide the suitable scope of the BLDC motor parameters, which is corresponding to the given specifications of the EV propulsion, and it is accomplished by computing the dynamic acceleration (4) coupled with the electrical equation (5) and (6). The Proposed parametric design process is consists of two steps and the concept of this process is shown in Fig. 1.

IV. RESULT AND DISCUSSION

Characteristic analysis according to the change of the induced voltage and inductance is illustrated from Fig. 2 to Fig. 5. At the condition of instant rated power, the EV velocity in 15 second is shown in Fig. 2 and the armature current is illustrated like as Fig. 3.

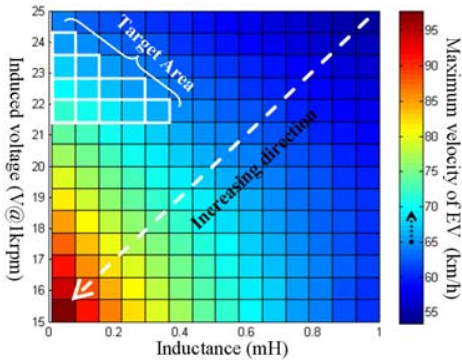

Fig. 2. Velocity map in 15 sec. at instant rated power

Fig. 3. Armature current map at instant rated power

Fig. 3. Velocity map in 30 sec. at continuous rated power

Fig. 5. Armature current map at continuous rated power

Fig. 6. DC link voltage at continuous rated power

At the condition of continuous rated power, the EV velocity in 30 second is shown in Fig. 4 and the armature current is described in Fig. 5. Fig. 6 shows the minimum voltage, which will be able to operate at the continuous rated power. The target area on the figures is estimated by considering the condition of EV top speed and the limitation of armature current. From now on, the BLDC motor should be design within the target area of its parameters, and the design results will be described in the full paper.

Discrete Magneto-Elasticity: A geometrical approach

Alain Bossavit

Bossavit@lgep.supelec.fr

Abstract— We show that magnetism and elasticity have very similar mathematical structures when fields are considered as differential forms of adequate nature. The same discretization principles and techniques that succeeded in electromagnetism, notably the use of edge elements, then lead to a manageable form of coupled elasto-magnetic problems.

I. INTRODUCTION

Given a steady current density J and a spatial distribution of reluctivity ν , magnetostatics consists in finding fields B and H such that

$$\operatorname{div} B = 0, \quad H = \nu B, \quad \operatorname{rot} H = J \quad (1)$$

(plus boundary conditions that we shall ignore here). In terms of differential forms b , h and j for which B , H and J stand proxy, this becomes

$$db = 0, \quad h = \nu b, \quad dh = j, \quad (2)$$

where ν is a Hodge operator. The differential geometric framework in which (2) makes sense is pictured in the Tonti diagram of Fig. 1, which displays the underlying structure and how to fit magnetostatics in it. Its *discrete* counterpart, left aside in this Digest, will be addressed in the full-length version.

Fig. 1. The Tonti diagram of magnetostatics.

Our purpose here is to enlarge the framework, both at the continuous and discrete level, to make it home also to Elasticity, in order to fit coupled problems in magnetoelasticity into a diagram similar to Fig. 1. But in spite of meaningful analogies [1], the parallel between magnetism and elasticity is fraught with obvious difficulties: For instance, though the strain tensor ϵ derives from a potential u (displacement) like b derives from a , and must satisfy a compatibility condition

($\operatorname{rot}^t \operatorname{rot} \epsilon = 0$) somewhat reminiscent of $db = 0$, the analogy is weak, since d is a first order, instead of second order, differential operator. Finding a usable analogy requires some conceptual changes about "stress" and "strain", as follows. (We work in 3D affine space A_3 , not oriented, not metricized. Vectors we may mention are elements of the 3D real vector space V_3 , covectors are elements of its dual.)

II. THE GEOMETRY OF STRESS AND STRAIN

Let us start from the equality $\partial_t q + dj = 0$, or in integral form, $d_t \int_{\Omega} q + \int_{\partial\Omega} j = 0$ for all volumes Ω , that expresses (electric) charge conservation. We shall write this, using a Dirac-like bracket notation, $d_t \langle \Omega ; q \rangle + \langle \partial\Omega ; j \rangle = 0 \forall \Omega$, or as well, $\langle \Omega ; \partial_t q + dj \rangle = 0 \forall \Omega$, which shows how d and ∂ are dual to each other. There, q and j are *twisted* differential forms, of respective degrees 3 and 2, which means their integrals make sense over submanifolds (volumes and surfaces, respectively) with *outer* orientation. (In the case of $\partial\Omega$, this means providing it with a crossing direction. By convention, this direction is inside out with respect to Ω .)

Next, *momentum* (of a particle, say), being the integral in time of force, is a covector, since applied force—which linearly maps virtual displacements, i.e., vectors, to virtual work, a real number—is a covector itself. So we naturally represent the distribution of momentum in a continuum by a density of covectors, that is, a covector-valued twisted 3-form, denoted p . (Thus, the integral $\langle \Omega ; p \rangle$ is a covector, expressing total momentum inside Ω . Observe how the existence of *distant parallelism*, between vectors or covectors at different points, in affine space, is essential to give sense to this integral.)

Now, momentum also is a conserved entity, like charge, with the only difference that it is covector-valued: The rate of change $d_t \langle \Omega ; p \rangle$ of total momentum inside Ω plus the momentum flux across $\partial\Omega$ must add up to the rate at which momentum is poured into Ω by applied forces. We therefore introduce a twisted 2-form s , similar to j , but covector-valued, to represent this flux, hence the relation $\partial_t p + ds = f$, where the twisted 3-form f represents the applied force field, to encode momentum conservation. (The relation between this form s and the standard stress tensor σ^{ij} is a bit involved: As it happens, σ^{ij} is a *proxy* (when V_3 is equipped with a scalar product) for $-s$, the same way J, H , etc., are proxies

for j, h , etc. The minus sign results from a historically established convention about stress, to which we shall conform by setting $\sigma = -s$, and calling this the "stress $\tilde{2}$ -form".) The full version will give the discrete form, with edge-based covector-valued degrees of freedom.

Fig. 2. The Tonti diagram of elasticity. Potentials, here, are the Beltrami one χ and the displacement u . The latter, being a point-to-vector map, is indeed a vector-valued 0-form.

Strain is more of a problem, even in the context of small deformations to which we shall restrain. We have a *material manifold* M , representing the deformable bodies. This deformation is often described by a map u from M into A_3 , called a *placement*. Instead of that, we shall prescribe the placement of material *vectors* (i.e., the vectors tangent to M , that form the tangent bundle TM) in physical space A_3 . So we have a map β_0 from TM to TA_3 for which *compatibility* is assumed, i.e., there is a point-to-point map $u_0 : M \rightarrow A_3$ the gradient of which is β_0 . This is the *reference placement*. Now, consider β from TM to TA_3 again, close to β_0 , but not necessarily compatible, since it need not preserve material continuity. Vectors $\beta(v_x)$ and $\beta_0(v_x)$, though not anchored at the same point, can be compared thanks to distant parallelism, so let's set $\epsilon_x(v_x) = \beta(v_x) - \beta_0(v_x)$: This is a linear map from $T_x M$ to $T_{u(x)} A_3$, hence a vector-valued 1-form ϵ , the "strain 1-form", that describes deformation with respect to the reference placement. [Again, the relation between this ϵ and the traditional tensor ϵ^{ij} is not simple: To say it briefly, the symmetric ϵ^{ij} proxy is obtained by "quotienting rotations out" of ϵ , as justified by the universal constitutive law according to which any material chunk can be rotated without deformation work.]

Since β is not a priori compatible, a compatibility condition must be imposed on ϵ . This is easily seen to be $d\epsilon = 0$ (for a simply-connected M), and we shall give the discrete form, in which degrees of freedom are vectors, one for each edge. Discretization, to say it briefly, consists in describing how *edges* of the mesh are displaced by ϵ . Interpolation will be done by using Whitney 1-forms.

It remains to link ϵ and σ by a constitutive law. This is done by assuming an energy functional (similar, in the isotropic case, to the standard $\lambda/2 \text{tr}(\epsilon)^2 + \mu|\epsilon|^2$, but expressed, as we shall show, in terms of the present strain 1-form ϵ), hence a linear relation $\sigma = \kappa\epsilon$ and equations similar to (2),

illustrated by the Tonti diagram of Fig. 2,

$$d\epsilon = 0, \quad \sigma = \kappa\epsilon, \quad d\sigma = f. \quad (3)$$

At this stage, one sees that the desired parallelism between magnetism and elasticity has been achieved, but (2) and (3) are still independent from each other, unless—and this is what coupling is about— v in (2) depends on ϵ – σ and/or κ in (3) depends on b – h .

III. COUPLED CONSTITUTIVE LAWS

Such dependences are best expressed in variational form, for which (non-hysteretic) magnetostatics gives a model: One introduces magnetic energy $\Psi_{\text{mag}}(b)$ and coenergy $\Phi_{\text{mag}}(h)$, Legendre–Fenchel transforms of each other, one sets $\mathcal{F}_{\text{mag}}(b, h) = \Psi_{\text{mag}}(b) + \Phi_{\text{mag}}(h) - \int b \wedge h$ (integrating over the whole domain of interest), and one requires $\mathcal{F}_{\text{mag}}(b, h) = 0$ (instead of ≥ 0 , which holds for *any* pair $\{b, h\}$ by definition of the L–F transform). This equality is equivalent to $h = \partial\Psi_{\text{mag}}(b)$ and $b = \partial\Phi_{\text{mag}}(h)$, so it's a way to state the behavior law. Problem (2) then becomes (see [2] for details) *find a pair $\{b, h\}$ that minimizes $\mathcal{F}_{\text{mag}}(b, h)$ under the linear constraints $b \in B^s$, $h \in H^s$, where B^s and H^s are functional spaces that account for source conditions such as $db = 0$ and $dh = j$, and for boundary conditions.*

Similarly, (3) consists in finding a pair $\{\epsilon, \sigma\}$ that stationarizes the quantity $\mathcal{F}_{\text{ela}}(\epsilon, \sigma) = \Psi_{\text{ela}}(\epsilon) + \Phi_{\text{ela}}(\sigma) - \int \epsilon \wedge \sigma$ under suitable linear constraints, $\epsilon \in E^s$, $\sigma \in \Sigma^s$, where Ψ_{ela} is elastic energy (an example of which was given in the previous Section) and Φ_{ela} its Legendre transform. (The wedge product $\epsilon \wedge \sigma$, a *real*-valued twisted 3-form, thanks to the vector-covector pairing, is a density of deformation work, just as $b \wedge h$, in magnetics, is a density of energy.) Introducing the total energy $\Psi(b, \epsilon) = \Psi_{\text{mag}}(b) + \Psi_{\text{ela}}(\epsilon)$ and its Legendre transform $\Phi(h, \sigma)$, we may set the two problems simultaneously, as the stationarization of $\mathcal{F}(b, \epsilon, \sigma, h) = \mathcal{F}_{\text{mag}}(b, h) + \mathcal{F}_{\text{ela}}(\epsilon, \sigma)$ under suitable linear constraints. So far, this only describes a parallel treatment of two independent problems. But this form of the problem allows one to grasp what a truly coupled problem is: *Coupling* occurs when $\Psi(b, \epsilon)$ *cannot* be written as a sum $\Psi_{\text{mag}}(b) + \Psi_{\text{ela}}(\epsilon)$ of distinct energy terms. The constitutive laws are then $h = \partial_b \Psi(b, \epsilon)$ and $\sigma = \partial_\epsilon \Psi(b, \epsilon)$, with now *partial* derivatives, and the variational form of the coupled problem has

$$db = 0, \quad d\epsilon = 0, \quad h = \partial_b \Psi, \quad \sigma = \partial_\epsilon \Psi, \quad d\sigma = f, \quad dh = j \quad (4)$$

as its "strong" counterpart. Discretization is then easy.

How one can know the energy functional $\Psi(b, \epsilon)$ in concrete situations, and why one should associate b and ϵ , instead of (say) b and σ , will be discussed in the full paper.

Abstract — This paper presents a coupled Finite Element – Reluctance Network model for a hybrid motor. The equivalent permeances of the air-gap are determined by two dimensional (2D) nonlinear finite element (FE) computations. The 2D results are used for setting up a 3D analytical model. Spectral decomposition and a nonlinear fitting of the amplitudes of the permeance harmonics is performed to account for both saturation and high order harmonics effect. The method is validated with a 2D FE computation and then applied in the case of a highly saturated 3D hybrid stepping motor.

I. INTRODUCTION

Three dimensional Finite Element (FE) method is a useful tool for the modelling of axial flux machines such as hybrid motors. However, this method requires a very long CPU time and a large space memory especially when the saturation phenomenon should be taken into account. The use of 2D finite element method coupled with nonlinear circuit model can be an alternate solution which combines accuracy, precision and fastness. Analytical models using reluctance networks have been developed which include the effect of saturation in well designed machines [1,2]. Various approximations and simplifications are often used which can be justified by FE computations.

The authors present a coupled FE – analytic model for a highly saturated hybrid stepping motor that can be applied for the design and the optimization of such devices. The main idea is based on the use of 2D FE parameter identification and a spectral analysis of the permeance function that can easily achieve the computation of the torque waveforms.

II. HYBRID MOTOR: DESCRIPTION AND EQUIVALENT MODEL

The general architecture of the hybrid motor is shown on Fig. 1 where the case of a 4-phase motor supplied by unidirectional currents is considered. The axial flux is provided by a cylindrical magnet axially magnetized located in the rotor. The number q of stator phases and N_r of rotor teeth allow determining the period of the permeance function motor according to:

$$\tau = 360^\circ / (q N_r) \quad (1)$$

The two slotted half-rotors are shifted by 180 electrical degrees and separated with an axial gap x . A reluctance network model, which is shown on Fig.2, is developed. It includes two circuits of 4 parallel branches representing the two half-machines. These two circuits are series connected via a circuit corresponding to the magnet and the yoke. According to the winding mode and the angular shift between the two rotors, there are permutation relationships between the permeances P_k on one hand, and equality relationships between the MMF sources V_k , $k = 1..8$ on the other hand.

Fig. 1. (a) Longitudinal view of the hybrid machine, (b) Axial view

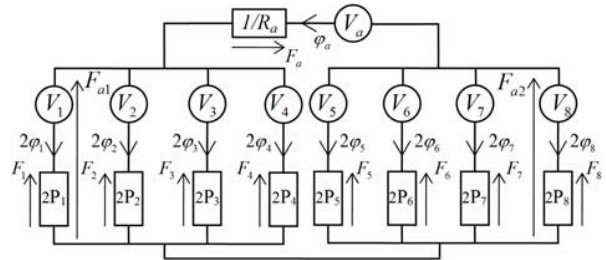

Fig. 2. reluctance network equivalent model.

Fig. 3. Permeance function and its Fourier's coefficients.

III. FE IDENTIFICATION OF THE MODEL PARAMETERS

The principle of the proposed model consists firstly on a numerical computation of the phase fluxes with a nonlinear 2D FE code [3]. Then a numerical post-processing of the FE results is performed for setting up the circuit model. The flux-ampere turn curves of each coil are determined over one electrical period of the rotor, which allows determining the permeance $P(\theta, F)$ as a function of the ampere turns and position which is shown on Fig. 3-a. The spectral decomposition of this function is performed and expressed with the following expansion:

$$P(\theta, F) = \sum_n p_n(F) \cos(nN_r \theta) \quad (2)$$

where F is the magnetomotive force (MMF). The functions $p_n(F)$ are shown in Fig.3-b. According to some permutation rules corresponding to the winding arrangement, the Fourier coefficients of the 8 permeances (p_n^k , $k = 1..8$) are easily

determined. Therefore, p_n^k is the Fourier coefficient of order n of the the k^{th} branch permeance.

A nonlinear resolution of the flux equations of the circuit model is performed for different positions of the rotor thanks to an iterative process. A rigorous convergence criterion is adopted to ensure the correct final solution of the problem. Indeed, due to the high saturation level of the teeth, the nonlinearity of the permeances is important as illustrated on Fig. 4. The saturation level is represented by the position of the points $\varphi_i(F_i)$ in the flux-ampere turn diagram. The general structure of the algorithm is based on the following steps:

- a) F.E. identification of the parameters
- b) For a given position θ
 - b.1 : Initialize the permeances P_0^k
 - b.2 : Solve nonlinear circuit equations
 - b.3 : Compute the fluxes $\varphi_i^k(F_i^k)$
 - b.4 : Deduce the new values of permeances P_{i+1}^k
 - b.5 : Test the convergence and go to b.2 or B.6
 - b.6 : $\theta = \theta + \delta\theta$ go to b)
- c) Compute external performances energy and torque

According to the saturation level of the different permeances P^k , the convergence of the resolution process is reached after less than 9 iterations. The algorithm is tested in different situations and changing starting point does not disturb the convergence process. Indeed, on Fig. 4 two different starting points which are represented by (*) are considered. The two figures show the trajectories of the points

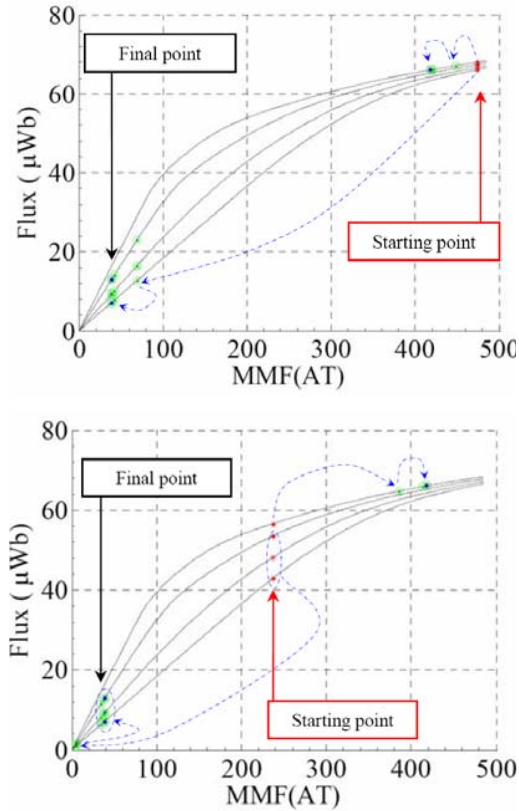

Fig. 4. Trajectories of the points $\varphi_n^k(F_n^k)$ during the iterative process

Fig. 5. Some static torques

$\varphi_i^k(F_i^k)$ that converge to the same final point $\varphi_\infty^k(F_\infty^k)$ after few iterations.

IV. EXTERNAL PERFORMANCES CALCULATION

The virtual works theorem is applied to compute the static torque of the motor for a given supply and for different positions. According to the spectral analysis of the permeance functions, we have:

$$T(\theta) = \partial_\theta \tilde{W}_m(\theta) = \partial_\theta \tilde{W}_m(\theta) - 2N_r \sum_{\substack{k=1:8 \\ n=1:\infty}} n \sin(n(N_r\theta + \alpha_k)) \int_0^{F_k} p_n^k(F) F dF \quad (3)$$

where: \tilde{W}_m is the coenergy in the magnet branch, F_k and α_k are the total ampere-turns and the phase shift of the permeances of the k^{th} branch respectively. Fig.5 shows the static torque waveforms obtained in different supplying modes: (1): the cogging torque (no current), (2): the phase 1 is supplied with a direct current i , (3): the phases 1 and 3 are supplied with the currents $i/2$ and $-i/2$ respectively.

The coupling between the results of numerical FE computation and the permeance network model is ensured by the good representation of $\mathbf{P}(\theta, F)$ functions, which takes into account the locals high saturation levels and high harmonic ranks of the MMF.

The developed model allows calculating the torque waveforms for any supplying mode. For high speed motors, the optimization of the supply according to the motor parameters is a serious problem that can be solved with such model. The computation of the optimal current waveforms can be performed with a minimal CPU time.

V. CONCLUSION

A nonlinear coupled Finite Element – circuit model is developed for the study and optimization of a hybrid motor.

The model is based on 2D FF results which are applied to simulate the 3D behaviour of the electromagnetic field in such devices. The use of nonlinear spectral analysis of the permeances allows determining the torque waveforms with an easy formulation. The model can be used for the optimization of the supply of such motors for high speed applications.

Abstract— This paper demonstrates how to take advantage of multirate behavior in the time-integration of electromagnetic field problems coupled to lumped electric circuits. The necessity of multiple time step sizes in different parts of the model according to their dynamics is explained and corresponding methods like the co-simulation are introduced to reduce the computational effort. This becomes especially important in cases where large field models are unnecessarily evaluated at a high frequency.

I. INTRODUCTION

The electromagnetic field is mathematically described by Maxwell's set of partial differential equations (PDEs), but in many applications simplified models of devices are accurate enough and one models them as a lumped electric circuit using a network approach. This leads to a time dependent system of differential algebraic equations (DAEs).

The coupling of both the field PDEs and circuit DAEs results in a system of partial differential algebraic equations that avoids the computationally expensive field simulation where possible, but allows particular devices to be given by field models. Finally, the spatial discretization of the field models yields a system of coupled DAEs, which leads to an efficient simulation scheme.

A. Multirate Phenomenon

The numerical solution of the coupled DAE system is obtained by integration schemes based on time discretization. This discretization has to resolve the dynamics of the system as a whole and thus yields a series of time steps that matches the dynamics of the most active component (respectively the one working at the highest frequency).

In coupled systems considering multiphysical behavior (e.g. heating) one can easily split the equation corresponding to their time constants since this is determined by the propagation speed of the effects. In contrast to this, the field and circuit equations are more describing the same effects, hence the same time constants occur. Anyhow due to switches, filters or high integration there may only be a small number of devices active at a time, while the others remain latent. In either case the time integrator will resolve parts of the model with an unnecessarily high resolution and hence higher computational costs than the problem requires are caused. Therefore a splitting w.r.t. the activity level is beneficial.

Fig. 1. A simple field/circuit configuration requiring different time constants in the time integration. The parameters are $R = 10\Omega$, $C = 100\mu\text{F}$ and $u_P(t) = 12 \sin(2\pi f_1 t) \text{V} + 0.5 \sin(2\pi f_2 t) \text{V}$ composed of two voltages with frequencies $f_1 = 50\text{Hz}$ and $f_2 = 10\text{kHz}$. The field model is approximately given by an equivalent circuit with $R_{\text{str}} = 0.07\Omega$ and $L_{\text{str}} = 1.7\text{mH}$.

B. Demonstration Example

The configuration shown in Fig. 1 demonstrates the phenomenon of different time constants within one circuit. Let $u_P(t)$ represent a simplified circuit model and the boxed inductor part is given by a stranded conductor model that is described by a large non-linear system of equations. Then the application of an adaptive time integration scheme would yield time step sizes in the order of $h_C = 10^{-5}\text{s}$, although step sizes of $h_L = 10^{-3}\text{s}$ would be sufficient to render the dynamics of the field model.

II. COUPLING

A. Electric Circuit

Electric circuits are commonly simulated by using the modified nodal analysis, this yields an DAE due to redundant coordinates, where voltages e and currents i are the unknowns

$$F_1\left(\frac{dx}{dt}, x, i_\lambda, t\right) := A \frac{dq}{dt}(x) + f(x, t) + A_\lambda i_\lambda = 0 \quad (1)$$

with incidence matrices A , the unknown $x := (e, i)$, charge and resistance functions q and f ; currents i_λ through field devices as modeled below, [1].

B. Magnetoquasistatic Field

The electromagnetic field is described by Maxwell's equations. We assume their spatial discretization based on the finite element method with lowest order Whitney elements or by the finite integration technique, [2, 3]. Then all equations can be combined such that one obtains the *curl-curl* equation (2)

$$M_\varepsilon \frac{d^2 \bar{a}}{dt^2} + M_\sigma \frac{d \bar{a}}{dt} + C^T M_\nu C \bar{a} = \hat{j}, \quad (2)$$

with the unknown magnetic vector potential (MVP) \bar{a} , the discrete curl operator C , the electric current density due to external sources \hat{j} ; the material matrices M_ν , M_ϵ and M_σ represent the reluctivities, permittivities and conductivities, with M_σ singular in general.

C. Coupling with Conductor Models

In [4] the solid, stranded and foil conductor models have been proposed for the usage in circuits. In all those cases the coupling is established by relating circuit currents i_λ and voltages $u_\lambda = A_\lambda^T x$ as defined in (1) to derivatives of the field's MVP \bar{a} in (2). The curl-curl equation is excited by currents that are derived from the coupling equation

$$\hat{j} = Q i_\lambda \quad \text{and} \quad R i_\lambda + Q^T \frac{d\bar{a}}{dt} = A_\lambda^T x, \quad (3)$$

where Q is the coupling matrix that imposes the circuit currents and voltages onto edges of the grid; R contains the dc resistances of all conductor models.

Finally, the field problem is given abstractly by the DAE

$$F_2\left(\frac{d^2}{dt^2}\bar{a}, \frac{d}{dt}\bar{a}, \bar{a}, A_\lambda^T x, i_\lambda\right) = 0 \quad (4)$$

III. SIMULATION

A. Monolithic Simulation

The DAE (4) defines a current/voltage relation and hence can be used as an element stamp in a circuit simulation package. This *monolithic* (or strongly coupled) approach will use the time integrator of the circuit simulator and serves as reference solution.

Typical circuit integrators do not yet use multirate techniques and thus the integration may become unnecessarily expensive because of the different time constants. Furthermore they focus on first order DAEs and hence one is forced to rewrite the curl-curl equation to first order with the drawback of doubling the number of unknowns or to disregard the displacement current at all. The latter approach is known as the *magnetoquasistatic* approximation and is the valid for low frequencies, but is numerically cumbersome due to the singularity of the conductivity matrix M_σ .

B. Waveform Relaxation

Instead of stamping the equations into one combined system, both subproblems can be simulated independently from each other by a *waveform relaxation scheme*, typically either of Jacobi or Gauß-Seidel type, [5]. We suggest the Gauß-Seidel scheme (5) that states the iteration in one time frame and is employed to further frames according to Fig. 2.

The scheme starts from given initial values and an additional initial guess for the current $i^{(0)}$. It iterates for $k = 1, \dots, N$ and in each iteration the circuit is computed first and the field afterwards. The first circuit solution $x^{(1)}$ is based on the initial guess $i^{(0)}$, while later computations ($k > 1$) rely on the previous field solution $i^{(k-1)}$. In Gauß-Seidel's scheme

Fig. 2. Integration of three time frames using a waveform relaxation schemes

the field computation always utilizes the latest available field solution $x^{(k)}$:

$$\begin{aligned} \text{Circuit:} \quad & F_1\left(\frac{dx^{(k)}}{dt}, x^{(k)}, i_\lambda^{(k-1)}, t\right) = 0 \\ \text{Field:} \quad & F_2\left(\frac{d^2\bar{a}^{(k)}}{dt^2}, \frac{d}{dt}\bar{a}^{(k)}, \bar{a}^{(k)}, A_\lambda^T x^{(k)}, i_\lambda^{(k)}\right) = 0. \end{aligned} \quad (5)$$

This approach allows the usage of problem-specific software packages for the field and circuit equations („*co-simulation*”) and therefore supports the full Maxwell case including the displacement current. The convergence of this scheme is not trivial due to the algebraic parts of the DAE, but convergence has been shown in [6].

The co-simulation uses different time integrators and thus supports different time steps towards each subproblem. But this will not unlock all possible benefits of the multirate phenomenon: different time scales within one subproblem are not exploited and one may need too many iterations of one time frame. Furthermore the consistency of the time integration is only ensured on the subproblems. Therefore one has to pick up the idea of multirate methods as they were proposed in [7].

C. Implementation

A demonstration code for simulating the field/circuit coupled problem is implemented within the CoMSON demonstration platform: the package FIDES for field devices is coupled to the CoMSON circuit integrator (OCS). The results of Fig. 1 are obtained by the monolithic approach using a field model discretized by FEMM.¹

Abstract—Multidimensional field diffusion problems with front-type behaviour, moving boundaries and non-linear material properties are analysed by a finite volume front fixing method. Advantages and implementation challenges of the method are discussed with special attention given to conservation properties of the algorithm and achieving accurate solutions close to the moving boundaries. The technique is validated using analytical solutions of diffusion problems with cylindrical symmetry.

I. INTRODUCTION

Design and development of modern devices based on High Temperature Superconductors (HTS) requires numerical modelling since electromagnetic and thermal parts of the problem are coupled together via high sensitivity of HTS material properties to temperature [1, 2]. Both field variation and heat flow can be formulated in terms of diffusion. This allows utilising a standard modelling approach on fixed grids and thus simplifying the equipment design. But such approach often fails to deliver appropriate balance between accuracy and efficiency, especially when modelling pulse events or shallow field penetration. Special methods, such as adaptive meshes, front fixing and level sets methods [3], offer advantages in such applications but they have to be assessed and probably adapted for each particular problem. The paper focuses on the analysis of the front fixing technique [3] since it requires only a small modification of the computational algorithm in comparison with models based on fixed grids [4, 5]. The major challenges are an implementation of conservation laws and achieving accurate solutions close to the moving curved boundaries. The paper uses analytical solutions of common front type problems to evaluate the performance of the numerical method. Two types of the problem are considered, namely a current pulse and an imposed external magnetic flux.

II. PROBLEM FORMULATION

A. Governing equation and material properties

It is possible to describe the problem in terms of either magnetic or electric field diffusion [6, 7]. The electric field formulation is preferred for HTS materials with non-linear properties as it provides much more stable solutions [7]. The governing equation takes the diffusion-like form

$$\text{curl} (\text{curl} \mathbf{E}) = -\mu_0 \frac{\partial \mathbf{J}}{\partial t} \quad (1)$$

expressed in terms of the electric field \mathbf{E} and current density \mathbf{J} . HTS materials exhibit strong flux creep E - J behaviour often

described by Rhyner's power law [6], $E_c^{-1}E = (J_c^{-1}J)^\alpha$, where the critical current density $J_c \approx 10^9 \text{ A m}^{-2}$ corresponds to a critical electric field $E_c \approx 10^{-4} \text{ V m}^{-1}$. For practical HTS materials the power exponent α could be as high as 20. Substitution of the material properties into (1) results in a formulation of the problem in terms of the electric field only.

B. Boundary and initial conditions

A HTS wire with a round cross section of radius R is considered. For the first test, a pulse $I_z(r, t) = I_0 \delta(r) \delta(t - t_0)$ of current is applied along the z axis at an instant $t = t_0$. The second test case assumes an external magnetic flux B_z to be switched suddenly in the centre of the wire and maintained at a constant value afterwards.

C. Analytical solutions

The existence of an axi-symmetric analytical solution provides an opportunity to evaluate the performance of the algorithm on curved boundaries using the Cartesian coordinate system. The dimensionless solution for (1) in the case of cylindrical symmetry under the conditions of the current pulse can be derived as shown in [8]

$$\frac{E(\rho, \tau)}{E_c} = \frac{1}{(\alpha\tau)} \left[\left(\frac{i_0}{4} \right)^{\frac{\alpha-1}{\alpha}} - \frac{\rho^2(\alpha-1)}{4\alpha(\alpha\tau)^{1/\alpha}} \right]^{\alpha/(\alpha-1)}, \quad (2)$$

$$\rho = \frac{r}{R}, \quad \tau = \frac{(t-t_0)E_c}{\mu_0 J_c R^2}, \quad i_0 = \frac{I_0}{J_c \pi R^2}. \quad (3)$$

The electric field and the current gradually spread from the centre of the wire towards the edges and there is a sharp interface between the region with a non-zero field and the outside part of the wire. A similar solution exists for the second test case of the applied external magnetic flux [9].

III. THE FRONT FIXING METHOD

The spatial transformation uses new positional variables [3] adjusted to the front position and, generally, introduces a co-ordinate system in which all of the spatial boundaries are fixed to 0 or 1. As a result, the new computational domains remain the same with an additional advection term in diffusion equation plus an implicit non-linear equation for the boundary motion. This allows treating the nodes close to the interface as being independent of the motion, which gives higher accuracy for the same number of nodes used [4, 5]. In practical applications it is often sufficient to apply the transformation in

only one direction, resulting in additional simplification [3]. Equation (4) is an example of the transformed (1) in notations (3) for the case of cylindrical symmetry:

$$\frac{\partial(us^2e^{1/\alpha})}{\partial\tau} = \frac{ds}{d\tau} \frac{\partial(su^2e^{1/\alpha})}{\partial u} + \frac{\partial}{\partial u} \left(\frac{\partial e}{\partial u} \right), \quad e = (E_c^{-1}E). \quad (4)$$

with a boundary at $s(t)$ and a new coordinate $u = \rho/s(t)$. A divergent form of (4) ensures that there are no artificial energy sources [5].

Fig. 1. Analytical and numerical predictions for a wire with $I_0 = 2A$, $R = 0.5mm$ and $\alpha = 6$: mesh size effects. Dimensionless electric field $E_z(r)$ at $t = 0.01s$ (time step $0.1ms$).

Fig. 2. Front-fixing method predictions of electric field inside the HTS wire after different times. Modelling conditions are similar to those in Fig. 1.

IV. COMPARISON OF COMPUTATIONAL TECHNIQUES

Predictions from fixed grid calculations and the front-fixing method are summarized in Figs. 1-3. Fixed nodes cannot adequately describe the field profile in the case of a shallow penetration (Fig. 1). At least 4 nodes per penetration depth are required, which could be computationally expensive for large devices. Placing nodes close to the boundary does not always solve the problem because the front propagates further into the material at later stages of the process. In contrast, the front fixing automatically adjusts the nodes towards the front boundary, Fig. 2, and good accuracy is achieved even by only 10 nodes in total. The particular

advantage of using a front-fixing method for modelling of superconductivity phenomena is that the high accuracy can be obtained with a small number of grid points. The interface motion can also be accurately predicted on a coarse moving mesh, Fig. 3.

Fig. 3. Interface position as a function of time. Modelling conditions are similar to those on Fig. 1.

V. CONCLUSIONS

The application of a front-fixing method for modelling of shallow field penetration into HTS materials is demonstrated for 2D geometry cases. Efficient techniques for incorporating conservation laws are suggested and potential problems with complex boundary conditions are considered. It is shown that high accuracy can be achieved on a coarse mesh since the interface is fixed in new coordinates. The analysis of errors and further implementation details will be given in the extended version of the paper. The finite volume method has been utilised in the paper as an example; the finite element scheme can also be used for successful discretisation of space and time in the transformed equations.

Abstract — In a dielectric liquid, unipolar and bipolar space charge injection and propagation were analyzed under simplified linear and Fowler-Nordheim charge injection conditions for parallel plane or needle-sphere electrodes stressed by a step voltage. Especially, here, the numerical aspects for solving space charge analysis were explored in a dielectric liquid by the Finite Element Method (FEM) employing the artificial diffusion scheme as a stabilization technique. We first tested parallel plane electrodes with a simplified linear charge injection law for unipolar space charge propagation that showed good agreement with older closed form with space charge limited condition. And tip-sphere electrodes, where the radius of tip was 40 μm , were also tested for bipolar space charge propagation including Langevin recombination.

I. INTRODUCTION

Dielectric liquids are widely used for many electrical insulation technologies such as transformer oil. When compared to gaseous or solid insulation, dielectric liquids generally offer greater electrical insulating strength, superior thermal conductivity, higher performance, and greater ease of use. One of the key issues for insulating liquids is to predict the electrical breakdown which is the final stage in the electrical breakdown process including several pre-breakdown stages.

This breakdown is basically based on the charge injection and transport phenomena between electrode and dielectric liquid. To analyze these mechanisms, charge continuity equations and Poisson's equation for the electric scalar potential must be self consistently satisfied [1]-[2]. The distributions of space charge in streamer propagating channel might have a shock-wave pattern, which causes severe numerical instabilities, due to the abrupt injection and propagation of space charge.

We briefly verified our numerical method by comparing analytic solutions earlier obtained by using the method of characteristics in the previous proceeding [3]. To stabilize this numerical difficulty, we, here, tested and discussed in the artificial diffusion technique incorporating the Finite element Method (FEM) considering the Peclet number in detail. The terminal current during discharge was calculated by using the principle of energy conservation for the electric field. Finally, we successfully applied the analysis to a tip-sphere electrode system, where the radius of tip was 40 μm , for analyzing bipolar space charge propagation in a dielectric liquid medium.

II. NORMALIZED GOVERNING EQUATIONS FOR UNIPOLAR SPACE CHARGE PROPAGATION

To deal with numerical aspects, we tested the parallel plane electrodes with the lower electrode as anode at $x=0$ and the upper electrode as cathode at $x=d$, the distance between two electrodes. To employ the normalized forms, we took the normalized variables as

$$\begin{aligned}\tilde{\nabla} &= d\nabla, \tilde{t} = t\mu V_0 / d^2, \tilde{V} = V / V_0, \tilde{\rho} = \rho d^2 / \varepsilon V_0, \\ \tilde{\mathbf{J}} &= 2\mathbf{J}d^3 / \varepsilon\mu V_0^2, \tilde{\mathbf{E}} = \mathbf{E}d / V_0, \tilde{A} = \tilde{A}d / \varepsilon\end{aligned}\quad (1)$$

where the tilde denotes non-dimensional variables, t the time, μ the charge mobility, V_0 the applied voltage, ρ the volume charge density, ε the dielectric permittivity, \mathbf{J} the current density, and V the electric scalar potential related to the electric field intensity as $\mathbf{E} = -\nabla V$. Then, the normalized governing equations can be expressed as

$$\tilde{\nabla} \cdot (-\tilde{\nabla} \tilde{V}) = \tilde{\rho} \text{ in } \Omega \quad (2)$$

$$\text{with } \tilde{V}(\tilde{x} = 0) = 1 \text{ and } \tilde{V}(\tilde{x} = 1) = 0 \text{ on } \partial\Omega$$

$$\frac{\partial \tilde{\rho}}{\partial \tilde{t}} + \tilde{\nabla} \cdot (\tilde{\rho} \tilde{\mu} \tilde{\mathbf{E}}) = 0 \text{ in } \Omega \quad (3)$$

$$\text{with } \tilde{\rho}(\tilde{x} = 0, \tilde{t}) = \tilde{A} \tilde{E}(\tilde{x} = 0, \tilde{t}) = \tilde{A} \tilde{E}_0 \text{ on } \partial\Omega$$

where \tilde{E}_0 is the non-dimensional electric field at $x=0$ and Ω is the domain region between electrodes. This governing equation for space charge propagation belongs to the hyperbolic-type PDE of which solution has a pattern of steep change in solution space resulting in numerical instabilities.

III. STEADY-STATE SOLUTIONS BY DIFFERENT LINEAR INJECTION AND SPACE CHARGE LIMITED CONDITION

In simple charge injection condition, when $\tilde{A} \rightarrow \infty$, then $\tilde{E} \rightarrow 0$. This condition is the same as the space-charge limited condition. Figs. 1(a) and 1(b) show the dc steady-state distributions of the normalized electric field and the normalized space charge distributions. These all trends are match well with Zahn's results published in [1]. The maximum value, therefore, $\tilde{A} = 5000$ can be regarded as the case of space charge limited condition as shown in Fig. 1.

(a) Normalized electric field distributions vs. normalized position

(b) Normalized charge density distributions vs. normalized position

Fig. 1. DC steady-state distributions with respect to normalized charge injection constant, \tilde{A} .

IV. NUMERICAL ASPECTS OF TRANSIENT ANALYSIS WITH ARTIFICIAL DIFFUSION SCHEME

The governing equation, (3), strongly depends on the convective term and the discretization of convective-dominated transport problems can introduce numerical instabilities in the solution. In this case, these instabilities might be noted as oscillations and non-convergence in the field solutions, primarily where steep gradients are present such as at the fronts of moving charge. The oscillations can even be large enough to prevent the solution from converging. To check this instability, the Peclet number at each element, $P_{e_{cell}}$, can give a useful information related to a numerical stability, which can be expressed as [4]

$$P_{e_{cell}} = h |\beta| / c \quad (4)$$

where h is the local mesh diameter, β the magnitude of the convective velocity, and c the diffusivity. Numerical solution will be unstable when the Peclet number exceeds two [4]. For our problem, because there is no diffusion term ($c=0$), $P_{e_{cell}} \rightarrow \infty$. To resolve this numerical instability, an artificial diffusion technique was adopted, which yield more reliable results, as

$$\frac{\partial \tilde{\rho}}{\partial \tilde{t}} + \tilde{\nabla} \cdot (\tilde{\rho} \tilde{\mu} \tilde{\mathbf{E}}) - \tilde{D} \tilde{\nabla}^2 \tilde{\rho} = 0 \quad (5)$$

where \tilde{D} is the non-dimensional artificial diffusion coefficient.

Figs. 2(a) and 1(b) show the transient solutions of electric field intensity and space charge propagation with the different artificial diffusion factors at normalized time $\tilde{t} = 0.1$ comparing to those from analytic approach with space charge limited condition [1].

(a) Normalized electric field distributions vs. normalized position

(b) Normalized charge density distributions vs. normalized position

Fig. 2. Electric field and charge density with respect to different artificial diffusion factors (Delta) in case of space charge limited condition (SCL) and simple charge injection condition ($\tilde{A} = 1000$) at normalized time $\tilde{t} = 0.1$.

In extended paper, more results will be presented in detail including the Fowler-Nordheim field emission condition and a tip-sphere electrode system, where the radius of tip was $40 \mu\text{m}$, for analyzing bipolar space charge propagation in a dielectric liquid medium.

Abstract—In this paper, a generalization of cloaking is presented: instead of an empty region of space, an inhomogeneous structure is transformed via Pendry’s map in order to give, to any object hidden in the central hole of the cloak, a completely arbitrary appearance.

I. INTRODUCTION

In 2006, it was suggested by Pendry et al. [1] that an object surrounded by a coating consisting of an exotic material becomes invisible to electromagnetic waves. This device was named “invisibility cloak” in reference to Harry Potter, the popular character of J.K. Rowling. Beside his famous cloak, the little wizard has other spells to go unnoticed. Among the most spectacular is the “polyjuice potion” that is able to turn somebody into anybody else’s appearance [2]. In this paper, we do not present a potion but rather an optical device able to accomplish the same task, i.e. to give an arbitrary optical response chosen in advance to any other object placed inside the device. In fact, the principle is here very similar to the design of Pendry’s invisibility cloak but, instead of geometrically transforming an empty domain, it is a region containing the object to be imitated that is transformed leading thus to a generalization of cloaking.

II. GENERALIZED CLOAKING

In this section, we present a generalization of cloaking able to arbitrarily transform the electromagnetic appearance of an object. The basic principle is to obtain the constitutive relations of the cloak by application of a space transformation to a non-empty region.

A geometric transformation is given by a map φ from a space N to a space M . For all our practical purposes, M and N will be here the whole or parts of \mathbb{R}^3 . Given a Cartesian coordinate system \mathbf{x} on M and an arbitrary coordinate system \mathbf{x}' on N , $\varphi : N \rightarrow M$ is described by $\mathbf{x}(\mathbf{x}')$, i.e. \mathbf{x} given as function of \mathbf{x}' . All the useful information, i.e. necessary to transform differential forms and other covariant tensors, is contained in the Jacobian matrix field $\mathbf{J}(\mathbf{x}') = \partial\mathbf{x}(\mathbf{x}')/\partial\mathbf{x}'$.

The basic principle of transformation electromagnetics is that, when you have an electromagnetic system described by the tensor fields $\underline{\underline{\epsilon}}(\mathbf{x})$ for the dielectric permittivity and $\underline{\underline{\mu}}(\mathbf{x})$ for the magnetic permeability in the space M , if you replace your initial material properties by equivalent material

properties given by the following rule [3], [4]:

$$\begin{aligned}\underline{\underline{\epsilon}}'(\mathbf{x}') &= \mathbf{J}^{-1}(\mathbf{x}')\underline{\underline{\epsilon}}(\mathbf{x}(\mathbf{x}'))\mathbf{J}^{-T}(\mathbf{x}')\det(\mathbf{J}(\mathbf{x}')), \\ \underline{\underline{\mu}}'(\mathbf{x}') &= \mathbf{J}^{-1}(\mathbf{x}')\underline{\underline{\mu}}(\mathbf{x}(\mathbf{x}'))\mathbf{J}^{-T}(\mathbf{x}')\det(\mathbf{J}(\mathbf{x}')), \end{aligned} \quad (1)$$

(\mathbf{J}^{-T} is the transposed of the inverse of \mathbf{J}), you get an equivalent problem on N . Here, an equivalent problem means that the solution of the new problem on N , i.e. electromagnetic quantities described as differential forms, are the pulled back of the solution [4], [5] of the original problem on M and that the same Maxwell’s equations (i.e. as if we were in Cartesian coordinates or, more accurately, having the same form written with the exterior derivative) are still satisfied.

In the case of the cylindrical Pendry’s map [1], [6], described by the transformation of the 2D cross section, the plane \mathbb{R}^2 minus a disk D_1 of radius R_1 is mapped on the whole plane \mathbb{R}^2 in such a way that a disk D_2 of radius $R_2 > R_1$, concentric with D_1 , is the image of the annulus $D_2 \setminus D_1$ by a radial transformation. In cylindrical coordinates, this transformation is given by:

$$\begin{cases} r = (r' - R_1)R_2/(R_2 - R_1) \text{ for } R_1 \leq r' \leq R_2, \\ \theta = \theta', \quad z = z'. \end{cases} \quad (2)$$

As for the outside of the disk D_2 , the map between the two copies of $\mathbb{R}^2 \setminus D_2$ is the identity map.

The material properties given by rule (1) corresponding to this transformation provide an ideal invisibility cloak: outside D_2 , everything behaves as if we were in free space, including the propagation of electromagnetic waves across the cloak, and is completely independent of the content of D_1 .

Now, rule (1) may be applied to D_2 containing objects with arbitrary electromagnetic properties so that a region cloaked by this device is still completely hidden but has the appearance of the objects originally in D_2 . We may call this optical effect masking [7] or “polyjuice” effect.

III. NUMERICAL MODELING

Figs. 2 and 3 shows the effect of masking on a scattering structure. On Fig. 2, a cylindrical TM wave emitted by a circular cylindrical antenna is scattered by a conducting triangular cylinder (the longest side of the cross section is 1.62λ and $\epsilon_r = 1 + 40i$). The field map represents the longitudinal electric field $E_z(x, y)$ and the outer boundary of

Fig. 1. This figure shows a part of the triangular mesh used for the finite element modeling of the scattering problem of Fig. 3. The singular behavior of the permittivity and of the permeability requires a very fine mesh along the inner boundary of the cloak in order to achieve a satisfactory accuracy with the numerical model.

Fig. 2. A conducting triangular cylinder is scattering cylindrical waves.

the cloak is shown to ease the comparison with the masked case. On Fig. 3, the same cylindrical TM wave is scattered by a masked triangular cylinder. This triangular cylinder is the symmetric of the previous one with respect to the horizontal plane containing the central fibre of the cylindrical antenna. This bare scatterer would therefore give the Fig. 2 image inverted upside-down but, here, this object is surrounded by a cloak in order to give the very same scattering as before. Indeed, on both sides, the electric fields outside the cloak limit are alike.

The numerical computation is performed using the finite element method (via the GetDP freeware [8]). The mesh is

made of 148,000 second order triangles. The singularity of ϵ

Fig. 3. A triangular cylinder different from the one on Fig. 2 is surrounded by a cloak designed to reproduce the scattering pattern of the Fig. 2 triangular cylinder in spite of the change of diffracting object.

and μ requires a very fine mesh in the vicinity of the inner boundary of the cloak and is also responsible for the small discrepancies between the numerical model and a perfect cloak (including the non zero field in the hole of the cloak).

The rule (1) is applied but a small problem arises in practice: the material properties are defined piecewise on various domains and it is very useful to know explicitly the boundaries of these domains, e.g. to build the finite element mesh. These boundaries are curves in the cross section and are thus contravariant objects. Therefore, their transformation requires the inverse map φ^{-1} from M to N . Fortunately, map (2) is very simple to invert. On Fig. (2) the image by φ^{-1} of the triangle in the left side picture is the curvilinear triangle inside the cloak in the right side picture. In practice, this anamorphosis of the triangle is described by three splines interpolating each 40 points.

Abstract— Acceleration of micromagnetic calculations on symmetric multiprocessing (SMP) system is investigated. A speed up of more than 20 times has been realized compared with the serial processing software. The SMP system with the optimized software has a speed up of 5.6 times compared to a previous version on an 8-CPU cluster system. Micromagnetic analysis of a write head with trailing and side shields is performed to derive the dynamic recording field and magnetization rotation process. The dynamic recording field is found to be affected by the shields.

I. INTRODUCTION

Micromagnetic simulation is a powerful tool to understand the complicated phenomena in recording write heads [1] that occur in the sub-nanosecond and sub-nanometer regions, where experiments are fairly hard. In micromagnetic analysis the computational load is large; therefore, parallel computing is essential. We have previously reported on a cluster system and parallelized program with full Fast Fourier Transform (FFT) [2]. In that system the communication time is not negligible and amounts to almost half the total computation time if a Gigabit network is used. An *infiniband* network would reduce this time but they are fairly expensive.

The first half of this paper investigates the acceleration of the micromagnetic analysis. We have used the symmetric multiprocessing (SMP) system to avoid problems with communication time between nodes and optimized the software. The major contributions to the speed-up are the use of a three-dimensional FFT in place of the two-dimensional FFT, and the reduced FFT procedure. In the second half, a single-pole-type (SPT) head with trailing shield (TS) and/or side shields (SSs) is analyzed, and the dynamic recording field and the magnetization rotation process are investigated. It is found that the recording field is affected not only by the magnetization rotation process of main pole (MP) but also the presence of trailing and side shields.

II. CALCULATION MODEL

Throughout this paper we use the SPT head model shown in Fig. 1 with material characteristics shown in Table I, where M_s is the saturation magnetization, K_u is the anisotropy energy, A is the exchange constant, and α is the Gilbert damping factor. For both the head and media soft underlayer (SUL), the anisotropy direction is assumed to be the cross-track (+y) direction. The recording layer was assumed to be air. The model dimensions are close those of commercial

heads except that the main pole tip has a large area (160 nm wide \times 260 nm long) with a throat height of TS = 200 nm and a neck height of MP = 200 nm. The model is divided into 20-nm side cubic cells and the total number of cells is 3,672,000. The recording field distributions are observed at 28 nm from the air-bearing surface (ABS), where the distance between ABS and SUL = 66 nm.

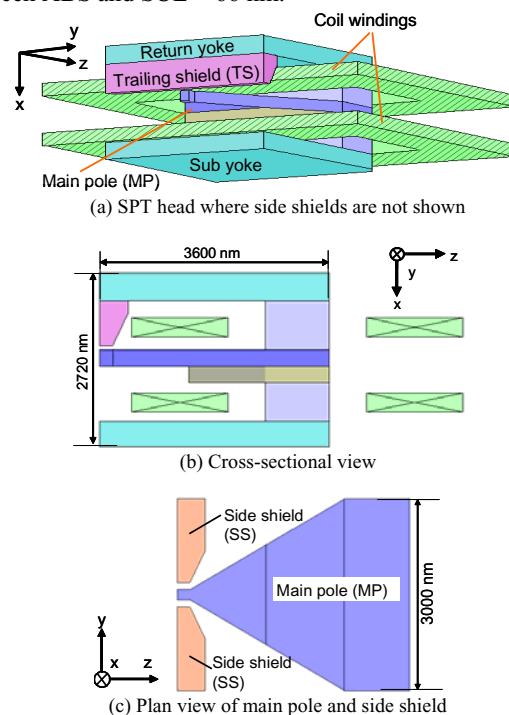

Fig. 1. SPT head model with trailing and side shields. Medium (soft underlayer) is not shown.

TABLE I
MATERIAL CHARACTERISTICS FOR HEAD AND SOFT UNDERLAYER

	SPT head	Soft underlayer
M_s emu/cm ³	1910	955
$(4\pi M_s)$ kG	24	12
K_u erg/cm ³	3×10^4	3×10^4
A erg/cm	1×10^{-6}	1×10^{-6}
α	0.2	0.2

The Landau-Lifshitz-Gilbert (LLG) micromagnetic analysis,

$$(1 + \alpha^2) \dot{\mathbf{M}} = -\gamma |\mathbf{M} \times \mathbf{H} - \frac{\gamma \alpha}{M_s} \mathbf{M} \times (\mathbf{M} \times \mathbf{H}) \quad (1)$$

that treats the whole magnetic material micromagnetically was

solved by using the finite-difference method, where \mathbf{M} is the magnetization vector, \mathbf{H} is the effective field vector and V is the gyro magnetic constant.

III. ACCELERATION OF MICROMAGNETIC CALCULATIONS

In Tables II and III the hardware and software used are shown. We have optimized the software on an Intel Xeon SMP system. The speed-ups are summarized in Fig. 2 for one-thread and eight-threads, where the original program was the parallelized program optimized for the cluster system. Program 1 is a serial processing program where the message passing interface (MPI) feature has been removed from the original program. Program 2 was parallelized using OpenMP and automatic parallelization was performed with a compilation option. Program 3 uses the three-dimensional FFT in place of the two-dimensional FFT. In program 4, the FFT procedure was reduced with the help of the symmetric nature of the FFT. Program 4 has a calculation speed which is more than 20 times faster than program 1. It is also noted that the processing speed of program 4 on the Xeon SMP system is 5.6 times faster than the 8-CPU Pentium4 cluster system. With regard to the memory requirement, the SPT head model can be solved with 8.5 GB. Note that the recording fields obtained by program 1 and program 4 agree with 6 digits of precision.

	Cluster system [2]	SMP system
CPU	Pentium4	Xeon
Clock	3.0 GHZ	2.5 GHz
RAM	4 GB (x 8)	16 GB
Compiler	Intel Fortran 9.1	Intel Fortran 10.1
Library	Intel MKL 8.1	Intel MKL 10.0
Notes	8 nodes	Quad core x 2

Name	Major feature	Parallel/serial
Program 1	Cluster program, MPI removed	Serial
Program 2	OpenMP + automatic parallelization	Parallel
Program 3	3-D FFT	Parallel
Program 4	3-D FFT + reduced FFT procedure	Parallel

Fig. 2. Comparison of calculation times on Xeon SMP System.

IV. CALCULATED RESULTS FOR VARIOUS SHIELD SPT HEADS

In Fig. 3, head field time variations are shown for various head structures: head 1 has no TS and no SS; head 2 has TS (60 nm from MP) and no SS; head 3 has TS (60 nm from MP) and SSs (60 nm from MP). Shielded head 3 has the smallest

field amplitude and the response is quite different from the other two heads. In Fig. 4, snapshots of the magnetization vectors in MP, in the cells facing ABS, are shown for head 1 and head 3 at $t = 1.5$ ns when current is 0; $t = 1.65$ ns when the driving current reaches positive peak; and $t = 2.05$ ns when the current starts to decrease from the positive peak. It is seen that the magnetization in MP is affected by the trailing and side shields, and directed towards the TS and SSs. It is also seen that, in dynamic response, the magnetization rotation process in MP is affected by the magnetization in the shields, which finally affects the head field response.

The head field time variations and the magnetization process for various head structures and materials will be shown in the full paper. We will also try to propose a SPT head with fast response, large recording field, and small stray field to the adjacent tracks.

Fig. 3. Head field time variations for head 1 (without TS, SS), head 2 (with TS, without SS) and head 3 (with TS, SS). Driving current frequency is 667 MHz.

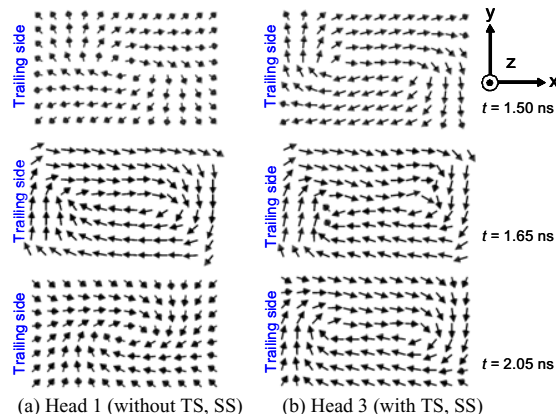

Fig. 4. Magnetization vectors in MP for head 1 and head 3.

Abstract—We show how to use hexahedral and prismatic elements for the efficient development of UPML around an unstructured tetrahedral primal mesh using the finite integration technique (FIT). Taking into account the properties of the UPML medium, we obtain a simple scheme for the time-domain solution of Maxwell's equations. The implementation of the method is presented for the general 3D case, and numerical results are given for a 2D test case.

I. INTRODUCTION

Perfectly matched layers (PML) have been developed for the numerical approximation of electromagnetic radiation and/or scattering problems by the finite element method (FEM) and the finite difference time domain method (FDTD). PML have been introduced by Berenger in 1994 in the context of the FDTD method using a formulation in cartesian coordinates [1]. Berenger derived a split-field formulation of Maxwell's equations where each vector field component is split into two orthogonal components. Subsequently, another formulation has been proposed by Chew and Weedon [2] using the concept of stretching complex coordinates. Both of these approaches yield non-Maxwellian fields within the PML domain.

It has been demonstrated by Sacks et al [4] that Maxwellian PML can be realized as a uniaxial anisotropic medium with suitably defined permittivity and permeability tensor. The introduction of losses into these tensors results in a perfectly matched absorbing medium. This mathematical model (UPML) was first applied within the FDTD method by Gedney [5].

The implementation of the UPML-FDTD method is simple for the termination of regular hexahedral meshes [3]. UPML termination of an unstructured tetrahedral mesh is much more difficult. It can be performed with time-domain finite element method, but this approach has some difficulties in terms of computational and analytic effort, especially because of the convolution term [7]-[8].

In this paper, a new efficient implementation of UPML is proposed for the finite integration technique. Hexahedral and prismatic elements are used to extend the tetrahedral primal mesh. The resulting scheme is very similar to the usual FDTD one but can be applied to the termination of general unstructured meshes.

II. IMPLEMENTATION OF UPML IN THE FIT

We start with the tetrahedral primal mesh of an hexahedral region (PML free region) around which we have to build the PML. The PML mesh is built by extrusion of the primal triangular faces of the boundaries. There are two types of region to study in the PML:

- Regions where the absorption is done in one direction. In these regions, the mesh is obtained by normally extruding the triangular faces of the boundaries: the resulting mesh is prismatic.
- Corner regions, where the absorption is done in two or three directions, are made up of hexahedral elements.

The dual mesh is assumed to be the barycentric one on for all regions.

In corner regions, the FIT formulation is based on the direct application of the FDTD-UPML [3], using appropriate diagonal constitutive matrices. In the other type of region, we consider that x is the absorption direction. Amperes Law in the matched UPML is expressed as

$$rotH = jw\epsilon \begin{pmatrix} \frac{1}{S_x} & 0 & 0 \\ 0 & S_x & 0 \\ 0 & 0 & S_x \end{pmatrix} E \quad (1)$$

where $S_x = \kappa_x + \frac{\sigma_x}{j\omega\epsilon}$ with κ_x and σ_x the PML parameters. Direct transformation into the time domain would lead to a convolution between the tensor coefficients and the E field. This approach has some difficulties because implementing this convolution would be computationally intensive. A much more efficient approach is to define the proper constitutive relationship to decouple the frequency-dependent terms. We chose to define D in order to obtain an isotropic time independent behavior for the UPML in the directions perpendicular to the absorption direction (y,z):

$$D_x = \epsilon \frac{1}{S_x} E_x \quad (a); \quad D_y = \epsilon E_y \quad (b); \quad D_z = \epsilon E_z \quad (c) \quad (2)$$

Then, applying the inverse Fourier transform and using the identity $j\omega \rightarrow (\frac{\partial}{\partial t})$:

Fig. 1. Notations for primal and dual meshes in the prismatic PML region

$$rotH = \frac{\partial}{\partial t} \begin{pmatrix} 1 & 0 & 0 \\ 0 & \kappa_x & 0 \\ 0 & 0 & \kappa_x \end{pmatrix} D + \frac{1}{\epsilon} \begin{pmatrix} 0 & 0 & 0 \\ 0 & \sigma_x & 0 \\ 0 & 0 & \sigma_x \end{pmatrix} D \quad (3)$$

The FIT formulation is obtained by integrating equation (3) on the faces of the dual mesh (Fig. 1). For the faces associated to a primal edge parallel to the absorption direction, the equation is implemented directly by the following expression:

$$(Rh)_{\parallel} = \frac{\partial d_{\parallel}}{\partial t} \quad (4)$$

where R is the discrete rotational operator, h and d the degrees of freedom. On the dual faces associated with edges perpendicular to the absorption direction, we have:

$$(Rh)_{\perp} = \kappa_x \frac{\partial}{\partial t} d_{\perp} + \frac{\sigma_x}{\epsilon} d_{\perp} \quad (5)$$

Then, it is necessary to formulate the constitutive relations. A special constitutive matrix is built in order to take advantage of the choice made for equations (2). The edges parallel to the absorption direction are assumed to be independent of the edges perpendicular to the absorption direction. In consequence, equation (2a) can be directly expressed by:

$$d_{\parallel} = \epsilon \frac{1}{S_x} \frac{S}{l} e_{\parallel} \quad (6)$$

where l is the length of the primal edge and S the surface of the dual face. By transformation into the time domain, this equation gives an update scheme similar to the one of an FDTD implementation. As equations (2b) and (2c) are both independent of time, the constitutive relation can be treated in a similar way that in the PML free region: for each layer of the PML, the edges perpendicular to the absorption direction form a 2D triangular mesh. The associated entries of the constitutive matrix can be calculated using the 2D Galerkin's method [6], taking into account the thickness of the layer.

A similar formulation can be obtain for the other Maxwell's equation and constitutive law.

III. NUMERICAL RESULTS

For validation, a parallel plate waveguide is considered. A plane TE gaussian pulse is generated at one end of the waveguide, and the UPML medium is used to absorb the pulse

Fig. 2. Error with respect to the numerical solution without PML (x1000 of the maximum value of the pulse) near the UPML medium

at the other end. The mesh consists of triangular elements in the waveguide, and rectangular elements in the UPML. The electric field is computed at a point near the PML boundary. The result is compared to the numerical solution obtained without PML but on a longer waveguide avoiding any reflection during the simulation time. The error is given by the difference between these two numerical solutions (Fig.2). It remains under 5.10^{-4} on the whole simulation time which shows that the UPML is efficient.

IV. CONCLUSIONS

In this paper, we have introduced the use of hexahedral and prismatic elements for the development of UPML. We have shown that the implementation using the FIT is very simple, practical and compatible with unstructured primal tetrahedral meshes. Normally extruded prisms and an appropriate choice of the UPML scheme give the key to an efficient FIT formulation. Numerical results on a 2D problem show the applicability of the method. A complete 3D problem with absorption in all directions will be presented at the conference.

tmatsuo@kuee.kyoto-u.ac.jp

Abstract— A finite integration technique (FIT) on a space-time grid is studied for electromagnetic wave computation, where nonuniform time-step distribution is naturally introduced. Orthogonality between dual grids is given by the Lorentz metric to obtain a constitution equation for electromagnetic variables. An analysis of TE-wave scattering by the FIT on a nonuniform space-time grid is presented.

I. INTRODUCTION

The finite difference time domain (FDTD) method [1] is widely used for electromagnetic field computation because of its efficiency and accuracy. However, the conventional Yee grid requires brick-type representation of analyzed objects. The finite integration technique (FIT) [2], [3] can use flexible spatial grids including tetrahedron, prism, and pyramid elements. However, both conventional FDTD method and FIT use a uniform time-step. The FDTD method using sub-grids [4], [5] uses nonuniform time-steps, but it uses only brick-type spatial grids.

On the other hand, space and time are handled in a unified manner by the special theory of relativity [6]. Although usual electromagnetic field computation does not require the relative theory, electromagnetic fields can be analyzed in space-time because Maxwell equations are not affected by the special theory of relativity.

This study examines an electromagnetic field computation on a space-time grid, where nonuniform time-step distribution is naturally introduced.

II. FINITE INTEGRATION METHOD ON A SPACE-TIME GRID

The Euclid metric is used in this article for an analogous explanation to the conventional electromagnetics in two- or three-dimensional (2D or 3D) space.

For simplicity, permittivity ϵ and permeability μ are assumed to be constant. A time-variable w is introduced as

$$w = ct, \quad c = (\epsilon\mu)^{-1/2}. \quad (1)$$

A 2D electromagnetic field is described by (2) and (3), where E_x , E_y and B_z propagate in (x, y, w) space-time.

$$\partial\epsilon_x/\partial x - \partial\epsilon_y/\partial y + \partial B_z/\partial w = 0 \quad (2)$$

$$\partial\mathfrak{C}_z/\partial y - \partial D_x/\partial w = 0, \quad -\partial\mathfrak{C}_z/\partial x - \partial D_y/\partial w = 0 \quad (3)$$

$$\epsilon_x = E_x/c, \quad \epsilon_y = E_y/c, \quad \mathfrak{C}_z = H_z/c \quad (4)$$

Two electromagnetic vectors are formally defined in (x, y, w) space-time as

$$\mathbf{F} = (\epsilon_y, -\epsilon_x, B_z), \quad \mathbf{G} = (-D_y, D_x, \mathfrak{C}_z). \quad (5)$$

Equations (2) and (3) can be rewritten with \mathbf{F} and \mathbf{G} as

$$\nabla_2 \cdot \mathbf{F} = 0, \quad \nabla_2 \times \mathbf{G} = 0 \quad (6)$$

where ∇_2 means $(\partial/\partial x, \partial/\partial y, \partial/\partial w)$.

The integral form of (6) is given as

$$\oint_S \mathbf{F} \cdot \mathbf{n} dS = 0, \quad \oint_C \mathbf{G} \cdot \mathbf{t} ds = 0 \quad (7)$$

where \mathbf{n} and \mathbf{t} are the unit normal and tangential vectors, respectively.

Equation (7) derives an FIT in the space-time using electromagnetic variables defined as

$$e_x = \int \epsilon_x dw dx, \quad e_y = \int \epsilon_y dy dw, \quad b = \int B_z dx dy \quad (8)$$

$$d_x = \int D_x dy, \quad d_y = \int D_y dx, \quad h = \int \mathfrak{C}_z dw \quad (9)$$

The integration of d_x , d_y , and h along the z -direction is implicitly assumed for unit length in (9).

When orthogonal primal and sub grids in (x, y, w) space-time are used, the FIT reduces (7) to (see Fig. 1)

$$-b_{i,j}^{n-1} + e_{x,i,j-1/2}^{n-1/2} - e_{y,i-1/2,j}^{n-1/2} + b_{i,j}^n - e_{x,i,j+1/2}^{n-1/2} + e_{y,i+1/2,j}^{n-1/2} = 0 \quad (10)$$

$$-d_{y,i+1/2,j}^{n-1/2} - h_{i,j}^n + d_{y,i+1/2,j}^{n+1/2} + h_{i+1,j}^n = 0 \quad (11)$$

$$+ d_{x,i,j+1/2}^{n-1/2} - h_{i,j}^n - d_{x,i,j+1/2}^{n+1/2} + h_{i,j+1}^n = 0. \quad (12)$$

Those result in the conventional FDTD scheme.

Fig. 1 FIT using orthogonal space-time mesh.

The following electromagnetic variables are defined when a non-orthogonal primal grid and its dual grid are used.

$$f = \int \mathbf{F} \cdot \mathbf{n} dS, \quad g = \int \mathbf{G} \cdot \mathbf{t} ds \quad (13)$$

Variables f and g are defined on the primal and sub grids, respectively. Integration of g along the z -direction is assumed implicitly for unit length in (13).

Let $\mathbf{n}_p = (n_1, n_2, n_3)$ be the normal vector of a face of the primal grid. To relate f to g , the tangential vector of the corresponding edge of the sub grid is given as $\mathbf{t}_s = (-n_1, -n_2, n_3)$, as presented in Fig. 2. Thereby,

$$\begin{aligned} \mathbf{F} \cdot \mathbf{n}_p &= \mathcal{E}_y n_1 - \mathcal{E}_x n_2 + B_z n_3 \\ &= (\mu/\epsilon)^{1/2} (D_y n_1 - D_x n_2 + \mathcal{K}_z n_3) = Z \mathbf{G} \cdot \mathbf{t}_s. \end{aligned} \quad (14)$$

$$Z = (\mu/\epsilon)^{1/2} \quad (15)$$

It is noted that \mathbf{t}_s is orthogonal to the corresponding face of the primal grid by the Lorentz metric.

Fig. 2 Relation between face of primal mesh and edge of sub mesh

III. APPLICATION TO TE-WAVE COMPUTATION

Fig. 3 depicts a space-time primal grid with 2D-space. The grid has three domains according to the time-step: (I) the domain with time-step Δw , (II) the domain with $\Delta w/2$, and (III) the domain connecting (I) and (II). The FIT can use prism elements in domain (II) similarly to the usual brick elements. Fig. 3(c) and (d) portray connecting domain (III). An explicit time-marching scheme is developed for the space-time grid.

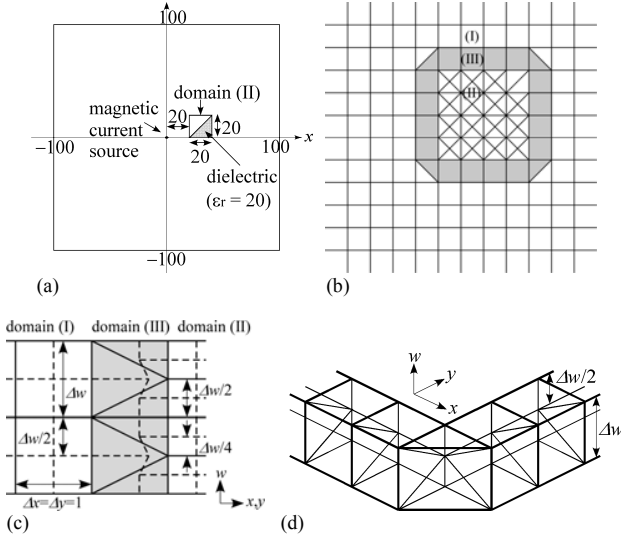

Fig. 3 Geometry of application example and space-time grid: (a) source and domain (II), (b) three domains, (c) connecting part (solid lines: primal grid, dashed lines: sub grid), and (d) domain (III)

The TE-wave induced by a magnetic current source is analyzed, where the TE-wave is scattered by a triangle dielectric. The permittivity and permeability are set to unity by normalization in the domains except the dielectric. The dielectric has $\epsilon = 20$ and $\mu = 1$, which occupies half of domain (II). The spatial cell size is unity and $\Delta w = 0.5$ in domain (I).

Domain (II) and the magnetic current source with normalized frequency of 0.1 are located as depicted in Fig. 3(a).

Fig. 4 depicts distributions of B_z obtained from the FIT on space-time grid and from the conventional FDTD method. The FDTD uses the same cell size and time-step as in domain (I) uniformly. Fig. 8(b) shows that the FDTD method results in insufficient resolution in the dielectric because of the fixed cell size. The FIT on space-time grid can zoom in/out according to the locally required resolution of the electromagnetic wave.

Fig. 4 Distribution of B_z : (a) by FIT on the space-time grid, and (b) by FDTD

IV. ACKNOWLEDGMENT

The author would like to express his gratitude to Mr. A. Kameari, Science Solutions International Laboratory, Inc. for his advice on the orthogonality in space-time.

Abstract—We report on recent efforts towards the development of a high order, non-conforming, discontinuous Galerkin method for the solution of the system of frequency domain Maxwell's equations in heterogeneous propagation media. This method is an extension of the low order one which was proposed in [1].

I. INTRODUCTION

In the recent years, there has been an increasing interest in discontinuous Galerkin (DG) methods for solving the time-domain Maxwell equations [2]- [3] due to their ability to easily deal with unstructured meshes and heterogeneous media. The development of DG methods for solving the frequency domain Maxwell equations has been less impressive and mostly done in the context of the Maxwell eigenvalue problem [4]. Besides, a hp -adaptive DG method has been proposed in the context of the low-frequency time-harmonic Maxwell equations [5]. In this paper, we report on recent efforts towards the development of a discontinuous Galerkin method for the solution of the system of frequency domain Maxwell's equations in heterogeneous propagation media. This DGFDF (Discontinuous Galerkin Frequency Domain) method is formulated on simplicial meshes (triangle in 2D and tetrahedron in 3D). Within each mesh element, the approximation of the electromagnetic field relies on an arbitrarily high order nodal polynomial interpolation. Moreover, as a first step towards the development of a hp -adaptive method, the approximation order p is allowed to vary across mesh elements resulting in a non-conforming DGFDF method. We present preliminary results for the simulation of two-dimensional propagation problems.

II. DGFDF METHOD

We consider solving the non-dimensioned time-harmonic Maxwell equations in the first order form:

$$i\omega\varepsilon_r\mathbf{E} - \text{curl}\mathbf{H} = 0 \quad , \quad i\omega\mu_r\mathbf{H} + \text{curl}\mathbf{E} = 0, \quad (1)$$

where \mathbf{E} and \mathbf{H} are the unknown electric and magnetic fields. Parameters ε_r and μ_r are respectively the complex-valued relative dielectric permittivity and the relative magnetic permeability; we consider here the case of linear isotropic media. Eq. (1) is solved in a bounded domain Ω . On the

boundary $\partial\Omega = \Gamma_a \cup \Gamma_m$, the following boundary conditions are imposed: a perfect electric conductor condition on Γ_m : $\mathbf{n} \times \mathbf{E} = 0$, and a Silver-Müller (first-order absorbing condition) condition on Γ_a : $\mathbf{n} \times \mathbf{E} + \mathbf{n} \times (\mathbf{n} \times \mathbf{H}) = \mathbf{n} \times \mathbf{E}^{\text{inc}} + \mathbf{n} \times (\mathbf{n} \times \mathbf{H}^{\text{inc}})$. Vectors \mathbf{E}^{inc} and \mathbf{H}^{inc} represent the components of an incident electromagnetic wave and \mathbf{n} denotes the unitary outward normal. Eq. (1) can be further rewritten under the following form:

$$i\omega G_0 \mathbf{W} + G_x \partial_x \mathbf{W} + G_y \partial_y \mathbf{W} + G_z \partial_z \mathbf{W} = 0. \quad (2)$$

Let Ω_h denote a discretization of the domain Ω into a union of conforming tetrahedral elements $\bar{\Omega}_h = \bigcup_{K \in \mathcal{T}_h} K$. We look

for the approximate solution $\mathbf{W}_h = (\mathbf{E}_h, \mathbf{H}_h)^t$ of (2) in $V_h \times V_h$ where the functional space V_h is defined by $V_h = \{\mathbf{U} \in [L^2(\Omega)]^3 / \forall K \in \mathcal{T}_h, \mathbf{U}|_K \in \mathbb{P}_p(K)\}$ where $\mathbb{P}_p(K)$ denotes a space of vectors with polynomial components of degree at most p over the element K . The discontinuous Galerkin discretization of system (2) leads to find \mathbf{W}_h in $V_h \times V_h$ such that:

$$\begin{aligned} & \int_{\Omega_h} (i\omega G_0 \mathbf{W}_h)^t \bar{\mathbf{V}} dv \\ & + \sum_{K \in \mathcal{T}_h} \int_K \left(\sum_{l \in \{x,y,z\}} G_l \partial_l (\mathbf{W}_h) \right)^t \bar{\mathbf{V}} dv \\ & + \sum_{F \in \Gamma^m \cup \Gamma^a} \int_F \left(\frac{1}{2} (M_{F,K} - I_{FK} G_{\mathbf{n}_F}) \mathbf{W}_h \right)^t \bar{\mathbf{V}} ds \\ & - \sum_{F \in \Gamma^0} \int_F (G_{\mathbf{n}_F} \llbracket \mathbf{W}_h \rrbracket)^t \{ \bar{\mathbf{V}} \} ds \\ & + \sum_{F \in \Gamma^0} \int_F (S_F \llbracket \mathbf{W}_h \rrbracket)^t \llbracket \bar{\mathbf{V}} \rrbracket ds \\ & = \sum_{F \in \Gamma^a} \int_F \left(\frac{1}{2} (M_{F,K} - I_{FK} G_{\mathbf{n}_F}) \mathbf{W}^{\text{inc}} \right)^t \bar{\mathbf{V}} ds, \end{aligned} \quad (3)$$

$\llbracket \mathbf{V} \rrbracket \in V_h \times V_h$, where Γ^0 , Γ^a and Γ^m respectively denote the set of interior (triangular) faces, the set of faces on Γ_a

and the set of faces on Γ_m . The unitary normal associated to the oriented face F is \mathbf{n}_F and I_{FK} stands for the incidence matrix between oriented faces and elements whose entries are given by 0 if the face F does not belong to element K , 1 if $F \in K$ and their orientations match, -1 if $F \in K$ and their orientations do not match. We also define respectively the jump and the average of a vector \mathbf{V} of $V_h \times V_h$ on a face F shared by two elements K and \tilde{K} : $[\![\mathbf{V}]\!] = I_{FK}\mathbf{V}|_K + I_{F\tilde{K}}\mathbf{V}|_{\tilde{K}}$ and $\{\mathbf{V}\} = \frac{1}{2}(\mathbf{V}|_K + \mathbf{V}|_{\tilde{K}})$. Finally, the matrix S_F , which is hermitian positive, allows to penalize the jump of a field or of some components of this field on the face F and the matrix $M_{F,K}$ is a numerical flux which can be either a centered flux or all the upwind flux (see [1] for more details).

III. NUMERICAL RESULTS

Numerical results are presented here for the solution of the 2D TMz Maxwell equations. We first illustrate the convergence properties of the conforming (i.e. p is the same for all elements $K \in \mathcal{T}_h$) DGFD- \mathbb{P}_p method by considering the propagation of a plane wave ($F=300$ MHz) in vacuum. The computational domain is the unit square $[0,1] \times [0,1]$ discretized by non-uniform triangular meshes. The numerical convergence of the method is visualized on Fig. 1 and convergence orders are summarized in Tab. I. One can note that an optimal convergence order is obtained in the case of an upwind numerical flux function.

Fig. 1. Propagation of a plane wave in vacuum. Numerical convergence of the DGFD- \mathbb{P}_p method: central flux (left) and upwind flux (right).

TABLE I

PROPAGATION OF A PLANE WAVE IN VACUUM. CONVERGENCE ORDERS OF THE DGFD- \mathbb{P}_p METHOD.

Numerical flux	\mathbb{P}_1	\mathbb{P}_2	\mathbb{P}_3	\mathbb{P}_4
Centered	1.1	2.1	2.9	4.0
Upwind	1.9	3.0	3.9	5.0

The second test problem that we consider is the scattering of a plane wave ($F=300$ MHz) by a dielectric cylinder. For that purpose, we make use of a highly non-uniform triangular mesh which consists of 2078 vertices and 3958 triangles. The relative permittivity of the inner cylinder is set to 2.25 while the vacuum is assumed for the rest of the domain. We compare the solutions obtained using a conforming DGFD- \mathbb{P}_p method for $p = 1, 2, 3, 4$ and a non-conforming DGFD- \mathbb{P}_{pK} method and adopting a centered numerical flux function. In the latter case, the approximation order is defined empirically

at the element level based on the triangle area resulting in a distribution for which the number of elements with $p = 1, 2, 3, 4$ is respectively equal to 1495, 2037, 243 and 183. For each method, the algebraic systems resulting from the discretization of the time-harmonic Maxwell equations is solved using an optimized sparse direct solver. In Tab. II we summarize the performances of the methods in terms of accuracy (L_2 error on the E_z component using the existing analytical solution for the considered problem), the CPU time and the memory overhead (for storing the L and U factors). These results clearly show the benefits resulting from a local definition of the approximation order, especially in terms of memory requirements and overall computational efficiency. The present work is currently proceeding towards the design of a p -adaptive solution strategy in the context of the proposed non-conforming DGFD- \mathbb{P}_{pK} method, and its extension to the 3D case.

Abstract—By exploitation of eddy current effects, hidden conductive objects can be detected on principle. A particular challenge is posed by the task of exactly recognizing the position of an object known in shape while hidden by other material with sensor - object distances of several centimeters. This paper will show how positioning parameters of the device under test can be obtained by a sensor array, consisting of commercially available standard-GMRs (giant magnetoresistors), and according algorithms for solving the inverse problem. The array of sensors allows to obtain all measurement data within a single measurement operation.

Index Terms—Identification, ECT, Inverse Problem, GMR

I. INTRODUCTION

Electromagnetic methods enabling the localization of conductive objects hidden by non- or weakly conductive materials are well known and are used for numerous applications (e.g. [1]). However, if the object's position or attitude should be retrieved, sensor arrays offering finer resolutions and appropriate evaluation algorithms need to be applied or developed.

GMRs ([2]) are used for the realization of a cost-efficient sensor array featuring resolutions as high as possible. GMRs are available as ICs and deliver voltages proportional to the magnetic flux density. Apart from small geometric dimensions, GMRs have the advantage to deliver relatively high output voltages. The high sensitivity resulting from this fact clears the way to identify objects in large distances to the sensors.

A copper ring serves as the device under test. Its degrees of freedom and therefore the parameters for the reconstruction algorithms are the azimuthal angle ϑ_{obj} and the y-position y_{obj} (Fig. 1).

The raw measurement data obtained by the GMRs is then fed into algorithms designed for solving inverse problems. The forward problem is simulated using a 3D FEM model.

II. CONFIGURATION OF THE MEASUREMENT SYSTEM

The time harmonic excitation field is produced by two opposed saddle coils. 9 GMRs are positioned on a semi circle shaped circuit board inside the saddle coils. To get a sensor array, three layers of sensors are positioned along the y-axis at a distance of 1 cm from each other (sensor layer 1, 2 and 3). A conductive copper ring with given dimensions but variable

position (ϑ_{obj} and y_{obj}) as well as the excitation coil is shown in Fig. 1.

Fig. 1. Scheme of the present measurement configuration.

III. SOLVING THE INVERSE PROBLEM

In order to retrieve both parameters ϑ_{obj} and y_{obj} describing position and attitude of the device under test from the measurement data, an inverse problem has to be solved. Therefore, it is necessary to simulate the forward problem with different sets of $(\vartheta_{obj}, y_{obj})$. The results obtained then have to be compared to the measurement readings.

Since these 3D calculations are very time-consuming, it stands to reason to approximate the simulation results in an adequate way. Using neural networks, this can be achieved very advantageously [3]. A qualified selection of simulation results is used to initially train the network. This training phase requires data sets consisting of the variable parameters ϑ_{obj} and y_{obj} and the respective simulated measurement values (Fig. 2). With these data sets, of which input and output are hence known, the neural network is built. It can then be used as a solver for the forward problem, once the error compared to simulated data is small enough. This work

Fig. 2. Training Process: the neural network is trained by using simulated FEM solutions $B_{r,t}$, which is the radial component of the magnetic flux density \mathbf{B} .

Fig. 3. Identification Process with the measured data $B_{r,m}$ and the already trained neural network.

uses a feed forward network containing an input and a hidden layer, each comprising five tan-sigmoidal neurons.

An (8/2, 20) evolution strategy [4] is employed for identification (Fig. 3). The objective function of given in (1) was set up in a least square sense, taking the difference between the actual data values ($B_{i,act}$), calculated with the forward problem solver (the neural network), and the measured data values ($B_{i,meas}$).

$$of = \sum_i (B_{i,act} - B_{i,meas})^2 \quad (1)$$

IV. RESULTS

Currently only one layer of GMR is available for measuring purposes. A complete array with three layers of GMRs and the necessary electronics will be available soon and presented in the full paper. Fig. 4 shows a comparison of the measured and simulated data, which shows a very good agreement. In a preliminary step, measurement data is obtained using the FEM package EleFAnT3D [5] with some noise added.

Fig. 4. Comparison of simulated and measured data.

Fig. 5 shows the "simulated measurements" of the GMR located at 90° in each layer for different y -positions of the

reconstructed position	3.2°	0.98 cm

conductive ring. There is a distinguishable difference of the obtained voltages even if the difference of the magnetic flux density is not more than $0.2 \mu T$. Using this data, the position $(\vartheta_{obj}, y_{obj})$ of the conductive ring could be determined very well (see Tab. I).

Fig. 5. Simulation results at different object positions y_{obj} .

V. CONCLUSION AND OUTLOOK

A sensor array using GMRs was used to measure the magnetic field distorted by a hidden conductive ring. These measurements can advantageously be used to detect different parameters of the hidden object.

The first results concerning the reconstruction of two parameters seem to be very promising. Further investigations will focus on the following topics:

- Finding the most suitable objective function.
- Design of the sensor array arrangement.
- Increase in parameters respectively degrees of freedom of the measurement object.
- Taking low conductive material into account.

Abstract—In recent years, particle swarm optimization (PSO) approaches has been successfully implemented to different problem domains with multiple objectives. In this paper, a multi-objective PSO approach, based on concepts of Pareto optimality, dominance, archiving external with elite particles and Cauchy distribution, is proposed and applied in the design with the constraints presence of a brushless DC wheel motor. Promising results in terms of convergence and spacing performance metrics indicate that the proposed multi-objective PSO scheme is capable of producing good solutions.

I. INTRODUCTION

In the last decades, many bio-inspired algorithms have been developed for optimization of electromagnetic devices, such as evolutionary algorithms and swarm intelligence paradigms. These methods have attracted a great deal of attention, because of their high potential for optimization problems in environments, which have been resistant to solution by classical mathematical programming techniques. The design of electromagnetic devices provides many optimization problems involving multiple objectives (multi-objective optimization, MOPs), which should be optimized simultaneously. There is a set of compromise solutions in multi-objective optimization problem and none of the corresponding trade-offs can be said to be better than the others in the absence of preference information.

A considerable number of multi-objective algorithms have been proposed for solving MOPs because they can deal simultaneously with a set of possible solutions in a single run instead of a series of separate runs as in the traditional optimization techniques. In this context, particle swarm optimization (PSO) approaches can be useful in MOPs [1].

PSO is a stochastic optimization technique developed by Eberhart and Kennedy [2] that is inspired by the emergent motion of a flock of birds searching for food. Generally, PSO approaches present reduced memory requirement, computationally effective and is easier to implement when compared to typical evolutionary algorithms. PSO is based on the hypothesis that members of a swarm can profit from their past experiences and the experiences of other particles. During the exploration of the search space, each particle has access to two kinds of information: the best potential solution (*gbest*, global best) that it has encountered and the best potential solution encountered by its vicinity (*pbest*, personal best).

The aim of this paper is to propose an enhanced multi-objective PSO (EMOPSO) approach based on Pareto dominance, archiving external and Cauchy distribution to the design with the constraints presence of a brushless DC wheel motor. We compare our results with those generated by another multi-objective PSO (RNMOPSO) proposed by Raquel and Naval [3]. RNMOPSO incorporates the concept of nearest neighbor density estimator for selecting the global best particle, mutation operator and the constraint-handling technique from the NSGA-II [4]. The EMOPSO proposed in this paper is inspired in [3].

II. FUNDAMENTALS OF EMOPSO

The RNMOPSO algorithm had difficulties in striking a balance between exploration and exploitation. Hence, the global search ability of PSO algorithm is restricted. To address this problem, some improvements proposed in EMOPSO are made on RNMOPSO as described.

The EMOPSO uses a truncated Cauchy distribution to update the social and cognitive factors. EMOPSO does not use the mutation operator. The implementation of EMOPSO is based on following steps:

- i) Initialize a swarm (population), NP , with positions and velocities using a generator of random solutions based on uniform distribution. Set the initial value of counter of iterations (generations), $t = 0$;
- ii) Evaluate the particles and store nondominated ones in an archive A with size A_s . Pareto-dominance concept is used to evaluate the fitness of each particle and thus determine which particles should be selected to store in the archive of non-dominated solutions. The archive absorbs superior current non-dominated solutions and eliminates inferior solutions in the archive through interacting with the generational population in every iteration.
- iii) Compute the crowding distance of each member of A ;
- iv) Sort A in descending crowding distance order;
- v) Randomly select the *gbest* for the swarm from a specified top portion (e.g. top 20%) for the sorted A and store its position in *gbest*.
- vi) Update velocities and positions according to:

$$v_i(t+1) = w \cdot v_i(t) + c_1 \cdot cd \cdot [p_i(t) - x_i(t)] + c_2 \cdot Cd \cdot [p_g(t) - x_i(t)] \quad (1)$$

$$x_i(t+1) = x_i(t) + \Delta t \cdot v_i(t+1) \quad (2)$$

where $\Delta t=1$, w is the inertia weight; $v_i=[v_{i1}, v_{i2}, \dots, v_{in}]^T$ stands for the velocity of the i -th particle, $x_i=[x_{i1}, x_{i2}, \dots, x_{in}]^T$ stands for the position of the i -th particle of population, and $p_i=[p_{i1}, p_{i2}, \dots, p_{in}]^T$ represents the best previous position of the i -th particle. Positive constants c_1 and c_2 are the cognitive and social factors, respectively, which are the acceleration constants responsible for varying the particle velocity towards p_{best} and g_{best} , respectively. Index g represents the index of the best particle among all the particles in the swarm. Variables cd and Cd are two random numbers using truncated Cauchy distribution in range $[0, 1]$.

- vii) Evaluate the particles in swarm;
- viii) Insert all new nondominated solution into A if they are not dominated by any of the stored solutions;
- ix) Update the iteration counter, $t = t + 1$;
- x) Return to Step (iii) until a criterion is met. In this work, a maximum number of iterations, t_{max} , is adopted.

III. RESULTS

The optimization problem is the design of a brushless DC wheel motor for a race solar car [5], which has 10 optimization variables and 6 constraints (see Fig.1). The objective functions are the minimization of the mass (f_1) and the maximization of the efficiency (f_2). In this work, we include a penalty function on f_1 and f_2 to punish unfeasible solutions. The penalty function measures how much the solution has violated the constraints. Due to a weight, only feasible solutions could become a nondominated solution.

Fig. 1. The geometry of the brushless DC wheel motor.

On [5], the authors propose 3 different benchmarks. In this work, we will analyze a problem, which concerns all the variables except the number of poles (fixed to 6). The variables are: the stator diameter (D_s), the induction in the air gap (B_e), the density current on the windings (δ), the average magnetic induction in the teeth (B_d), the magnetic length of the motor (L_m), the average magnetic induction in the stator back iron (B_{cs}), the ratio of the length rotor-stator (R_{rs}), the airgap (e), the DC bus voltage (U_{DC}) and the average magnetic induction in the rotor back iron (B_{cr}).

The great majority of the optimization variables are associated to the magnetic circuit unless U_{DC} , which is linked to the electronic converter. In this problem, the constraints play a very important role and they have a very different nature. There are typical sizing constraints, like the internal

diameter, thermal constraint, magnetic constraints, like the average magnetic induction in the stator back yoke iron and electrical constraints, like the current rise time. The problem is typically a multidisciplinary optimization one.

We adopted the following control parameters for RNMOPSO [3] and EMOPSO for the motor design: population size $NP = 30$, factors $c1=c2=1.0$, size of archive $A_s = 200$, and $t_{max}=200$ iterations.

In comparative studies, the choice of performance metrics is very important. The optimization goal of multiobjective algorithms is (i) to minimize distance between the generated and Pareto front, (ii) to obtain a good distribution and (iii) to obtain a good spread. Thirty independent simulation runs with different initial conditions were performed to evaluate the performance of RNMOPSO and EMOPSO on the brushless DC wheel motor design. Simulation results were presented in Fig. 2 showed and the non-dominated solutions (30 runs) obtained by EMOPSO dominated the solutions obtained by RNMOPSO.

Fig. 2. Pareto set points using RNMOPSO and EMOPSO.

IV. CONCLUSION

In this paper, the RNMOPSO and EMOPSO approaches are compared. Fig. 2 shows the effectiveness of the proposed EMOPSO algorithm, which produces solution sets that are highly competitive in terms of convergence, diversity and distribution with the RNMOPSO.

 pmtrien@chungbuk.ac.kr

Abstract — This paper proposes a novel multimodal optimization method, Coupling particles swarm optimization (PSO), to find all optima in design space. This method based on the conventional Particle Swarm Optimization with modifications. The Coupling method is applied to make a couple from main particle and then each couple of particles searches its own optimum by using *non-stop-moving* PSO. We tested out our method and other one, such as Clustering Particle Swarm Optimization and Niche Particle Swarm Optimization, on three analytic functions. The Coupling Particle Swarm Optimization is also applied to solve a significant benchmark problem, the TEAM workshop benchmark problem 22.

I. INTRODUCTION

In many electromagnetic designs, a stationary design which has small design sensitivities is preferred to an optimum design having big design sensitivities. It is because a design with big design sensitivities, when it is related with mass production process, may have a poor performance due to a manufacturing error. Finding all optima of an objective function, in this viewpoint, is necessary so that a designer may select a good robust design taking account of constraints. In recent years, therefore, there have been many attempts to improve particles swarm optimization (PSO) so that it may find not only a global optimum point but also all optima including local optimum point [1]-[2]. The Clustering PSO and Niche PSO, among them, are popular.

The Clustering PSO has its base on clustering algorithm which classifies particles into different groups and allows each group to move toward not a global best point but a group best point [1]. On the other hand, the Niche PSO basically follows the conventional PSO at the beginning of iterations, and divides the whole particles into several groups and, then, follows the idea of Clustering PSO [1]-[2]. This is known more effective than the Clustering PSO, however, it failed to find all optima, or it requires a huge number of objective function calculations when it is applied to engineering optimization problems [3].

In this paper, a robust and efficient PSO algorithm, Coupling PSO, is developed to locate all optima of a multimodal function with less number of objective function calculations. The proposed algorithm is applied to some analytic functions to test its effectiveness and applied to TEAM problem 22 [4].

II. COUPLING PARTICLES SWARM OPTIMIZATION ALGORITHM

In the conventional PSO, the velocity of i -th particle is updated as follows [1]-[3]:

$$\mathbf{v}_i(t) = \omega \cdot \mathbf{v}_i(t-1) + \alpha_1 \cdot r_1 \cdot (\mathbf{p}_i(t-1) - \mathbf{x}_i(t-1)) + \alpha_2 \cdot r_2 \cdot (\mathbf{g}(t-1) - \mathbf{x}_i(t-1)), \quad i = 1, 2, \dots, N \quad (1)$$

where \mathbf{x}_i , \mathbf{v}_i , \mathbf{p}_i are the position, velocity and personal best position of the i -th particle, respectively, and \mathbf{g} is the global best position, ω is the inertia, α_1 , α_2 are cognitive and social coefficients, and r_1 , r_2 are uniform random number within [0,1], and N is the total number of the particles. When the coefficient α_2 is set to zero, equation (1) is called as *cognition only* model.

The overall flow of the proposed Coupling PSO is summarized as follows:

Step 1. Initial particles

Initially N main particles are randomly generated, and allowed to move according to the *cognition only* model. Each main particle is expected to move toward not a global optimum point but its nearest local optimum point.

Step 2. Coupling

When a main particle updates its personal best position, i.e., when $F(\mathbf{x}_i(t)) < F(\mathbf{p}_i(t-1))$ is satisfied, it forms a i -th couple by generating a new particle near by itself as shown in Fig. 1. The position of the new particle is given randomly as follows:

$$\mathbf{c}_i(t) = \mathbf{x}_i(t) + r_i \cdot (\mathbf{x}_i(t) - \mathbf{p}_i(t-1)) \quad (2)$$

where r is a uniform random number within [0,1].

Step 3. Movement of a couple

The movement of a couple is just like that of a group in the Clustering PSO. The two particles in this i -th couple will move according to the following rule:

$$\mathbf{v}_k(t) = \omega \cdot \mathbf{v}_k(t-1) + \alpha_1 \cdot r_1 \cdot (\mathbf{p}_k(t-1) - \mathbf{x}_k(t-1)) + \alpha_2 \cdot r_2 \cdot (\mathbf{c}_i(t-1) - \mathbf{x}_k(t-1)) + \delta \cdot r_3 \cdot \varepsilon, \quad k = 1, 2. \quad (3)$$

where \mathbf{c}_i is the couple best position of i -th couple and r_3 is a uniform random number within [0,1], and ε is a very small number (for example, 10^{-4} % of the design space). The last term is for *non-stop-moving* and δ becomes 1 only when the condition, $\mathbf{c}_i(t) = \mathbf{p}_k(t) = \mathbf{x}_i(t)$, $k = 1, 2$, is satisfied for 3 consecutive iterations.

Step 4. Elimination of a couple and main particle

When a couple or a main particle is very near to another couple, the couple or the main particle is eliminated as shown in Fig. 2. This process will increase the numerical efficiency of the proposed Coupling PSO.

Step 5. Stopping criterion

Fig. 1. Generation of a new particle.

Fig. 2. Elimination.

The i -th couple will stop its moving when its movement is very small (for example, less than 10^{-4} % of the design space) for 10 consecutive iterations and its couple best position will be an optimum. The algorithm will be terminated when all couples stop without regard to main particles.

III. NUMERICAL RESULTS AND DISCUSSION

A. Analytical Problems

In order to check the validity and numerical efficiency of the proposed Coupling PSO, the following three analytic functions with two design variables are considered:

$$F_1(\mathbf{x}) = (x_1^2 + x_2 - 11) + (x_1 + x_2^2 - 7)^2 - 200, \mathbf{x} \in [-5, 5]^2 \quad (4)$$

$$F_2(\mathbf{x}) = \sum_{i=1}^2 \{x_i^2 - 10 \cos(2\pi x_i) + 10\}, \mathbf{x} \in [-1.3, 1.3]^2 \quad (5)$$

$$F_3(\mathbf{x}) = \frac{1}{4000} \sum_{i=1}^2 x_i^2 - \prod_{i=1}^2 \cos\left(\frac{x_i}{\sqrt{i}}\right) + 1, \mathbf{x} \in [-9.5, 9.5]^2 \quad (6)$$

The three functions are tested 100 times. In each test the number of initial particles is set to 50, and the maximal iteration is limited to 800. The performances of three methods are compared in Table I by their percentages of successful trials

TABLE I
EXPERIMENTS RESULTS

Function	Optima	% of all optima found			Average function calls	
		Clustering	Niche	Proposed	Niche	Proposed
$F_1(\mathbf{x})$	4	100	100	100	40,000	20,546
$F_2(\mathbf{x})$	9	83	100	100	40,000	26,144
$F_3(\mathbf{x})$	17	14	100	100	40,000	38,352

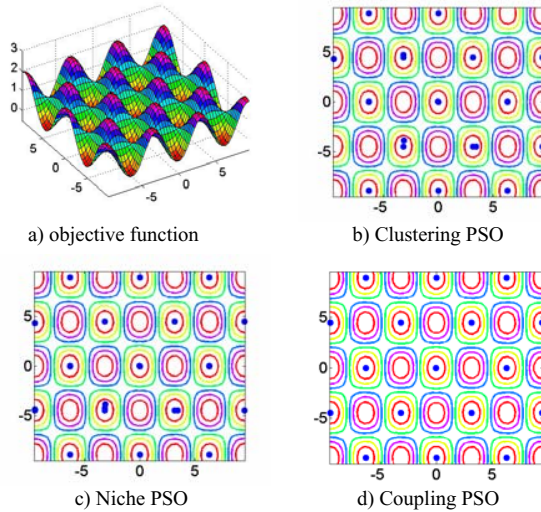

Fig. 3. Positions of particles for function $F_3(\mathbf{x})$ after 800 iterations.

of finding all optima. It is clearly shown that, the Coupling PSO and Niche PSO successfully locate all optima while the Clustering PSO can not, and the Coupling PSO requires less number of function calls than the Niche PSO. It is thought because the Coupling PSO eliminates the couples and main particles which would locate the same local optimum. It is also shown that the number of function calls in the proposed Coupling PSO is proportional to the number of optima found. Fig. 3 shows that the Coupling PSO gives better convergence to optimal points than other PSOs for $F_3(\mathbf{x})$.

B. Optimization in Electromagnetic Device

TEAM problem 22 was chosen to show the application of Coupling PSO in electromagnetic optimization. The aim is to find the maximum stored magnetic energy with minimum stray field B_{stray} . It can be evaluated by (7) with three design variables as shown in Table II:

$$B_{stray}^2 = \frac{1}{22} \sum_{i=1}^{22} B_{stray,i}^2 \quad (7)$$

If the B_{stray} values of these optima are similar, solution with higher stored magnetic energy is preferred. Therefore, in this study, firstly the minima of B_{stray} are located by using Coupling PSO, and then the stored magnetic energy values at these minima are calculated as shown in Table III. Finally, by considering the maximum stored magnetic energy values at these minima of B_{stray} , the minimum 1 is selected as the solution because it has small stray field and high stored magnetic energy.

Abstract—Simulation is ubiquitous in many scientific areas. Applied for dynamic systems usually by employing differential equations, it gives the time evolution of system states. In order to solve such problems, numerical integration algorithms are often required. Automatic Differentiation (AD) is introduced as a powerful technique to compute derivatives of functions given in the form of computer programs in a high level programming language such as FORTRAN, C or C++. Such technique fits perfectly in combination with gradient based optimization algorithms, provided that the derivatives are valued with no truncation or cancellation error. This paper intends to use Automatic Differentiation employed for numerical integration schemes of dynamical systems simulating electromechanical actuators. Then, the resulting derivatives are used for sizing such devices by means of gradient based constrained optimization.

I. INTRODUCTION

Sizing by optimization is nowadays of major interest since it provides a fast and reliable way to achieve, with low manufacturing costs, desired performances for products lacking of optimality usually by means of minimizing a cost function. We are particularly interested by constrained gradient based optimization using Sequential Quadratic Programming (SQP) algorithms [1]. Such algorithms require accurately valued derivatives of the objective function. This may be the origin of serious problems provided that often such functions may result from complex numerical algorithms. We are particularly interested in this paper by those objective functions resulting from numerical integration of Initial Value Problems (IVPs) of Ordinary Differential Equations (ODEs) simulating the motion of an active body actuated by the electromagnetic force in the context of electromechanical actuators.

A good compromise in the optimization context is Automatic Differentiation (AD) that is a term applied for a technique able to compute derivatives of functions described by computer programs. That is, this paper only uses AD for sizing dynamical actuators by means of gradient based constrained optimization. In particular, AD will be applied using ADOL-C tool [2].

II. OPTIMIZATION PROBLEM

This paper considers the particular optimal problem of an IVP formulated as in (1) to (5):

$$\text{minimize } J(x_f, P) \quad (1)$$

$$\dot{x} = f(x, u(x, P)) \quad (2)$$

$$\dot{x} = f(x, u(x, t, P)) \quad (3)$$

$$x(0) = x_0 \quad (4)$$

$$x_i(t_f) = \tilde{x}_f, \quad \tilde{x}_f \in P \quad (5)$$

where $x \in \mathbb{R}^n$ denotes the state with its associated initial values x_0 . In the paper, two formulations of the state system are intentionally specified. The formulation in (2) represents an autonomous system, meaning that the time variable does not appear in the differential equation, while the formulation in (3) refers to a non-autonomous system. $P \in \mathbb{R}^p$ is the constraint design parameters set and u denotes the control. The objective function J depends on the reached final states and parameters. Equality (5) represents the simulation end criterion in Fig. 1, meaning that the simulation stops when a state x_i reaches a prescribed final state, $\tilde{x}_f \in \mathbb{R}$. This implies the existence of the final time or response time, t_f , depending implicitly on parameters. Note that \tilde{x}_f makes part of design parameters.

Fig. 1. Integration end criterion

The gradient based optimization algorithms applied for the optimization problem in (1) require the gradients of the objective function. These are evaluated like in (6) provided that the final states depend also on parameters:

$$\nabla J = \left[\frac{\partial J}{\partial x_f} \right] \left[\frac{\partial x_f}{\partial P} \right] + \left[\frac{\partial J}{\partial P} \right] \quad (6)$$

Also, one may calculate the partial derivatives of the response time with respect to parameters set. So, the response time is carried out in optimization as a constrained parameter in addition to formulation in (1).

III. AUTOMATIC DIFFERENTIATION

Automatic Differentiation is introduced as a powerful technique that computes error-free derivatives, up to machine precision, of functions described as computer programs in high-level languages such FORTRAN or C/C++. In [5] a rich list of tools implementing AD is provided. Therefore, an AD

tool could be a library that instruments a user program in order to be differentiated. Such tools require minor modifications on the initial source and they are implemented in packages like ADOL-C that is subject to this paper. In general they are using the operator overloading capabilities of certain programming languages such C++ and FORTRAN95. In order to value the partial derivatives in (1) one may employ ADOL-C over a numerical scheme integrating the ODE system in (2) or (3). The paper is then subject to two numerical integration strategies. First, it applies AD over an adaptive step size Runge-Kutta (RK) scheme as in (7):

$$x_{t_{i+1}}(P) = x_{t_i}(P) + h(P) \cdot \dot{x} \quad (7)$$

where \dot{x} denotes a slope estimation and h is the integration step which depends on design parameters for an adaptive step size scheme.

Recent studies [4] were carried out for differentiating such schemes. The difference in [4] is that the response time is prescribed in advance at a fixed value. Our approach intends to make use of it as a constrained design parameter carried out further in optimization, so, its corresponding derivatives are to be valued as explained before.

Secondly, truncated Taylor Series (TS), as in [5] are applied to advance the solution of the ODE system in (2) or (3) over a time interval as in (8):

$$x_{t_{i+1}}(P) = x_{t_i} + \frac{x_1}{1!} \cdot h + \frac{x_2}{2!} \cdot h^2 + \dots + \frac{x_n}{n!} \cdot h^n \quad (8)$$

where $x_i = (d^i x)/(dt^i)$ denotes the i^{th} order Taylor coefficient. Paper [5] provides numerical solutions for adaptive step size schemes for ODE solvers using Taylor expansion. Interesting here is that AD is used for solving the dynamic system, provided that ADOL-C is capable to value high-order Taylor coefficients of the autonomous system in (2) supposing that f is sufficiently smooth. In the non-autonomous case like in (3) a special version of the ADOL-C routine responsible for Taylor coefficients valuation is applied. The differentiation of such integration schemes is made by using special drivers implemented in ADOL-C.

The differentiation of a RK integration scheme in (7) tends to be slower since the slope usually is represented by a complex algorithm in the case of schemes up to second degree. Contrary, the differentiation of (8) is faster since it represents a sum expansion. However, here a cost of high-order derivatives computation should be paid up to second degree. In the full paper comparisons will be carried out for both schemes in terms of efficiency as also as helpful aspects regarding the AD of such numerical integration algorithms.

IV. OPTIMIZATION GOAL

The benchmark in [6] of the electromechanical actuator modeling a circuit breaker in Fig. 2 is proposed for sizing by gradient constrained optimization. When the switch is turned off, the vacuum force produced by the magnet equilibrate the spring force. The simulation starts when the switch turns on. The electromagnetic force created by the coil cancels

partially the magnet force. Consequently, the plunger will move, starting from initial position, z_0 , toward the upper bound, z_{max} .

Fig. 2. Electromechanical actuator

The dynamical system of the proposed device combines both the equations of the electrical circuit feeding the coil and the movement equations. The states are:

$$\dot{x} = \begin{pmatrix} i & di/dt & z & v \end{pmatrix} \quad (9)$$

The response time is found from the end criterion in (5), that is satisfied when the mobile plunger is bounded at z_{max} .

A multi objective optimization problem raises from this particular case. These objectives are given in table I.

TABLE I
OPTIMIZATION SPECIFICATIONS

Variable	Constraint	Formula
Percussion energy at z_{max}	[0.12, 10] J	$m \cdot v^2/2$
Response time	[0, 3.5] ms	-
Total force at z_{max}	15 N	-
Shock resistance at z_0	[2000 - 10000] m/s ⁻²	$\frac{F_{sp} - F_{mag}}{m}$
Total mass	minimize	-

The design parameters in (2) are represented by all geometrical parameters of the studied benchmark. The optimization results will be presented in the full paper.

V. CONCLUSION

This paper presents a particular optimization problem on a benchmark dealing with state variables in Ordinary Differential Equations. Runge-Kutta and Taylor expansion integration schemes are used to approximate these states. Both schemes are differentiated by employing Automatic Differentiation in order to value the gradients needed by SQP algorithms.

Abstract—We examine the influence of randomized variations of the sensor direction on the condition of the linear inverse problem in magnetostatics. Setups with varied sensor directions are compared with setups using perfectly in parallel oriented sensors. As evaluation criterion for the condition of the linear inverse problem, the condition number of the leadfield matrix is used. The results indicate that for mono-axial planar sensor setups the condition of the linear inverse problem can be considerably improved, when the sensors are oriented non-uniformly.

I. INTRODUCTION

In geoprosection, magnetic field distributions are measured by moving a SQUID based sensor system over a field of interest [1]. Since the movement of the sensor system is performed by a vehicle and the underground is typically very rough, the orientation of the sensors in the measurement system is altered while moving. This results in slightly different sensor orientations for each measurement position. When analyzing such measured magnetic field distributions with varying sensor orientations it turned out, that the reconstruction was more robust than in some of our simulation runs with perfectly aligned parallel sensor directions. Consequently, the aim of this paper is to analyze the influence of random variations in sensor orientation on the solution robustness of the magnetostatic linear inverse problem. With simulations we evaluate, if the experimentally observed effect holds also on simple generic sensor setups.

II. METHODS

A. Inverse Model

In our study we consider the linearized inverse problem of estimating the activity vector \vec{p} on basis of the measurement vector \vec{m} corresponding to $\vec{m} = L \cdot \vec{p} + \vec{n}$, whereas \vec{n} represents noise and L the leadfield matrix. The leadfield matrix incorporates all relevant information on the sensor setup, source space grid, and the forward model. The source space is formed by regular grids given in Tab. I (positions are given in m). At each grid position, three orthogonal magnetostatic dipoles are located to facilitate arbitrary source directions. Parameters for the sensor setups are shown in Tab. II. Setup B represents a three-axial setup with three orthogonal magnetometers at each sensor position. Default configurations used in this study are represented by the combinations A1, A2, B1, B2, and C3.

TABLE I
PARAMETERS OF THE REGULAR SOURCE SPACE GRIDS.

	X,Y-Directions			Z-Direction			Number of Sources
	Grid	Min(pos)	Max(pos)	#Rows	Min(pos)	Max(pos)	
1	-0.01	0.21	10	-0.11	-0.11	1	100
2	-0.01	0.21	15	-0.11	-0.11	1	225
3	-0.005	0.205	8	-0.15	-0.20	2	128

TABLE II
PARAMETERS FOR THE SIMULATED PLANAR SETUPS IN THE Z=0 PLANE.

Setup	X,Y-Directions		Sensor Directions	Number of Sensors
	Min(pos)	Max(pos)		
A	0	0.2	-Z	144
B	0	0.2	+X, +Y, -Z	3 × 144 = 432
C	0	0.2	-Z	441

These default configurations were each changed with random variations as follows.

B. Random Variations

Sensor directions were changed by Δdir using Gaussian distributed random numbers with standard deviations $SD(\Delta\text{dir})$ between 0.5° and 25° . For setup B, the orthogonality between the three sensors was preserved. To examine the influence of random variations on the sensor directions, 100 repeated runs for each of the configurations A1 - C3 were conducted. In Fig. 1, A1 with randomly varied sensor directions is shown.

Fig. 1. Example configuration A1 with source positions of grid 1 (○) and sensor positions of setup A (●). The sensors are randomly oriented around the -Z direction with $SD(\Delta\text{dir}) = 10^\circ$.

	5°	6.35e+06	1.557e+06	0.0403	0.009883
	10°	5.01e+06	1.17e+06	0.0318	0.007425
B1	0.5°	3.56e+10	2549	1	7.167e-08
	5°	3.56e+10	2999	1	8.434e-08
	10°	3.56e+10	3234	1	9.094e-08
B2	0.5°	5.52e+13	9.646e+09	1	0.0001748
	5°	5.52e+13	1.049e+10	1	0.0001814
	10°	5.52e+13	1.049e+10	1	0.0001902
C3	0.5°	3.28e+17	2.628e+16	0.845	0.06768
	5°	2.93e+17	1.748e+16	0.754	0.04502
	10°	2.88e+17	2.306e+16	0.742	0.05938

C. Criterion for Comparing Sensor Arrays

To evaluate the condition of the linear inverse problem, we use the condition number (CN) of the related leadfield matrix L (see also [2], [3]). Relative changes to the CN when random sensor variations are applied are denoted by $\Delta\text{CN}(L_i) = \text{CN}(L_i)/\text{CN}(L^0)$, where $\text{CN}(L^0)$ is the CN for the leadfield matrix of the default configuration given in section II-A, and $\text{CN}(L_i)$ is the CN for the i -th of 100 leadfield matrices created from the configuration described by L^0 but using randomly varied sensor directions. Mean value and standard deviation (SD) for $\Delta\text{CN}(L_i)$ and $\text{CN}(L_i)$ are computed for $1 \leq i \leq 100$.

III. RESULTS

As indicated in Fig. 2, the CN of leadfield matrices representing mono-axial setups (A,C) can be significantly reduced by small random variations of the sensor directions compared to a perfectly to -Z directed sensor array (Tab. III). Larger variations of the directions lead to higher reductions of the CN (Fig. 3 and Tab. IV). The decay of the average CN is reduced for larger values of Δ dir. The improvements of the CN by variations of the sensor directions of the 12×12 setup A are higher compared to the denser 21×21 sensor setup C. As expected, the CN of leadfield matrices for the three-axial setup B are not influenced by variations of the sensor directions. In the tested two examples, the CN of the mono-axial sensor array A is superior to the three-axial array B, whereas both are using identical sensor positions and source grids.

Fig. 2. Effect of 100 random variations of the sensor directions on the CN for configuration A1 using SD(Δ dir) of 0.5° (dashed line in the middle) and 10° (bold line at the bottom). The mean values are indicated by the thin lines, the default CN by the dash-dotted line on the top.

Fig. 3. Average CN (o) for configuration A1 using randomly varied sensor directions with SD(Δ dir) between 0.5° and 25°. The value for Δ dir = 0° represents the default CN for A1.

IV. CONCLUSION

Small variations in the sensor directions compared to sensors that are perfectly oriented to -Z lead for mono-axial setups to clearly smaller CN and consequently to an improved condition of the inverse problem. Therefore, mono-axial sensors should be directed non-uniformly in sensor arrays to support more robust source reconstructions. In future work we will evaluate the influence of random variations of sensor and source positions. Besides the CN, further evaluation criteria will be used.

The Application of Topological Gradients to Defect Identification in Magnetic Flux Leakage-type NDT

Min Li, and David A. Lowther
 McGill University
 3480 University Street, Montreal, H3A 2A7, Canada
 David.lowther@mcgill.ca

Abstract — An inverse problem is formulated to identify the shape and size of the defects in a nonlinear ferromagnetic material using the signal profile from magnetic flux leakage-type NDT. This paper presents an efficient algorithm based on topological shape optimization which exploits the topological gradient to accelerate the process of shape optimization to identify the defect.

I. INTRODUCTION

The magnetic flux leakage (MFL) method is a fast and reliable nondestructive testing (NDT) technique that has been widely used for decades. When a piece of ferromagnetic material is placed in a magnetic field and is magnetized to saturation, small defects or flaws in the material cause a significant flux anomaly due to the permeability variation. The anomalous fields are captured by Hall-effect probes or sensing coils, placed closely above the surface of the test object, which generate signals that can be used to identify the defect.

A key problem in the design and analysis of a MFL sensing system is the ability to determine the shape, size and location of the defect rapidly and precisely in the presence of a large number of uncertainties, expressed as noise in the signal. The use of finite element method (FEM) based simulation of MFL began in the late 1980's [1], [2].

In this paper, an inverse algorithm for defect identification in the MFL-type NDT is presented. The novel approach employs topological sensitivity analysis to first explore the search space and then to predict an appropriate initial structure for the use of efficient shape optimization. The robustness of the solution in the presence of noise will also be investigated, and this may provide useful information for improved sensor design and computer-enhanced signal processing.

Fig. 1. A design domain with a small hole

II. TOPOLOGICAL GRADIENT BASED TOPOLOGY AND SHAPE OPTIMIZATION

Although shape optimization is being extensively studied in electromagnetic design, it suffers from the limitation that the overall change in a device is usually relatively small and

no topological change is allowed. However, the topological gradient (TG) provides the sensitivity information of a design with respect to topological changes, such as the insertion of a small air hole at any point inside the solid material. Topological sensitivity analysis, which originated from the classical shape gradient information, is derived using a topological asymptotic expansion for PDE systems. Fig.1 illustrates a design domain Ω defined on \mathbb{R}^n ($n=2$ or 3), with boundary Γ . Consider a small hole $B(x, r)$ in Ω , where x is the center and r is the radius of the hole. The topological gradient $G(x)$ is given as :

$$G(x) = \lim_{r \rightarrow 0} \frac{\Psi_{obj}(\Omega \setminus B(x, r)) - \Psi_{obj}(\Omega)}{\delta(\Omega)}. \quad (1)$$

where Ψ is an objective function defined on Ω , $\Omega \setminus B(x, r)$ is the domain excluding the small hole B , and $\delta(\Omega)$ is the volume of B with a negative sign.

Assuming a perturbation of the boundary of the small hole $B(x, r)$, the shape sensitivity of a scalar function $J = \Psi(\Omega \setminus B(x, r))$ can be expressed in terms of the state variable A and adjoint variable λ from the field solution [3]

$$J'(r) = \int_{\Gamma_r} L(A_1, \lambda_2) d\gamma. \quad (2)$$

$$L(A_1, \lambda_2) = (v_1 - v_2)(\nabla \times A_1)(\nabla \times \lambda_2)$$

After some manipulation [4], J' is approximated as:

Fig. 1. A design domain with a small hole

$$J'(r) = -4\pi r L(A_1, \lambda_2) + o(r). \quad (3)$$

Hence, we obtain

$$\begin{aligned} \Psi_{obj}(\Omega \setminus B(x, r)) - \Psi_{obj}(\Omega) &= J(r) - J(0) \\ &= \int_0^r J'(\rho) d\rho = -2\pi r^2 L(A_1, \lambda_2) + o(r^2) \end{aligned} \quad (4)$$

Combining (4) and (1), $G(x)$ is given, in 2D, as:

$$G(x) = 2L(A_1, \lambda_2). \quad (5)$$

(1) can be re-written using a local expansion as:

$$\Psi_{obj}(\Omega \setminus B(x, r)) - \Psi_{obj}(\Omega) = \delta(\Omega)G(x) + o(\delta(\Omega)). \quad (6)$$

In order to minimize the objective function Ψ , i.e. $\Psi(\Omega \setminus B(x, r)) - \Psi(\Omega) < 0$, a hole should be created in the region where $G(x)$ is greater than zero. Thus the following optimality conditions must be satisfied [4]

$$\begin{aligned} G(x) &= 0 & \text{on } \Gamma \\ G(x) &\leq 0 & \text{in } \Omega \end{aligned} \quad (7)$$

III. NUMERICAL EXAMPLE

A. FEM modeling of MFL

A permanent magnet MFL model and a test plate 6mm thick is created using MagNet [5]. The back yoke and the iron arm are made of linear material and test plate is made of cold rolled steel with a nonlinear permeability. A sensing array is placed 4.5 mm above the testing plate. For simplicity, the magnetic fields are solved with 2D finite-element analysis.

Fig. 2. Magnetic flux plot for model with and /without defect

The upper plot in Fig. 2 shows the magnetic field without the defect, while the lower one shows the effect of a defect, on the far side of the test plate, on the field.

B. Calculation of Topological gradient

In order to identify the size and the shape of the defects in the material, an objective function F is formulated from the field signals B_{io} captured by MFL sensors (obtained from the simulation model with the defect in Fig. 2) and the field values B_i computed from the FEM solution of a model where the shape of the plate is allowed to change at each iteration as the system tries to create the defect shape to minimize F .

$$F = \sum_{i=1}^n (B_i - B_{io})^2 \quad (8)$$

Based on the asymptotic expansion of (6) and the optimality condition (7), we would expect that the defects lie in the regions where the topological gradient has the largest positive value.

The domain of interest is defined as a region from $x = -15$ to 15 in the center of the plate. It is then divided to 6X40 small blocks, and the topological gradient is evaluated at the center of each block.

Fig. 3. Topological gradient plot for one defect model

Fig. 3 presents the topological gradient plot for the model with one defect of 5 mm wide and centers at $x = 0$; Fig. 4

illustrates the topological gradient of a model with two defects of 4 mm wide and center at $x = -12$ and $x = 12$ respectively. As can be seen from the above figures, the regions of the highest values of topological gradient coincide with the position of the defects.

Fig. 4. Topological gradient plot for two defects model

C. Determination of defect size and shape

In order to test the topology prediction, a defect is created on the near side of the steel of 5 mm wide and 80% of the thickness in depth. The topological gradient is computed over the domain of interest. From this, about 5% of the area is removed from the domain. Next, the boundary of this hole is modified through a shape optimizer using continuum design sensitivity analysis [3].

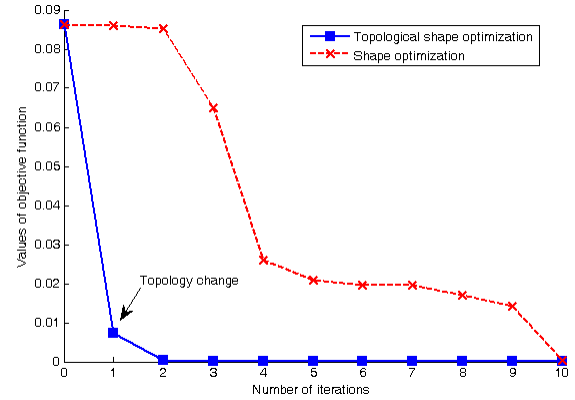

Fig. 5. Objective function values through the optimization

The values of objective function F during the shape optimization are shown in Fig. 5. The initial value of the objective is 0.0865. The topological change reduces it to 10% of this value. The remaining improvement is then obtained through shape optimization. Fig. 5 also shows the convergence of the process if only shape optimization is used.

IV. CONCLUSION

The topological gradient provides information which can be used to reduce the objective function value. It provides a fast, but approximate, exploration of the solution space. Shape optimization can then refine the solution. The full paper will provide results for buried defects in 2-D and 3-D.

Grid-enabled Tabu Search for Electromagnetic Optimization Problems

S. Carcangiu, A. Fanni, A. Mereu, and A. Montisci

Department of Electrical and Electronic Engineering, University of Cagliari

Piazza d'Armi, 09123, Cagliari, Italy

{s.carcangiu; fanni; anna.mereu; augusto.montisci}@diee.unica.it

Abstract—The use of Grid computing to solve electromagnetic optimization problems using the Tabu Search algorithm is proposed in this paper. In order to significantly reduce the prohibitive computational cost of the numerical analyses required by the majority of iterative algorithms, two different grid-enabled Tabu Search strategies have been ported in the grid. Both strategies belong to the Domain Decomposition family: the decomposition of the search space and the decomposition of the neighborhood. The performances of the different parallel implementations have been evaluated on some electromagnetic benchmarks.

I. INTRODUCTION

In the design of electromagnetic structures, it is often necessary to analyze the electromagnetic field distribution using numerical techniques such as the Finite Element Method (FEM). In order to optimize the design, it is usual to apply iterative techniques to search the potentially optimal configuration in the solutions domain. Moreover, when the number of design parameters to be optimized is considerable, the number of electromagnetic problems to be solved could be of the order of thousands. Since numerical electromagnetic solutions are often computationally intensive, the use of numerical solutions during the iterative optimization process can be unfeasible. One way to overcome this problem is to use approximating techniques, such as neural networks [1]. The main drawback of using approximating models is represented by the approximation errors, which can alter the value of the solution corresponding to the same design parameters.

Another way to avoid the prohibitive computational time of iterative optimization is to use the new Grid Computing technology. Grid computing is a family of technologies for dynamically and opportunistically provisioning computing power from a pool of resources. The Grid is a type of parallel and distributed system that enables the sharing, selection, and aggregation of geographically distributed “autonomous” resources dynamically at runtime depending on their availability, capability, performance, cost and user's quality-of-service requirements [2].

In this paper, a Tabu Search (TS) is proposed as search strategy, and its parallel implementation on a computational grid is presented. TS is a family of meta heuristic procedures, which perform the search for the optimal solution exploring the variable space and storing the features that correspond to bad previous moves. Such features are labeled as tabu and they are avoided during the search for the optimum [3].

In literature, different approaches have been adopted to implement a parallelization of the TS. In [4], a hierarchical

classification of the parallel TS strategies is presented. Two main types of parallelization can be performed: the first is the so-called *Multiple* TS task category, in which multiple TS algorithm are run in parallel that may differ for different parameters such as the initial solution and the tabu list size; the second class is the so-called *Domain Decomposition*. In this work, we will compare the performances of two parallel TS strategies belonging both to the Domain Decomposition family: the decomposition of the search space and the decomposition of the neighborhood. The decomposition of the search space implies that the domain space is decomposed in a number of smaller domains. Each sub-domain has to be solved by separate TS. The decomposition of the neighborhood is performed by assigning to each task a different portion of the neighborhood to evaluate. In this work the performances of the two types of Domain Decomposition strategies will be compared.

II. GRID-ENABLED TABU SEARCH ALGORITHMS

The computing infrastructure we used is based on several computation centers localized in the main research institutions and academies in Sardinia, Italy, and it consists of more than 100 nodes 1U System x3455 (200 CPU AMD Opteron 2218, 400 CPU core). The fiber optics connections allow to dynamically aggregate the distributed resources and to reach a pick aggregated computation power of some TeraFlops.

The optimization problem under investigation consists of finding a set of design parameters that allows the device to produce the desired effect depending on the value of the electric or magnetic field in prefixed points, under feasibility constraints.

In order to formalize the problem, the range of each design variable is subdivided into a finite number of sub-ranges uniformly distributed. A symbol of a discrete alphabet is associated to each sub-range, so that every configuration in the continuous can be identified with an ordered sequence of symbols. According to this choice, the search for the optimal solution is performed by the TS moving from one discrete solution to another by simply modifying the value of one variable at a time. At each iteration, the neighborhood associated to the current configuration is built performing all the possible moves that can be played starting from that configuration.

The simple iterative scheme of the TS is enhanced introducing several rule-of-thumb criteria such as intensification (deeply exploration of a region looking

promising), or diversification (leave a region that does not look promising).

A. Parallel strategy

The idea for a straightforward parallelization scheme is to decompose the search space into a set of disjoint subspaces, each of them explored by an instance of TS on a different CPU. When each process finishes, it writes in a secondary memory the obtained results. Once all the processes finish, a new process reads all the secondary memory files and gathers the results to obtain the optimal solution. The resulting parallel algorithm is simple, because inter-process communication is not necessary, and only a synchronization point is needed.

B. Master-Slave strategy

The previously described parallelization schema does not fully exploit the peculiarity of the TS meta-heuristics to make use of the past history of the search to enhance the solutions domain. An alternative use of the Grid-Computing paradigm is made in this paper, by decomposing the neighborhood. In fact, the most important requirement in using a TS algorithm consists of defining the set of admissible moves, i.e., in defining the neighborhood set of a given configuration. As previously mentioned, our TS implements Cartesian moves, which consists of changing the value of one design parameter at a time. The exploration of a single variable can be carried out by independent jobs, which means that, for each configuration in the neighborhood, a FEM analysis has to be performed in order to evaluate the fitness of that solution. It is important to notice that in the Grid the execution of cyclic jobs is not allowed. This leads us to design the core of our algorithm to run locally in the user interface and to run the parallel exploration of the neighborhood in the Grid. This has been possible by splitting the program in a master-slave architecture. To each slave, a different variable to explore is assigned, and it runs different FEM analyses. When the jobs are done, the master program analyzes the entries written by the slaves and performs the optimal current move.

III. RESULTS

The T.E.A.M Problem 25 “Optimization of Die Press Model” [5] is used here to compare the performance of the two grid-enabled TS codes. The four design parameters of the die mold have to be set up so that the magnetic flux density is radial and equal to 0.35 T in the cavity where the magnetic powder is inserted. The computation of the magnetic field is done using a magneto-static nonlinear FEM. The bi-dimensional model was created in FreeFem++ open source finite element code [6].

The performances of the Grid-enabled TS with the *Master-Slave* strategy are reported in Table I in terms of the speedup and the efficiency parameters usually used to evaluate the performance of parallel algorithms [7]. As the Grid we used is composed by a number of identical CPUs, we can extend the concept of speed up and efficiency, used in parallel systems, in the grid environment. The speedup is the ratio of the

TABLE I
PERFORMANCE OF THE GRID-ENABLED TS VERSUS SEQUENTIAL TS

p	T_p [s]	S_p	E_p
1	1550	1	-
4	773	2	50%
8	593	2.6	32%
16	503	3.1	19%
20	485	3.2	16%
32	458	3.4	10%
40	449	3.5	9%
80	431	3.6	4%

execution time of the algorithm when executed on one processor to that when executed on p processors: $S_p = T_1/T_p$, whereas the efficiency is the ratio of the actual speedup versus the theoretical maximum speedup equal to p. Here T_1 and T_p are the total times required to run one iteration of TS on a single CPU, and on p CPUs respectively. The maximum efficiency is obtained when the speedup is the closest to the theoretical speedup. Note that the algorithm in Grid environment has speedup limits and appears to saturate due mainly to communication overhead, and to some uncertain factors as instability of computing nodes, dynamic change of Grid environment, total load on the Grid, and so on.

IV. CONCLUSIONS

In the full paper, two Grid-enabled TS codes will be tested on standard electromagnetic test problems. The performed experiments showed that the porting of the algorithm on a computational Grid greatly reduces the computation cost, even if a degree of overhead is introduced. This is mostly due to the communication delay between the computing elements. The overhead can be neglected if the parallelized jobs have a high computational load, as it is the case of FEM analyses.

ACKNOWLEDGMENT

This work makes use of results produced by the Cybersar Project managed by the Consorzio COSMOLAB, a project co-funded by the Italian Ministry of University and Research within the PON 2000-2006. More information is available at <http://www.cybersar.it>.

Abstract—The purpose of this paper is to show a new methodology for solving inverse problems of design. It is based on the use of a deterministic global optimization algorithm. In front of limitations induced by the use of analytical models, the authors present a way to associate Interval Branch and Bounds techniques and numerical computations based on finite element method. Thank to this methodology, we are able to solve exactly the associated inverse problem of a magnetic coupling design.

I. INTRODUCTION

Magnetic couplings are very useful devices for many applications as seal-less pumps in the chemical and petrochemical industries, or the aeronautical and maritime ones for instance. Their functionalities are to transmit a motion between two separated zones without mechanical contacts. The studied structure is a co-axial synchronous magnetic torque coupling. It consists of two rings of permanent magnets separated by an insulating partition. On each side of it, we find an airgap and a binding band.

A. Previous Methodology

In [1], the authors solve the problem of such devices design by applying a rational methodology. The problem is understood and defined as an *inverse problem*, i.e. from some characteristic values given by the schedule of conditions (for example the torque), get the dimensions as well as the structure and the composition of a co-axial magnetic torque coupling. These inverse problems are formulated as a *mixed constrained global optimization problem*.

In order to solve exactly the so-formulated global optimization problems, a particular algorithm (called IBBA) based on a Branch and Bound technique where the bounds are computed using interval analysis has been developed and extended. See [1], [2] and [3] for details.

The advantages of these kinds of methods are :

- they use mixed variables (real, integer, boolean, ...);
- they do not need a starting point (or a set of ones);
- they guarantee to obtain the global minimum of the problem (they are *deterministic* and *global*).

Their main drawbacks are their computation times and the fact that they need (until nowadays) explicit analytic expressions of criteria and constraints.

The inverse problem of couplings design problem is formulated as a mixed constrained global optimization problem defined as follow :

$$\begin{cases} \min_{\substack{x \in \mathbb{R}^{n_r}, z \in \mathbb{N}^{n_e}, \\ b \in B^{n_b}, \sigma \in \prod_{i=1}^{n_c} K_i}} f(x, z, \sigma, b) \\ g_i(x, z, \sigma, b) \leq 0 \quad \forall i \in \{1, \dots, n_g\} \\ \Gamma(x, z, \sigma, b) = \Gamma_{fixed} \end{cases} \quad (1)$$

where f is a real function (for example the volume), K_i represents an enumerated set of categorical variables (for instance, the kind of magnet), and $B = \{0, 1\}$ is the boolean set (for the fact that there are binding bands or not). g_i are some geometrical constraints. Moreover, an equality constraint upon the maximum electromagnetic torque Γ is added, traducing the fact that it must be equal to a fixed value (Γ_{fixed}).

The torque expression comes from an analytical model based on the resolution of Poisson's equations using the separation of variables by keeping only the term due to the first non-zero harmonic (the fundamental) [1].

Several techniques of constraints propagation, and others adaptations were applied in order to reduce the time convergence. Indeed, it was very difficult to compute efficient bounds with interval arithmetic, because of the complexity of our torque formula. Thanks to these techniques, the authors obtained encouraging results dealing with the minimization of the global volume or with the volume of magnets. In our knowledge, it was the first time that such a problem was solved.

B. Need of a More Accurate Model

If a finite element software is used to compute the electromagnetic torque and the mean value of flux density in yokes (the physical constraints of our problem), we notice a non-negligible difference between the values given by our model and the numerical ones (around 20%). However, the kind of

analytical models used is known to provide results closed to those obtained by a numerical method [4]. Actually, the observed gap is due to the fact that we do not have considered the harmonics greater than the fundamental, and moreover the optimization process is inclined to maximize the error due to these assumptions.

II. NEW APPROACH : USE A HYBRID MODEL

The idea is to associate the advantages of two kind of models : the swiftness of analytics and the accuracy of finite elements based techniques.

The analytic expression of the electromagnetic torque is given by the resolution of Poisson's equations using the separation of variables. Instead of taking into account only the fundamental (Γ_{o1}) as in [1], the used expression (Γ_{o3}) is the sum of the two first non-zero harmonics (1 and 3). The thickness of iron yokes are deduced from the Gauss's law of magnetism and the fact that the mean value of flux density in the yokes B_y must be less or equal to the maximum value $B_M(\sigma_y)$ above which the iron is definitively saturated.

A specially dedicated finite element code has been written in order to automatically draw the geometry, create the mesh, and perform a magneto-static resolution of a magnetic coupling. In output, the torque Γ_{FE} (computed with the Maxwell Stress Tensor) and the mean values of flux density in the inner and outer yokes (B_{yi}^{FE} and B_{yo}^{FE}) are given in less than 1 second. This tool is in the form of a black-box (named NUMTFD) which can be easily called by another program.

III. FORMALIZATION OF THE NEW DESIGN PROBLEM

Now the question is to know how to associate such a model with an Interval Branch and Bound Algorithm.

A. Inverse Problem Formulation

The design problem must be re-formulated. In fact it is not possible to directly include our black-box as a constraint. Indeed, when the optimization process begins, the lengths of the intervals are too large to perform a valid finite element computation [3].

The idea is to defined several zones corresponding to different expressions. If we are far to the wanted value (Γ_{fixed}), we use Γ_{o1} . If we get close, but not close enough to call Γ_{FE} , Γ_{o3} is used. The associate problem is then :

$$\left\{ \begin{array}{l} \min_{\substack{x \in \mathbb{R}^{n_x}, z \in \mathbb{N}^{n_z}, \\ b \in B^b, \sigma \in \prod_{i=1}^{n_c} K_i}} f(x, z, \sigma, b) \\ g_j(x, z, \sigma, b) \leq 0 \quad \forall j \in \{1, \dots, n_g\} \\ \left\{ \begin{array}{l} (1 - \lambda_{ana})\Gamma_{fixed} \leq \Gamma_{o1} \leq (1 + \lambda_{ana})\Gamma_{fixed} \\ (1 - \lambda_{FE})\Gamma_{fixed} \leq \Gamma_{o3} \leq (1 + \lambda_{FE})\Gamma_{fixed} \\ \Gamma_{FE}(x, z, \sigma, b) = \Gamma_{fixed} \\ B_{yi}^{FE}(x, z, \sigma, b) \leq B_M(\sigma_{yi}) \\ B_{yo}^{FE}(x, z, \sigma, b) \leq B_M(\sigma_{yo}) \end{array} \right. \end{array} \right.$$

where λ_{ana} and λ_{FE} are used to define the different zones (for the tests, we have chosen 40% and 20%). Two inequality constraints are added to ensure that the yokes are not saturated.

B. New Interval Branch & Bound Algorithm

The corresponding Interval Branch & Bound Algorithm (IBBA+NUMTFD) has been coded. Its principle is to bisect the initial domain into smaller and smaller boxes and then to eliminate the boxes where the global optimum cannot occurs:

- by proving, using interval bounds, that no point in a box can produce a better solution than the current best one;
- by proving, using interval arithmetic, that at least one constraint cannot be satisfied by any point in such a box.

Some techniques of constraint propagation and limitations have been included to improve the convergence.

IV. RESULTS AND CONCLUSION

The problem corresponding to the minimization of the global volume of a studied magnetic coupling is solved and results are given in Table I (strike-through text represents non-satisfied constraints). We have chosen $\Gamma_{fixed} = 10$ N·m, the real parameters represent geometric quantities, the integer p is the number of poles pairs, and the different σ values are used to choose the kinds of materials. To compare with the previous methodology, the problem is solved using only Γ_{o1} (IBBA), next using Γ_{o3} (IBBAo3), and finally using our hybrid model (IBBA+NUMTFD).

TABLE I
MINIMIZATION OF THE MAGNETIC COUPLING'S GLOBAL VOLUME V_g

Param.	Bounds	Unit	IBBA	IBBAo3	IBBA+ NUMTFD
$\theta_{int}; \theta_{ext}$	[30; 70]	%	48.1; 30.0	55.6; 30.0	52.5; 37.5

Abstract—we present two new strategies to sequential optimization method (SOM) for optimization design problems of electromagnetic devices. One is a new space reduction strategy; the other is selection strategy of sequential optimization models. In the implementation, two kinds of radial basis functions (RBF) approximate models are considered for the response surface reconstruction of design objectives and constraints. Then, by two design examples of TEAM benchmark problems, we show that our methods can significantly speed the design process and obviously reduce the computational cost of finite element analysis.

I. INTRODUCTION

Electromagnetic optimization and design problems are often solved by means of two kinds of methods, direct optimization method and optimization based on approximate models. The former is always implemented with finite element model and stochastic optimization algorithms [1]. However, it is computationally expensive. So the latter has been widely considered as an alternative method [2]-[3]. They are proved fast, but not very accurate.

To improve the optimization efficiency, we have present sequential optimization method (SOM) to the electromagnetic design problems [4]-[5]. SOM can optimize the model and algorithm simultaneously. However, SOM was discussed only for response surface model (RSM) and Kriging model in the former study, and the sampling method is unique. In this paper, we will present a system discussion about the space reduction strategy and model selection strategy for SOM, including two kinds of radial basis functions (RBF) models.

II. RBF APPROXIMATE MODELS

RBF model is one of the most widely used approximate models to solve electromagnetic optimization problems. It uses a linear combination of RBF to interpolate sampled data. Given n sample points $\{x_1, x_2, \dots, x_n | x_i \in \mathbb{R}^D\}$ and responses $\{y_1, y_2, \dots, y_n | y_i \in \mathbb{R}\}$, for an input $x \in D \subseteq \mathbb{R}^D$, the response value of RBF model is given by

$$\hat{y}(x) = \sum_{i=1}^n \beta_i \cdot \varphi(\|x - x_i\|), \quad (1)$$

where β_i s are model parameters, $\varphi(r)$ is the RBF. Gauss and multiquadric (MQ) RBF are considered in this work.

RBF model can rapidly and effectively replace the finite element analysis for optimization tasks and conditions. However, it is generally globally supported and poorly conditioned, especially when the number of sampling points increases significantly.

Compactly supported RBF (CSRBF) model is a promising improvement. When CSRBF model is used, the evaluation of (1) will not run over the whole set of points and the coefficient matrix will be sparse. Several criteria for positive definiteness of CSRBF have been provided and a series of positive definite CSRBF have been produced. The following two CSRBF are studied in this work; they have the form as

$$\varphi_{C1}(r) = (1-r)_+^6 (6 + 36r + 82r^2 + 72r^3 + 30r^4 + 5r^5), \quad (2)$$

$$\varphi_{C2}(r) = (1-r)_+^8 (1 + 8r + 25r^2 + 32r^3), \quad (3)$$

where r is a norm with respect to the radius of the compactly supported domain, $(1-r)_+$ is a truncated function.

III. NEW SEQUENTIAL OPTIMIZATION STRATEGY

SOM has been successfully employed to solve optimization design of electromagnetic devices. It is composed of coarse optimization process and fine optimization process [4]. The main purpose of the former is to reduce the design space and find the most interesting region. Space reduction equation plays an important role in this process. A new reduction strategy is given as follows.

Let $I^{(k)}$, $h^{(k)}$ and $N^{(k)}$ are the interval, step size and number of the k th sampling and optimization process, respectively. $x_o^{(k)}$ is the optimization result of the approximate models. The new reduction strategy is designed with two steps.

Reduction step:

$$\hat{x}_{li}^{(k+1)} = \max \left\{ x_{li}^{(k)}, \text{round} \left[8(x_{oi}^{(k)} - \Delta l) / h_i^{(k)} \right] \cdot h_i^{(k)} / 8 \right\}, \quad (4)$$

$$\hat{x}_{ui}^{(k+1)} = \min \left\{ x_{ui}^{(k)}, \text{round} \left[8(x_{oi}^{(k)} + \Delta l) / h_i^{(k)} \right] \cdot h_i^{(k)} / 8 \right\}, \quad (5)$$

Correction step:

$$x_{li}^{(k+1)} = x_{li}^{(k)} + \text{round} \left[2(\hat{x}_{li}^{(k+1)} - x_{li}^{(k)}) / h_i^{(k)} \right] \cdot h_i^{(k)} / 2, \quad (6)$$

$$x_{ui}^{(k+1)} = x_{ui}^{(k)} + \text{round} \left[2(\hat{x}_{ui}^{(k+1)} - x_{ui}^{(k)}) / h_i^{(k)} \right] \cdot h_i^{(k)} / 2, \quad (7)$$

where $[x_{li}^{(k)}, x_{ui}^{(k)}]$ is the boundary of the i th variable, function $\text{round}(x)$ is round to the nearest integer of x . $\Delta l = l_i^{(k)} / n_l$, in which n_l is the reduction factors. If $n_l = p$, the interval of reduced space is $p/2$ of the last interval; default value is 4. The starting point of new reduction strategy is very different from the former [4]. We focus on the reduction speed in the former SOM, while sampling points of last set can be employed sufficiently in the current modeling process by the new reduction strategy. So the cost of finite element analysis can be saved to a great extent.

IV. EXAMPLES

In the section, we will compare the results with different reduction factors to discuss the limit cases of SOM. Moreover, model selection strategy will be discussed for SOM.

A. TEAM Workshop Problem 22

It is a well known benchmark problem for the optimization of superconducting magnetic energy storage (SMES) [1]-[2], [4]. The three-variable (R_2 , h_2 , d_2) case of SMES is a discrete problem which should be optimized with respect to the following objectives: (1) The stored energy should be 180 MJ; (2) $B_{\max} \leq 4.92$ T (superconductivity constraint); (3) The stray field (B_{stray}) should be as small as possible. Table I shows the optimal results given by SOM with different RBF models.

TABLE I
OPTIMIZATION RESULTS OF SMES

Var. Unit	R_2 m	$h_2/2$ m	d_2 m	B_{stray} mT	E MJ	FESP
DEA	3.18	0.428	0.211	1.03	180.00	2310
G-RBF	3.12	0.309	0.295	0.93	179.94	214
MQ-RBF	3.07	0.295	0.328	0.97	179.64	129
φ_{c1}	3.06	0.302	0.325	1.01	179.45	122
φ_{c2}	3.03	0.316	0.325	1.23	179.24	122
G- $n_l=6$	3.17	0.372	0.238	0.97	180.14	131
G- $n_l=8$	3.12	0.358	0.262	1.00	180.04	120

In Table I, DEA means the results derived from differential evolution algorithm (DEA) with finite element model. G-RBF shows the results given by SOM with Gauss RBF model. G- $n_l=6$ means the results given by Gauss RBF model with reduction factor $n_l = 6$; others cases have similar meanings.

(1) All the methods can deliver satisfied results, especially those based on RBF models.

(2) 2310 finite element sample points (FESP) are needed for DEA to get the optimal results. All FESP of SOM based on RBF and CSRBF models are less than 1/10 compared with that of DEA.

(3) The best results are from the case of Gauss RBF model with $n_l = 4$. If we use $n_l = 6$ and 8 to reduce design space, the FESP can be reduced obviously while the optimal results are only a little worse than that of the former case.

Fig.1 shows the convergence rate of SOM with different models, including RSM, RBF, CSRBF and Kriging models. From the comparison, we can see that RSM, RBF and Kriging are better than CSRBF for the modeling process of SOM.

B. TEAM Workshop Problem 25

This is also a benchmark problem for the optimization of die press model [3]. The three parameters (R_2 , L_2 , L_4) case is considered in this work. It is a continuous problem which should be optimized to maintain the radial magnetic induction equal to 0.35 T at the specified place. The objective function is the square error of the calculated and specified values. Table II shows the results given by our methods. As an abstract, we only present the SOM results based on MQ RBF model with different reduction factors.

Fig.1. Convergence rate of SOM with different models

From the table, we can see that 2420 FESP are sampled to get the optimization results by DEA. For the case of default SOM, only 331 FESP are needed, which is 13.68% compared with that of DEA. And for the case of $n_l = 6$ and 8, the optimal results can be derived with only 161 FESP, which are 6.65% compared with that of DEA, and less than half of the former case. The results given by SOM only a little worse than that by DEA, but they also satisfy design objectives.

TABLE II
OPTIMIZATION RESULTS OF TEAM WORKSHOP PROBLEM 25

Var. Unit	R_1 mm	L_2 mm	L_4 mm	f	FESP
DEA	7.5554	14.7212	14.8666	4.14×10^{-4}	2420
MQ-RBF	7.6125	14.6250	15.7188	1.49×10^{-3}	331

V. CONCLUSION

We present new strategies for SOM to solve design problems of electromagnetic devices, including two kinds of RBF models. From two TEAM benchmark examples, we can see that the computational cost of finite element analysis can be obviously saved by our methods.

A Metaheuristic Algorithm for Multiobjective Designs of Inverse Problems

S. L. Ho¹, and Shiyou Yang^{1,2}

¹Department of Electrical Engineering, The Hong Kong Polytechnic University, Hong Kong

²College of Electrical Engineering, Zhejiang University, Hangzhou, 310027, China

Abstract—A metaheuristic encapsulating a novel selecting strategy for finding the best solutions of both individual and a group, a desirability function to quantitatively take into account of dominance, the scaling of the objective functions etc., as well as an iterative mechanism of particle swarm optimization is proposed. Two numerical examples are reported to demonstrate the pros and cons of the proposed metaheuristic algorithm.

I. AN MULTIOBJECTIVE METAHEURISTIC

In engineering synthesis, it is not uncommon to ask the designer to satisfy several seemingly conflicting criteria/objectives simultaneously. Such problems therefore require the finding of the best possible designs to satisfy a set of objectives under different tradeoff scenarios. To reach this goal, increasing endeavors have been devoted to develop metaheuristic algorithms such as, to name but a few, genetic, differential evolution, simulated annealing, tabu search, and particle swarm optimization, in finding a near-complete and near-optimal Pareto front. However, most available metaheuristics have difficulties in finding the best tradeoffs to distributing the computational resources uniformly whilst accomplishing the aforementioned ultimate goal. In this regard, a metaheuristic encapsulating some improved approaches and an iteration mechanism of the Particle Swarm Optimization (PSO) method is proposed with the goal to try alleviating the deficiency of available vector algorithms.

The details about particle swarm optimization method are referred to [1],[2]. Hereafter only the approaches and methodologies for extending the PSO in solving a multiobjective design problem are described.

A. Selection of Best Solutions of Individual and Group

The solution of a multiobjective problem is not unique but is a set of tradeoffs of different objectives referred as the Pareto optimals. As a consequence, the best solutions searched by a particle, denoted by p_{best} stored in P_{best} , and those by its neighbors, denoted by g_{best} memorized in G_{best} , are multiple and these numbers will exceed one as the evolution advances. Since the fitness value of different Pareto optimals may be the same, this will give rise to difficulties when selecting the best solutions of both individual and the group. For example, if the best solutions are selected in a completely random way, due to considerable differences in the positions of the two selected best particles in the parameter space, the particle will oscillate within the parameter space in subsequent iterations, resulting in an inefficient iterative procedure; On the other hand, if the best solutions are always selected in a deterministic way, the distributions of the particles may have limited diversity, leading to a less robust vector optimizer for finding a well-

distribution of Pareto optimals. To keep the best balance of efficiency and robustness of the algorithm, the p_{best} and g_{best} of a particle are selected by using the roulette wheel selection mechanism, but for the former with a probability proportional to the distances of the specified particle to those of P_{best} and for the later, with a probability proportional to the fitness values of the components of G_{best} .

B. Taking Amount of Domination into Consideration

To assess the quality of a particle in a Pareto optimal sense, the dominance concept is commonly used to assign the fitness value [3]. However, such approaches can only determine qualitatively the relationships of dominances among different solutions, it cannot measure quantitatively the 'level' of domination [4]. However, a proper usage of such 'level' could guide the search towards the finding of more and better Pareto optimals with enhanced convergence performances. Hence a desirability function is introduced in that for the particle x_i in question, if its closest Pareto optimal searched so far is denoted by x_i^p , its j^{th} desirability function is formulated as

$$d_j(x_i) = \exp(-|Y_j'|^{n_j}) \quad (1)$$

$$Y_j' = (2Y_j - (USL_j + LSL_j)) / |USL_j - LSL_j| \quad (2)$$

where; $Y_j = |f_j(x_i) - f_j(x_i^p)|$; USL_j and LSL_j are, respectively, the upper and lower specification levels characterizing a symmetric desirability around a target value in the middle between two limits of the j^{th} objective or criterion; $n_j > 0$ controls the shape of the two-sided desirability function.

Once the desirability functions for all objectives are determined, the desirability function characterizing the "level" of dominances is defined as

$$d(x_i) = \prod_{j=1}^{N_f} d_j(x_i) \quad (3)$$

This *ad hoc* desirability function will then be used to incorporate the 'level' information into the fitness value of a particle using the following formula,

$$f_{fit}(x_i) = w_1 f_{fit}^{nor}(x_i) + (1 - w_1) [d(x_i) / \sum_{j=1}^{N_p} d(x_j)] \quad (4)$$

where, $f_{fit}^{nor}(x_i)$ is the normally defined fitness of x_i , w_1 is a weighting constant, N_p is the size of the swarm.

C. Scaling of Different Objectives

For an engineering design problem, different criteria or objectives have significant differences in magnitude, which

will result in an unevenly distributed Pareto frontier [5]. To eliminate this problem, the objectives are normalized to

$$\hat{f}_i = (f_i - f_i^{\min}) / (f_i^{\max} - f_i^{\min}) \quad (5)$$

where f_i^{\min} and f_i^{\max} are, respectively, the minimum and maximum values of the i^{th} objective function.

To fully use the information gathered from the so far searched Pareto solutions, a continuous approximation of these solutions at the end of each swarm is constructed using a 'support vector machine based' response surface model. As more promising solutions might be found on this response surface, an intensifying search is then designed to exploit the sampling points generated by means of an interpolation on this surface in order to find more Pareto solutions. Moreover, the multiplicative scheme for implementing the ε -dominance [6] is used to guarantee the diversity of the final solutions on the Pareto front.

II. NUMERICAL EXAMPLES AND CONCLUSIONS

Extensive numerical experiments on different multi-objective design problems are conducted to validate and to demonstrate the pros and cons of the proposed algorithm. However, due to the limitation of space, only the numerical results on two case studies are reported.

A. Example One

As the first application, the proposed algorithm is utilized to study the multiobjective shape optimization of a coreless solenoid with a rectangular cross-section $a \times b$ [7]. If the current is assumed to be uniformly distributed over the cross-section, the inductance L [μH] and the volume V [m^3] can be approximated by F_1 and F_2 , respectively, as follows:

$$F_1 = \frac{31.49 \frac{k_1^2}{4\pi^2 b}}{9 + 6 \frac{a}{b} + 5 \frac{k_1 k_2}{\pi a b^2}} \quad (6)$$

$$F_2 = \frac{\pi a^2 b}{4} + \frac{k_1^2 k_2^2}{4\pi a^2 b} + \frac{k_1 k_2}{2}$$

Under some simplifications [7], this multiobjective design problem can be formally defined as: maximize the inductance $L(a,b)$ and minimize the volume $V(a,b)$ of the solenoid for a given length $k_1 = 10$ m and cross-section $k_2 = 10^{-6}$ m^2 of the current carrying wire, subject to $a > \sqrt{k_1 k_2 / (4\pi b)}$. The searched Pareto front for this case study using the proposed algorithm is depicted in Fig. 1. It can be seen that the proposed algorithm produces a uniformly sampling of the Pareto front.

B. Example Two

The geometrical design of the multi-sectional pole arcs of a large hydrogenerator [8] is selected as another application of the proposed metaheuristic. The goals of the optimal design includes: maximize the amplitude of the fundamental component of the flux density in the air gap, B_{f1} ; minimize both the distortion factor of a sinusoidal voltage of the machine at no-load, e_v , and the Telephone Harmonic Factor,

THF . It is found that, for a typical run, after 2315 iterations, the proposed metaheuristic yields a set of acceptable Pareto solutions in the objective space, as shown in Fig. 2. Based on these experimental results, it can be seen that the viability of applying the proposed algorithm to multiobjective inverse problems is validated.

The Use of Feature Selection to Create a Compact Prototype for Electromagnetic Device Optimization

Jun Ouyang and David A. Lowther

Department of Electrical and Computer Engineering, McGill University,
3480 University Street, Montreal, H3A 2A7, Canada
jun.ouyang@mail.mcgill.ca, david.lowther@mcgill.ca

Abstract— The design space of an electromagnetic (EM) device is huge and complicate since such devices consist of a large number of interacting sub-components and strong inter-dependencies among elements related to a variety of physical areas such as mechanical, electrical and thermal. However, not all information is necessary when given a design task to build an EM device. In order to eliminate redundant information and speed up the design process, we have developed a compact EM device prototype through feature selection techniques which is described in this paper.

I. INTRODUCTION

Design is an ill-structured problem since its specifications are not always complete and functional goals are often inconsistent; and the corresponding definitions of algorithmic solutions lack clarity. Furthermore, the complexity of the design task increases as the designer addresses the intricacies of a field such as electromagnetic devices [1]. The problem to be considered is that of how to explore the design space with a very large number of dimensions (design features) in order to derive solution candidates which can be quickly improved through an optimizer. Thus it is necessary to develop a compact prototype with reasonable multi-dimensional size and enough information to model an electromagnetic device. One feasible approach to solving this problem is to use feature subset selection techniques. Such a system, as a critical preprocessing step to an intelligent learning system, is an effective way to identify and remove as much irrelevant and redundant information as possible. This reduces the dimensionality of the design space and may allow the design process to perform faster and more effectively. In some cases, accuracy on a future design task can be improved; in others, the derived design prototype is a more compact, easily interpreted representation of the target concept. The intention of this paper is to investigate the feasibility of building a compact prototype for electromagnetic device optimization. To do this, it is imperative to develop a methodology for determining “feature relevance” as a standard to measure the goodness of a selected feature subset in a generic situation. The remainder of this paper is going to illustrate the related concepts, theoretical fundamentals and algorithms. Finally, induction motor case instances are used as a test example to explain the practical significance of developing a compact prototype.

II. FEATURE RELEVANCE MEASURES

Based on the statement from Genari et al., features are relevant if their values vary systematically with category membership [2], the concepts and theoretical background of

how well a particular feature subset can be applied to represent the original design space are formally described with the following definitions and formulae. First, we adopt the definitions of strong relevance, weak relevance and irrelevance in any feature set as described in the paper from John et al.[3]; then introduce how to use correlation between two features as a measure to find the relevant features from the original feature space.

Given an original set of features F , let $F_i \in F$ and $S_i = F - \{F_i\}$.

The following definitions are then made:

Defintion1: (Strong relevance) A feature F_i is strongly relevant iff

$$P(C|F_i, S_i) \neq P(C|S_i)$$

Defintion2: (Weak relevance) A feature F_i is weakly relevant iff

$$P(C|F_i, S_i) = P(C|S_i) \text{ and} \\ \exists S'_i \subset S, \text{ such that } P(C|F_i, S'_i) \neq P(C|S'_i)$$

Defintion3: (Irrelevance) A feature F_i is irrelevant iff

$$\forall S'_i \subseteq S_i, P(C|F_i, S'_i) = P(C|S'_i)$$

Here $P(C|S_i)$ is the probability distribution of different category memberships given the feature values in S_i and $P(C|F)$ is the original distribution given the feature values in F . C is a set of different category memberships.

In order to evaluate the relevance of features for a given classification task, we adopt the correlation between two features as an approximation measure, then it is safe to state a good feature subset is one that contains features highly correlated with the class, yet uncorrelated with each other. So far there are two constant ways to calculate the correlation between feature variables. The first one is based on linear correlation and defined as follows.

For a pair of feature variables (X, Y) , the linear correlation r is defined by the following formula. Here \bar{x}_i is the mean of X , and \bar{y}_i is the mean of Y . The range of r is $[-1, 1]$.

$$r = \frac{\sum_i (x_i - \bar{x}_i)(y_i - \bar{y}_i)}{\sqrt{\sum_i (x_i - \bar{x}_i)^2 (y_i - \bar{y}_i)^2}} \quad (1)$$

The second is based on the information-theoretical concept of entropy, a measure of uncertainty of a random feature variable. It is defined as follows.

$$\text{entropy}(X) = -\sum_i P(x_i) \log_2(P(x_i)) \quad (2)$$

The entropy $(X|Y)$ is defined as the following formula.

$$\text{entropy}(X|Y) = -\sum_j P(y_j) \sum_i P(x_i | y_j) \log_2(P(x_i | y_j)) \quad (3)$$

Another concept, information gain (IG) [4], is given by the following formula.

$$\text{IG}(X|Y) = \text{entropy}(X) - \text{entropy}(X|Y) \quad (4)$$

It is applied to rank the level of correlation of one feature compared with the other two features. In other words, we can say that a feature Y is regarded more correlated to the feature X than to feature Z , if $\text{IG}(X|Y) > \text{IG}(Z|Y)$.

III. A FILTER FEATURE SELECTION ALGORITHM FOR EM DEVICES

The general process of feature subset selection is to iteratively evaluate a candidate subset of features, modify the subset and evaluate if the new subset has a better performance than the old. Since our purpose is to build a compact prototype for electromagnetic device optimization, it is necessary to explore as many design feature subsets as possible. Thus we adopt a filter algorithm [5] that employs correlation-based measures to evaluate the candidate feature subset and different search methods to generate a subset. The framework of a filter algorithm is presented in Fig.1. An induction motor case-base with 11 design features and 22 instances is chosen to test the feasibility of the method for selecting a feature subset from an original design space.

A filter algorithm

```

Input:  $D(F_0, F_1, \dots, F_{n-1})$  // an initial space with N features
       $S_0$  // an initial subset to start the search
       $\delta$  // a stopping criterion
Output:  $S_{\text{best}}$  // an optional subset
1 begin
2 initialize:  $S_{\text{best}} = S_0$ ;
3  $\gamma_{\text{best}} = \text{correlation-sub-eval}(S_0, D)$ ; //correlation-
   based evaluation criterion
4 do begin
5  $S = \text{generate}(D)$ ; // generate a subset for evaluation
6  $\gamma = \text{correlation-sub-eval}(S, D)$ ;
7 if ( $\gamma$  is better than  $\gamma_{\text{best}}$ )
8  $\gamma_{\text{best}} = \gamma$ ;
9  $S_{\text{best}} = S$ ;
10 end until ( $\delta$  is reached);
11 return  $S_{\text{best}}$ ;
12 end.
```

Fig. 1. The framework of a filter algorithm

The purpose of this experiment is to estimate the

dependencies between functional and geometrical design features. Here we choose a critical geometrical feature, stator outer diameter, as the classification feature against other functional features. The experimental result shown in the following table reflects the fact that it is consistent with the domain knowledge in an induction motor.

TABLE I
CRITICAL FUNCTIONAL FEATURES FOR STATOR OUTER DIAMETER

Original features	Selected features
power(KW)	
power(HP)	
poles	
Speed	
rated-current	rated-current
Efficiency	efficiency
power factor	power factor
locked-rotor-current	locked-rotor-current
locked-rotor-torque	locked-rotor-torque
max-torque	max-torque

This case base has been built with the help of MotorSolve provided by Infolytica Corporation [6].

IV. CONCLUSION

A filter feature selection algorithm to reduce the size of the design space for electromagnetic devices has been presented and applied to a database of induction motor designs. Using the information derived, it is possible to create a compact EM device prototype which can be used as the starting point for an optimization process. In effect, the feature subset selection technique provides an efficient and fast approach to exploring the potential design space allowing the optimizer to concentrate on the exploitation phase. The full paper will provide details of the algorithm and more experimental results to demonstrate the feasibility of the methodology presented in this paper.

Optimization of Electromagnetic and Magnetic Shielding using ON/OFF Method

Norio Takahashi, Shunsuke Nakazaki, Daisuke Miyagi

Dept. Electrical and Electronic Eng., Okayama University
3-1-1 Tsushima, Okayama 700-8530, Japan (E-mail: norio@elec.okayama-u.ac.jp)

Abstract — The ON/OFF method which was developed for the static field problem is extended to the dynamic field problem. The method makes them particularly useful in topology optimization, where the parameterization enables all feasible shapes of electromagnetic devices to be explored. We applied the ON/OFF sensitivity method to the steady state linear eddy current problem in order to determine the optimal topology of the electromagnetic and magnetic shield. As a result, the optimal shape of electromagnetic and magnetic shield, which we could not imagine beforehand can be obtained using the ON/OFF method. A criterion of how to choose the sensitivity with respect to the reluctivity or conductivity is discussed. It is shown that the ON/OFF method can be used for the design of electromagnetic or magnetic shielding, even when the material is the magnetic steel sheet which have two kinds of variables, magnetic permeability and conductivity. The best shielding configuration can be obtained for each frequency using a larger design sensitivity.

I. INTRODUCTION

We have already developed the ON/OFF method[1,2] which is attractive for the designer by applying it to the static magnetic field problem. If the ON/OFF method is extended to the optimization of eddy current problem, we may be able to get an optimal electromagnetic or magnetic shielding [3,4] from a comprehensive point of view by distributing conducting materials or magnetic materials in the design domain. As the electrical steel has both large permeability (small reluctivity ν) and conductivity σ , two kinds of design sensitivity $\partial W/\partial \nu$ and $\partial W/\partial \sigma$ (W : objective function) can be considered. However, a criterion for selecting the sensitivity $\partial W/\partial \nu$ or $\partial W/\partial \sigma$ for the optimal design of shielding is not clear.

In this paper, the ON/OFF method is extended to the optimization of the eddy current problem using the step by step method and the adjoint variable method. The shape of electromagnetic shielding (non-magnetic material) and that of magnetic shielding (non-conducting material) are obtained using the ON/OFF method. The possibility of optimizing the shape of shielding having two types of design variables, e.g. ν and σ , like the electrical steel sheet is examined, and the optimization is carried out.

II. OPTIMIZATION OF ELECTROMAGNETIC AND MAGNETIC SHIELDING

The shape of shield is optimized so that the average flux density in a target region is reduced. The analyzed model of the electromagnetic and magnetic shield is shown in Fig. 3. This is a model that the ac magnetic flux produced by the coil is shielded. The shieldings are set between a coil and target region (5mm×40mm×40mm) in which the magnetic flux should be reduced. The design domain (5mm×200mm×200mm) for forming the shielding is divided into cells. The current of the coil is set as 1939AT (60Hz, 1kHz and 10kHz). When the material is a solid (electrical steel), the conductivity σ is 0.7×10^7 (S/m), and the relative permeability μ_r is 1000 in the design region. When the material is a void, the conductivity σ is 0.1×10^3 (S/m), and the relative permeability is unity in the design region. The non-zero conductivity is put to the void, in order to design a current circuit.

The objective function is defined as follows in order to minimize the magnetic flux density at the target region:

$$W = \frac{1}{ne} \sum_{ie} \left\{ |B_x^{(ie)}|^2 + |B_y^{(ie)}|^2 + |B_z^{(ie)}|^2 \right\} \quad (1)$$

where ne is the number of elements in the target region, B_x , B_y , and B_z are the x -, y - and z -components of the magnetic flux density.

When the electrical steel is used in the ac field, it has two kinds of shielding properties, electromagnetic shielding and magnetic shielding. The applicability of the newly developed ON/OFF method which use larger sensitivity between $dW^{(istep)}/d\sigma$ and $dW^{(istep)}/d\nu$ is examined using such a shielding

Fig. 1. Analyzed model. (a) overview, (b) x - z plane.

6. Optimization

Fig.2. Optimal shapes obtained using various design variables (10kHz). (a) method A, (b) method B, (c) method C.

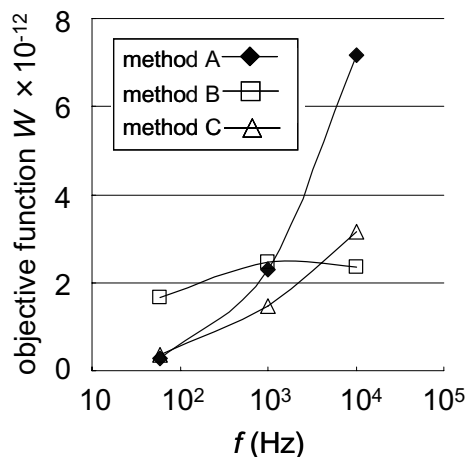

Fig.3. Objective function of optimal topology at each frequency.

composed of electrical steels. The following three kinds of optimization were performed:

(method A)

The design variable is the reluctivity. In this case, the sensitivity $dW/d\nu$ is only calculated.

(method B)

The design variable is the conductivity. In this case, the sensitivity $dW/d\sigma$ is only calculated.

(method C)

The design variables are both reluctivity and conductivity. The sensitivity for each design variable is calculated independently and the sensitivity of which the absolute value is larger is adopted.

Fig.2. Optimal shapes obtained using various design variables (10kHz). (a) method A, (b) method B, (c) method C.

Fig. 2 shows obtained optimal shapes of shielding at 60Hz and 10kHz. Fig. 9 shows the objective function of the optimal shape at each frequency. The flux density in the target region of the initial shape is about 6.6mT, and the value of the objective function is 1.2×10^{-10} . The shielding was most effective in the method A at 60Hz. The flux density in the target region is reduced to about 0.39mT. The shielding was most effective in the case B at 10kHz. This corresponds to the electromagnetic shielding.

The results of methods A and C (50Hz) are similar, and those of method B and C (10kHz) in Fig. 2 are similar. These facts suggests that the optimal topology of electromagnetic shielding or magnetic shielding can be automatically obtained using the technique of method C, which use the larger sensitivity between $dW/d\sigma$ and $dW/d\nu$. In this model, a best configuration of magnetic circuit is obtained by the method C at 1kHz as shown in Fig. 3. The case of 1kHz is the intermediate situation between magnetic shielding and electromagnetic shielding. In such a state, the method C proposed here is very effective.

III. CONCLUSION

The ON/OFF method for the topology optimization is extended to the linear eddy current problem. The technique to optimize the magnetic circuit composed of the material with two kinds of design variables (conductivity and reluctivity) is investigated. It is shown that the electromagnetic shielding and magnetic shielding can be automatically selected, moreover, the best shielding configuration can be obtained for each frequency using a larger design sensitivity with respect to design variable.

Reducing the Design Space of Standard Electromagnetic Devices using Bayesian Response Surfaces

Linda Wang and David A. Lowther

Department of Electrical & Computer Engineering, McGill University, Montreal, Quebec, Canada H3A 2A7

Email: linda.wang@mail.mcgill.ca

Abstract – This work proposes a procedure that reduces the design space of a standard electromagnetic device by using response surface methodology with multivariate Bayesian analysis. Our method seeks to provide a reduced design space that contains the optimal design with a probability of P , where P is specified by the designer and can be arbitrarily close to 1. The reduced design space can then be searched for the optimal device.

I. INTRODUCTION

When designing a standard electromagnetic device, an engineer often has available a library of existing optimal designs for the same type of device made to different specifications. The goal of our work is to make use of this library in order to reduce the search space of new designs. By using response surface methodology and multivariate Bayesian analysis, our method seeks to provide a reduced design space that contains an optimal new design with a probability P , where P is specified by the designer and can be arbitrarily close to 1. The reduced design space can then be searched using standard optimization algorithms.

II. BACKGROUND

The goal of device design is to find values for a set of design variables \mathbf{d} (such as physical dimensions) that satisfy a set of design specifications \mathbf{s} , while minimizing an objective (such as mass). Our work models the relationship between \mathbf{d} and \mathbf{s} by curve-fitting data from existing optimal device designs. This model is then used to predict new designs. The most common type of model used for curve-fitting is *linear regression*. This section explains the multivariate Bayesian version of linear regression that is used in this work.

A. Classic Linear Regression

Linear regression models a *response variable* y as a linear function of the components of a *covariate vector* \mathbf{x} . Note that the components of \mathbf{x} may be transformations of other underlying variables (e.g., $x_1 = s_2 + s_3^2$), so although the model is linear, it can take on many forms including polynomials.

The linear regression model is built by using n pairs of responses and covariates (y_i, \mathbf{x}_i) that already exist. The underlying statistical assumption is that each existing response y_i was generated by a random variable Y_i that has the form

$$Y_i = \beta_1 x_{i1} + \beta_2 x_{i2} + \dots + \beta_p x_{ip} + \varepsilon_i = \mathbf{x}_i^T \boldsymbol{\beta} + \varepsilon_i, \quad (1)$$

where $\boldsymbol{\beta}$ is a vector of p unknown constants called the *model parameters* (the same $\boldsymbol{\beta}$ is used to model all n Y_i 's), and ε_i a zero-mean normally distributed random variable with an unknown variance σ^2 (all n ε_i 's are identically distributed).

The matrix form of (1) is $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ for $\mathbf{Y} = (Y_1, Y_2, \dots, Y_n)^T$. Given the n pairs of existing responses and their covariates, the elements of $\boldsymbol{\beta}$ are then estimated for this model using least-squares analysis. Using this estimate, a new response at covariates \mathbf{x}_{new} can be predicted as $y_{\text{new}} = \hat{\boldsymbol{\beta}}\mathbf{x}_{\text{new}}$, where $\hat{\boldsymbol{\beta}}$ is the estimate of $\boldsymbol{\beta}$.

In response surface methodology (RSM) [1], this prediction model $y = f(\mathbf{x}) = \hat{\boldsymbol{\beta}}\mathbf{x}$ is called a *response surface*. RSM usually builds response surfaces to model device performance (i.e., the elements in the design specifications \mathbf{s}) as functions of design variables \mathbf{d} . This work, however, models \mathbf{d} as a function of \mathbf{s} instead (this is explained in Section III).

B. Bayesian Multivariate Linear Regression

The classic linear regression model can be modified to be Bayesian [2]. For this work, there are two major advantages of Bayesian analysis: 1) It provides a *distribution*, rather than just a single value, for any predicted response. This distribution takes into account the uncertainties in estimating model parameters. 2) It provides a way of modeling multiple responses that take into account their correlations.

When there are q response variables to be modeled instead of just one, then the single response y becomes a response vector $\mathbf{y} = (y_1, y_2, \dots, y_q)^T$. A *multivariate* model is then built with n pairs of responses and covariates $(\mathbf{y}_i, \mathbf{x}_i)$, where each $\mathbf{y}_i = (y_{1i}, y_{2i}, \dots, y_{qi})^T$. Whereas the univariate model in (1) assumes that each single response y_i was generated by a random variable Y_i , the multivariate model assumes that each response vector \mathbf{y}_i was generated by a random vector \mathbf{Y}_i . The elements of \mathbf{Y}_i are jointly distributed as follows:

$$\mathbf{Y}_i = \mathbf{B}\mathbf{x}_i + \mathbf{u}_i, \quad (2)$$

where \mathbf{B} , a $q \times p$ matrix of unknown constants, is the multivariate version of $\boldsymbol{\beta}$ in (1). \mathbf{u}_i is a zero-mean random vector with an unknown covariance matrix $\boldsymbol{\Sigma}$ (all n \mathbf{u}_i 's are identically distributed).

The matrix version of (2) is $\mathbf{Y} = \mathbf{X}\mathbf{B}^T + \mathbf{U}$, where \mathbf{Y} is an $n \times q$ matrix. For this work, we are interested in studying the *joint distribution* of a predicted response vector \mathbf{Y}_{new} . Given the n pairs of existing response vectors and their covariates, this joint distribution is estimated using Bayesian analysis (we use non-informative prior distributions as in [2]). It is found that the predicted \mathbf{Y}_{new} at \mathbf{x}_{new} has a multivariate student t distribution with mean vector $\hat{\mathbf{B}}\mathbf{x}_{\text{new}}$, and a covariance matrix given by

$$\mathbf{S} = \frac{\nu}{\nu - 2} \left(\frac{\nu((\mathbf{Z} - \mathbf{X}\hat{\mathbf{B}}^T)^T(\mathbf{Z} - \mathbf{X}\hat{\mathbf{B}}^T))^{-1}}{1 + \mathbf{x}_{\text{new}}^T(\mathbf{X}^T\mathbf{X})^{-1}\mathbf{x}_{\text{new}}} \right)^{-1}, \quad (3)$$

where \mathbf{X} is the $n \times q$ matrix formed by stacking the n existing covariates \mathbf{x}_i 's, \mathbf{Z} is the $n \times q$ matrix formed by stacking the n corresponding \mathbf{y}_i 's, $\hat{\mathbf{B}} = \mathbf{Z}^T \mathbf{X} (\mathbf{X}^T \mathbf{X})^{-1}$ is the estimate of \mathbf{B} , and $\nu = n - p - q + 1$ is the degree of freedom of the distribution. This distribution takes into account the errors in $\hat{\mathbf{B}}$ as well as correlations among the elements of \mathbf{Y}_{new} .

C. Confidence Region of Multivariate Normal Distribution

When the degree of freedom of a multivariate t distribution is high, it can be approximated by a multivariate normal distribution. Compared to the multivariate t distribution, much more is known about the properties of the multivariate normal distribution [3]. In particular, standard confidence regions can be constructed for a multivariate normal distribution [4]. If we assume that the distribution of a response vector \mathbf{Y}_{new} predicted at \mathbf{x}_{new} can be approximated by a multivariate normal distribution, then a P confidence region for \mathbf{Y}_{new} is a q -dimensional hyper-ellipse defined by

$$(\mathbf{y} - \hat{\mathbf{B}}\mathbf{x}_{\text{new}})^T \mathbf{S}^{-1} (\mathbf{y} - \hat{\mathbf{B}}\mathbf{x}_{\text{new}}) = \chi_{1-P, q}^2, \quad (4)$$

where $0 < P < 1$, $\hat{\mathbf{B}}$ and \mathbf{S}^{-1} are as defined in the previous section, q is the length of \mathbf{Y}_{new} , and $\chi_{1-P, q}^2$ is the value of the chi-squared distribution with q degrees of freedom evaluated at $1 - P$. This means that the probability that a vector generated by \mathbf{Y}_{new} falls within the given region is P .

III. PROPOSED METHOD

As explained in Section II, the goal of device design is to find a vector of optimal design variable values \mathbf{d}_{opt} that satisfies a specification vector \mathbf{s} while minimizing an objective. Our method seeks to reduce the design space so that the probability of finding \mathbf{d}_{opt} in that space is P . We achieve this by modeling design variables \mathbf{d} as a function of design specifications \mathbf{s} using existing optimal designs. In other words, \mathbf{d} is considered to be a vector of response variables, while a transformation of \mathbf{s} (see Section II-A) is the covariate vector \mathbf{x} . The details of our procedure is described as follows:

- 1) Build a multivariate linear regression model given in (2), where the design variables are the responses to be modeled.
- 2) Given a new set of design specifications, find the covariance matrix given by (3) for the predicted distribution of the design variables at this new specification point.
- 3) Using this covariance matrix, construction a P confidence region given in (4). The probability of finding \mathbf{d}_{opt} in the confidence region is ideally P .

IV. EXPERIMENTAL SETUP

We studied magnetic actuators in this work in order to test the proposed procedure. This required building a library of existing optimal actuator designs first. In order to do this, we optimized 28 actuators (using MagNet [5]) that met specifications found in manufacturers' catalogues [6] [7] while achieving minimum mass. These actuators have five design variables (NI, coil height, coil thickness, plunger diameter, and bushing height) and two design specifications (force and stroke). Fig. 1 shows the design specifications for the actuators.

Fig. 1. Specifications of the 28 existing actuator designs

TABLE I
OBSERVED FRACTION OF OPTIMAL DESIGNS IN P CONFIDENCE REGION

	Polynomial order			
	1	2	3	4
$P = 0.99$	0.87	0.86	0.83	0.79
$P = 0.95$	0.81	0.82	0.75	0.71
$P = 0.90$	0.80	0.79	0.69	0.63
$P = 0.75$	0.73	0.73	0.59	0.55
$P = 0.50$	0.55	0.63	0.45	0.37
$P = 0.25$	0.38	0.46	0.31	0.30

After the library was built, the data was fitted to four polynomial models of orders one to four (step 1 in the proposed method). Using steps 2 and 3, the method was tested with 121 new specifications located on an 11×11 grid covering the space shown in Fig. 1. Given a value of P , a confidence region was constructed for each new specification that ideally contains the desired optimal design with probability P . In order to verify whether the optimal design is indeed in the confidence region, we again used MagNet to find the true optimal design at each specification point.

V. PRELIMINARY RESULTS

Table I shows the fraction of optimal designs actually observed in the P confidence regions. For example, the $P = 0.50$ confidence region for the first-order polynomial model contained the optimal design in 66 out of the 121 test cases, hence the observed fraction is $\frac{66}{121} = 0.55$. The observed values show a reasonable correspondence with the ideal P , hence demonstrating that the proposed method is practical. The discrepancies between the observed and ideal values are caused by: 1) the approximation of the multivariate t distributions by multivariate normal distributions (especially for the higher order polynomial models), 2) the small number of samples tested, 3) the limitations in using RSM to model the design space.

Abstract—This paper considers the mesh discretization error as a source of noise which entails a non-smooth behaviour in the evaluated electromagnetic fields. This noise is filtered by a neural network (NN), which is constrained to impose a certain level of smoothness, such a way to retain the functions nonlinearities whilst filtering the noise. This is automatically achieved by a multiobjective training algorithm. Results considering a problem with a known analytical solution and a micro motor are presented. They show that this approach can be used to decrease the computational burden in the design of electromagnetic devices.

Index Terms—Mesh density, optimisation, neural networks.

I. INTRODUCTION

For many engineering problems, the objective functions and/or constraints, can only be evaluated by means of numerical techniques, such as the finite element method (FEM), which usually implies a huge computational burden. The FEM requires a mesh generator (a discretization of the domain), and, the evaluation of the real physical properties, are closely related to the mesh quality. Moreover, due mainly to discretization errors, the functions inherit a non-smooth behaviour which renders a more complex optimisation context. This can generate artificial local minima which can trap deterministic techniques and slow down the stochastic ones.

One way to avoid this shortcoming is increasing the mesh density. However, this increases the computational effort required in the optimisation procedure, which can become prohibitive in many cases. This paper treats this discretization error as a source of noise. This noise is then filtered by a NN trained with a multiobjective learning algorithm [1].

Some authors have applied machine learning techniques as an auxiliary tool in the optimisation of electromagnetic devices in the past years. Rashid et al. [2] have applied neuro-fuzzy methods in global optimisation of electromagnetic devices considering an evolutionary step, and, afterwards, a deterministic step using the neuro-fuzzy models. Their approach is based on the approximation of the function and its derivatives by analytically calculating the sensitivity information [3].

A similar approach [4] considers, instead of neuro-fuzzy models, a parallel layer perceptron (PLP) [5] neural network. The main advantage of the latter is a simpler analytical formulation and a faster training and testing algorithm. A slight different approach [6] integrates the NN in the optimisation procedure, where a neural network model is trained to define a deterministic operator inside a genetic optimisation algorithm.

The novelty of this paper relies on the fact that the global approximations are constrained to impose a certain level of smoothness to the objective function. This level of smoothness is automatic defined using the Q -norm complexity measure [7]. This technique is called the minimum gradient method (MGM) and it is applied to the PLP network [5]. The smoothness is defined by an adaptive filtering process. The MGM resembles the weight decay and pruning methods with the advantage of using only convex functions, and, therefore, a closed-form solution, in its formulation. Moreover, it has also some similarities with the Wiener filter [1].

The noise is treated as an uncorrelated residual in the cross-validation procedure. This guarantees to track the main behaviour of the evaluated functions, including nonlinearities. Wanner et al. considered second order model to fit the data and, even though it is capable to filter the noise, it does not model the real nonlinearities of the model [8]. Indeed their aim was to generate a hybrid deterministic/stochastic optimisation tool, which differs from the purpose of this work.

The NN formulation is shortly addressed in the next section. Next, are shown results considering a problem with a known analytical solution and a micro motor design.

II. NEURAL NETWORK FORMULATION

To achieve the desired filtering properties, the NN learning is modelled as a bi-objective optimisation problem which considers simultaneously the minimisation of the empirical error and network output complexity. It is theoretically reasonable to use the norm of the network output gradient as a complexity measure [7], based on output smoothness, high-frequency filtering, the concept of the larger margin, among others. In this way, the gradient norm can be used to compute the complexity for a given machine learning problem and, consequently, the learning problem can be formulated as

$$\min_w \begin{cases} R_{emp}(w) \\ \Omega(w) = \sum_{t=1}^{Tr} \|\nabla_x f(x_t, w)\|^2 \end{cases} \quad (1)$$

where R_{emp} is the empirical error, Ω is smoothness constraint, w are the NN weights, $\nabla_x f(\cdot)$ is the gradient of the NN output, and Tr is the training set size. The aim of this problem is to achieve the equilibrium between the two factors, which are in general conflicting. This equilibrium is responsible for the machine generalization abilities. For the PLP, this problem

can be solved in the linear layer by the closed-form solution,

$$l^* = [\lambda C^T C + (1 - \lambda)Q]^{-1} \lambda C^T d, \quad (2)$$

where l^* is the vector of optimal parameters, C enforces the error minimisation, the matrix Q defines the filtering, λ is defined by the minimum cross-validation error, and d is the desired output vector. See [7] for further details.

III. ELECTROMAGNETIC PROBLEM WITH KNOWN ANALYTICAL SOLUTION

This section considers the results for an electromagnetic problem with analytical solution. The problem is composed by a wire with circular cross-section of radius r carrying a constant current density J . The magnetic flux density B at $a > r$ away from the wire centre is given by $B(r) = \frac{\mu_0 J r^2}{2a}$.

The analytical, the FEM and the FEM smoothed solutions to several radii are shown in Fig. 1. The FEM smoothed solution is closer to the analytical solution than the FEM raw solution. This is due to discretization errors. The Fourier transform of the residual have a white noise characteristic, i.e., it ranges the whole frequency spectrum.

Fig. 1. Analytical, FEM, and FEM smoothed solutions for the wire electromagnetic problem.

IV. MICRO MOTOR

This section considers the average torque $\tau_m(x)$ of a electrostatic micro motor as in [9], parameterized by the rotor and stator teeth width in x . Given an initial design point x_0 , an optimising direction d , and a step α , Fig. 2 shows $\tau_m(x_0 + \alpha d)$ for the FEM result on a coarse mesh, its filtered version using NN, and the FEM result on a fine mesh. The smoothed FEM solution on a coarse mesh captured the main tendency of the problem, which would allow an effective use of derivative based methods.

V. CONCLUSION

This paper treated the mesh discretization error as a source of noise and it was filtered using a nonlinear filter based on NNs. These were trained with a multiobjective algorithm. This

Fig. 2. Results considering the average torque of a micro motor. The filtered version of the FEM solution with coarse is very close to the FEM solution considering a refined one.

assumption was investigated in a problem with known analytic solution and a micro motor, where a correct smoothing was observed. Although this cannot fully replace the FEM solution obtained with a good mesh, the proposed technique can be very useful in some intermediate step in the optimisation and design of electromagnetic devices. Finally, the proposed technique is based on a novel neural network training algorithm which is less dependent on user's defined parameters. This is a very important feature, since automatic design is required in many applications, and the cost to set the parameters can make approximation techniques unfeasible.

Abstract— Design optimization environment utilizing an Electromagnetic-Team Fuzzy Logic, EM-TFL, robust identifier for use with Particle Swarm Optimization, PSO, technique is presented. The developed environment is applied in a case study to optimize various components of a prototype Hybrid Electric Vehicle, HEV, powertrain. This optimization necessitates the characterization of the key electromechanical components of the HEV power train system which includes a generator, an electric motor drive system, and a battery pack in addition to an Internal Combustion Engine, ICE. The basic objective of improving the fuel economy while maintaining the performance of the vehicle is met through the implementation of a PSO algorithm.

I. INTRODUCTION

Growing concerns for clean environment and energy savings increased the demand for more environmentally friendly and fuel-efficient vehicles such as the Hybrid Electric Vehicle, HEV. The HEV makes use of hybrid powertrain which typically consists of an integrated Internal Combustion Engine, ICE, and electric power system. These two systems can be arranged into various configurations. The simplest and the most used configuration is the series configuration shown in Fig. 1 where the ICE is connected to a generator used to charge the batteries and deliver power to an electric motor drive that propels the vehicle [1]. This paper presents an Electromagnetic-Team Fuzzy Logic, EM-FL, module used to setup a robust identifier which is utilized with a Particle Swarm Optimization, PSO, algorithm for the design optimization of a prototype HEV powertrain system. The objective is to improve the efficiency and fuel economy of the HEV while maintaining maximum operating torque.

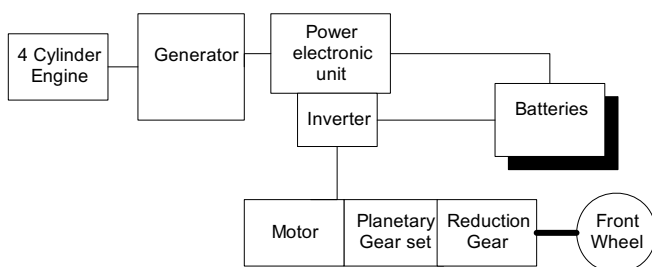

Fig. 1: HEV Series Configuration

II. INTEGRATED OPTIMIZATION ENVIRONMENT

A novel design optimization environment is developed and applied for the design optimization of HEV powertrain systems. The design optimization environment consists mainly of a PSO module and an Electromagnetic-Team Fuzzy Logic,

EM-TFL, module (robust identifier). The major components (functions) of this environment are shown in Fig. 2. It involves setting up several PSO populations to identify each objective and the different output powers used for each component

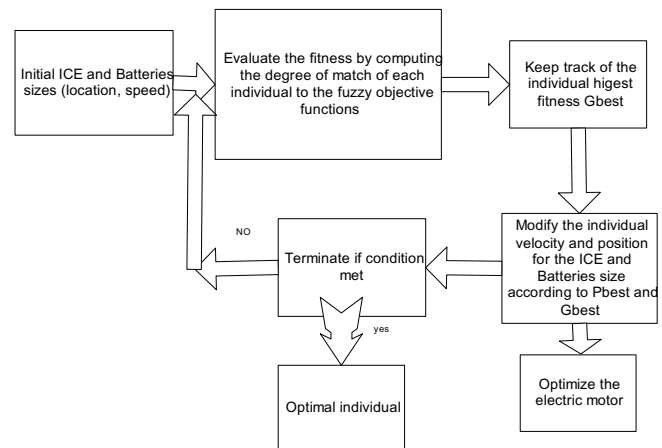

Fig. 2: Block Diagram of the Optimization Process of HEV

A. Particle Swarm Optimization

PSO is a population stochastic optimization technique developed by Eberhart and Kennedy in 1995 [3]. The system is initialized with a population of random solutions and searches for optima by updating generations. In PSO, the potential solutions, called particles, fly through the problem space by following the current optimum particles. Each particle keeps track of its coordinates in the problem space which are associated with the best solution, P_{best} , or fitness it has achieved in the process.

Another "best" value that is tracked by the particle swarm optimizer is the best value obtained during the optimization by any particle in the neighborhood of the particle. This location is called l_{best} . When a particle takes all the population as its topological neighbors, the best value is a global best and is called G_{best} .

B. HEV Powertrain Robust Identifier

The main components of the HEV series configuration under consideration, Fig. 1, are the electrical system which utilizes a Permanent Magnet, PM, generator and a Synchronous Reluctance Motor, SynRM, drive system in addition to an Internal Combustion Engine, ICE [4]. The design methodology of electromechanical systems must

include a robust identifier coupled with a design optimization model that “accurately” and “quickly” predict the performance and optimize the design of the system. The proper modeling of the electric drive under consideration must account for anisotropic effects, saturation effects resulting from the nonlinearity of the material, space harmonic effects resulting from the machine complex geometry and time harmonic effects resulting from the switching of power electronics in the motor drive system. This task is very involving as it requires extensive computations if one to use conventional computational electromagnetics in design optimization cases. In this work, an Electromagnetic-Team Fuzzy Logic, EM-TFL, environment is used for the characterization of the electrical components [5, 6], accordingly, setting up a robust identifier for use in a design optimization process.

This EM-TFL approach consists of two components. The first is the Electromagnetic, EM, module which utilizes a Finite Element-State Space, FE-SS, technique to accurately characterize the electric drive. This EM module is developed to provide the high accuracy needed for the Artificial Intelligence module. It involves iteration between the Finite Element and the State Space models based on the family of curves approach [5] and it is used to generate, mainly offline, a data base necessary to train and setup the second component which is a Team Fuzzy Logic, TFL, Artificial Intelligence, AI, module. This TFL based module is used online to quickly and accurately predict the performance characteristics of the electric drive for a wide range of design parameters and operating conditions [5]. The resulting robust identifier is used next for the design optimization of the HEV series configuration using a PSO technique.

III. APPLICATION AND RESULTS

The developed environment of Fig. 2 was used for the design optimization of a prototype HEV system. The objective is to compute the best size of the ICE, batteries and electric motors to obtain high efficiency and better fuel economy and performance HEV. In order to achieve this goal the ICE has to be sized to operate in the most efficient regions and the developed torque of the electric motor has to be maximized while minimizing its losses.

The HEV power train of Fig.1 includes the following major components: a 1.9-L, 4-cylinder 66 kW output power, 43 % maximum fuel efficiency turbo-charged compression-ignition direct-injection ICE; a 90 kVA PM generator; a 90 kVA SynRM drive; a five-speed transmission; and a battery pack which has a nominal voltage rating of 312 V with an energy content of about 1.56 kWh.

As a result of the optimization process, the ICE and battery bank ratings were determined to be at about 36 kW and 56 kW, respectively. Accordingly, the initial design ICE rated at 1.9-L, 4-cylinder, 66 KW output power was replaced by a smaller engine rated at 1.2-L, 4-cylinder, 36 KW output power. In addition, the electric motor was optimized to reach high torque to weight ratio and to minimize losses. The initial design of the SynRM had a rotor with 4 flux paths and a 4 pole stator with 4 slots per pole per phase, Fig. 3. The required

output torque was selected to be at 90 NM. The optimization process identified a solution with 5 flux paths [6]. A summary of results are shown in Table I where it is shown that both the torque ripple and machine losses were reduced, thus improving the HEV efficiency and fuel economy. In addition, the ICE performance indices are shown in Table II. An increase of 22% in predicted fuel economy and a significant decrease in the concentration of the harmful gas emission are found for the best solution as a result of utilizing smaller engine’s size.

FIG.3. NUMBER OF FLUX PATHS VARIATION

Table I: Electric Motor Initial and Optimal Design

	Initial Design	Optimal Design	Improvement
Losses (W)	6265	2400.9	61.7%
Torque Ripple	52%	29.85%	42.6%
Torque Average	90 N.m.	90 N.m.	N/A

Table II: ICE Output Indices Before and After Optimization

		Before optimization	After optimization
Fuel economy		38.6 mpg	47.1 mpg
Emissions	HC	0.673	.391
	CO	2.641	1.444
	NOx	.462	.322

IV. CONCLUSION

A novel design optimization environment utilizing an Electromagnetic-Team Fuzzy Logic, EM-TFL, robust identifier for use with Particle Swarm Optimization, PSO, technique was developed. The PSO algorithm is capable of optimizing various electromechanical components of HEV powertrain system despite the complexity of the optimization search space. This technique is equally applicable to various coupled electromagnetic – electromechanical systems.

Abstract—This paper presents a new self-adjoint sensitivity formulation for optimal designs and inverse problems in the RF domain. The proposed method is based on continuum approach and material sensitivity analysis. It eliminates the need of solving the adjoint system additionally when the objective function is the function of S -parameter. For verification, the method is applied to the numerical example of dielectric material reconstruction problem in the parallel plate waveguide.

I. INTRODUCTION

Since early '90s, sensitivity analysis has been widely adopted for optimal designs and inverse problems in low frequency domain. In RF domain, these gradient-based methods have also been used over the last several decades, but most of the work has been based on analytic sensitivity calculation with small number of design parameters.

Recently, increasing efforts have been made to introduce adjoint variable method in RF optimization and inverse problems for fast and efficient calculation of sensitivity. Our previous works afford an example, where dielectric waveguide filter [1], and microstrip low-pass filter (LPF) with defected ground structure [2] were optimized utilizing the adjoint variable method.

The heart of the adjoint variable method is to construct the adjoint system and to calculate the adjoint variables. In a normal method, an artificial adjoint source is obtained by differentiating the objective function with respect to the design variables. Then the additional adjoint system with new adjoint source is solved to get the adjoint variables. These adjoint variables are used along with the solutions of the primary (original) system to calculate sensitivity.

In the meantime, there have been some studies to remove this additional step and calculate the adjoint variable directly from the state variable of the primary system. In the low-frequency domain, using self-energy formulation derived from the mutual energy, the sensitivity can be calculated from the solution of the primary system alone if the objective function is defined in terms of the self flux-linkage in the source coil. As for RF systems, Nikolova et al. have presented time-domain formulation for S -parameter sensitivity based on discrete approach that does not require solution of the adjoint system [3]. However, this approach requires field solutions at regular perturbation grid points, making it best suited for the finite-difference time-domain (FDTD) method.

In this paper we propose a new frequency-domain, self-adjoint formula for S -parameter sensitivity calculation with respect to material properties. This method is based on the

recently derived continuum sensitivity analysis for RF systems, and does not require regular meshing of the design region or specific analysis method. The proposed method is applied to the reconstruction of dielectric material distribution inside parallel plate waveguide.

II. SELF-ADJOINT MATERIAL SENSITIVITY FORMULATION

Fig. 1 shows an exemplary 2-port RF system (rectangular waveguide) with dielectric discontinuity inside analysis domain Ω . Port 1 and 2 are defined on boundaries Γ_1 and Γ_2 .

Fig. 1. Rectangular waveguide with dielectric discontinuity.

Let's assume an objective function O is a function of s_{11} . Then O can be defined on boundary Γ_1 as

$$O = \int_{\Gamma_1} g(\mathbf{H}(\mathbf{p})) d\Gamma \quad (1)$$

where g is a scalar function, and the system parameter vector \mathbf{p} consists of permittivity ϵ or permeability μ . On Γ_1 where incident field is imposed, boundary condition of the third kind should be defined, which may be expressed as

$$\epsilon_r^{-1} \hat{\mathbf{n}} \times (\nabla \times \mathbf{H}) + \gamma_h \hat{\mathbf{n}} \times (\hat{\mathbf{n}} \times \mathbf{H}) = \mathbf{V} \quad (2)$$

where γ_h is a known parameter and \mathbf{V} is a known vector that has a magnitude proportional to that of the incident field.

In order to deduce a sensitivity formula, the variational form of the vector wave equation is added to (1) based on the augmented Lagrangian method.

$$\bar{O} = \int_{\Gamma_1} g d\Gamma + \int_{\Omega} \boldsymbol{\lambda} \cdot [-\nabla \times (\epsilon_r^{-1} \nabla \times \mathbf{H}) + k_0^2 \mu_r \mathbf{H}] d\Omega \quad (3)$$

where $\boldsymbol{\lambda}$ is the Lagrange multiplier vector interpreted as the adjoint variable. Applying the first vector Green's theorem to (3), we obtain

$$\bar{O} = \int_{\Gamma_1} g d\Gamma + \int_{\Omega} [-\epsilon_r^{-1} (\nabla \times \boldsymbol{\lambda}) \cdot (\nabla \times \mathbf{H}) + k_0^2 \mu_r \boldsymbol{\lambda} \cdot \mathbf{H}] d\Omega - \int_{\Gamma} \epsilon_r^{-1} \boldsymbol{\lambda} \cdot (\hat{\mathbf{n}} \times \nabla \times \mathbf{H}) d\Gamma \quad (4)$$

The only nonzero contribution of the second surface integral comes from Γ_1 . Substituting (2) into (4), we obtain

$$\begin{aligned} \bar{O} = & \int_{\Gamma_1} g \, d\Gamma + \int_{\Omega} \left[-\varepsilon_r^{-1} (\nabla \times \boldsymbol{\lambda}) \cdot (\nabla \times \mathbf{H}) + k_0^2 \mu_r \boldsymbol{\lambda} \cdot \mathbf{H} \right] d\Omega \\ & - \int_{\Gamma_1} \left[\gamma_h (\hat{n} \times \boldsymbol{\lambda}) \cdot (\hat{n} \times \mathbf{H}) + \boldsymbol{\lambda} \cdot \mathbf{V} \right] d\Gamma \end{aligned} \quad (5)$$

By taking the variation of both sides of (5) with respect to small changes $\delta \mathbf{p}$ of the system parameters, material sensitivity formula in RF system is derived as:

$$\frac{d\bar{O}}{d\mathbf{p}} = \int_{\Omega} \left[-\frac{\partial(\varepsilon_r^{-1})}{\partial \mathbf{p}} (\nabla \times \mathbf{H}) \cdot (\nabla \times \boldsymbol{\lambda}) + k_0^2 \frac{\partial \mu_r}{\partial \mathbf{p}} \mathbf{H} \cdot \boldsymbol{\lambda} \right] d\Omega \quad (6)$$

where $\boldsymbol{\lambda}$ is given by the following adjoint equation, given in a variational form as:

$$\begin{aligned} \int_{\Omega} \left[-\varepsilon_r^{-1} (\nabla \times \bar{\boldsymbol{\lambda}}) \cdot (\nabla \times \boldsymbol{\lambda}) + k_0^2 \mu_r \bar{\boldsymbol{\lambda}} \cdot \boldsymbol{\lambda} \right] d\Omega \\ - \int_{\Gamma_1} \left[\gamma_h (\hat{n} \times \bar{\boldsymbol{\lambda}}) \cdot (\hat{n} \times \boldsymbol{\lambda}) + \bar{\boldsymbol{\lambda}} \cdot \mathbf{g}_H \right] d\Gamma = 0 \end{aligned} \quad (7)$$

where $\bar{\boldsymbol{\lambda}} = (\delta \mathbf{H} + (\partial \mathbf{H} / \partial \mathbf{p}) \delta \mathbf{p})$ can be an arbitrary variable, and $\mathbf{g}_H \equiv \partial g / \partial \mathbf{H}$. Comparing the second and the third term on the right-hand side of (5) with (7), it can be seen that the only difference between the primary system and the adjoint one is the source \mathbf{V} and \mathbf{g}_H on the mixed boundary Γ_1 .

If the objective function is given as

$$O = \int_{\Gamma_1} |S_{11} - S_0|^2 \, d\Gamma \quad (8)$$

where S_0 is the target value of the S -parameter. Then the adjoint source \mathbf{g}_H can be written as

$$\mathbf{g}_H = 2(S_{11} - S_0) \frac{\partial S_{11}}{\partial \mathbf{H}}. \quad (9)$$

Since S_{11} is a linear function of \mathbf{H} on Γ_1 , \mathbf{g}_H can be considered as a constant coefficient. Therefore, by the linearity of the system equation, the adjoint field $\boldsymbol{\lambda}$ can be obtained by dividing the primary solution by the magnitude of \mathbf{V} , and accordingly multiplying the result by the magnitude of \mathbf{g}_H .

III. NUMERICAL EXAMPLE

The proposed method is applied to the reconstruction problem of dielectric material distribution in parallel plate waveguide. For this example, the S -parameter target value S_0 is calculated from dielectric material distribution shown in Fig. 2(a) at 27 frequency points between 300 MHz~3 GHz. The design variable is the normalized material density in each unit cell, which in turn controls the permittivity [1]. The reconstructed dielectric distribution is shown in Fig. 2(b), and the S -parameter plot is shown in Fig. 3. The normalized objective function converged to -48 dB after 728 iterations.

The sensitivity vector $d\bar{O}/d\mathbf{p}$ calculated with the proposed method agrees very well with those calculated by solving an additional adjoint equation. In other words, all components of the sensitivity vectors obtained from the two methods exactly match up to 7 significant figures as shown in Fig. 4.

Fig. 2. Dielectric material distribution for parallel plate waveguide. (a) Target model. (b) Reconstructed permittivity distribution.

Fig. 3. S_{11} plot of the target model, initial model, and reconstructed model.

Fig. 4. Comparison of the sensitivity obtained by the proposed and conventional method.

IV. CONCLUSION

This paper proposes a new methodology for optimal design and inverse problems of RF devices, where there is no need to solve the adjoint problem.

Abstract— The estimation of magnetic nanoparticle distributions is essential for their medical application. In this paper, novel spatio-temporal minimum norm approaches for this inverse problem are presented. These methods are quantitatively evaluated in simulations and compared to the conventional static technique. Our results indicate that the novel spatio-temporal approaches significantly improve the reconstruction quality.

I. INTRODUCTION

Medical applications of magnetic nanoparticles, like magnetic cell labeling, magnetic hyperthermia, magnetic drug targeting and tumor diagnosis, require the quantitative determination of distributions of these particles. Different approaches to this determination have been presented recently [1, 2, 3]. Our approach is based on magnetorelaxometry (MRX) [4]: The particles in the region of interest are magnetized by an externally applied magnetic field. After switching off this excitation field, the magnetic behavior of the particles is read out spatially resolved. From these measurements the distribution of the magnetic nanoparticles can be determined by means of inverse methods. Until now, inverse algorithms like the standard minimum norm estimation (MNE) were applied only to single time steps of the spatio-temporal signals. We propose a way to improve the reconstruction results by integrating the qualitatively known relaxation behavior. In this paper, reconstruction approaches incorporating both spatial and temporal information are investigated and compared to the conventional static inverse computation. In computer simulations, the reconstruction performance of these approaches is examined quantitatively.

II. INVERSE METHODS

A. Forward model

For all reconstruction approaches, the sources are approximated by multiple dipoles positioned on a regular grid below the measurement system. We use the magneto-static dipole to model the sources at the grid points. The magnetic field \vec{B} at position \vec{r} that is produced by a magnetic dipole at position \vec{r}' with moment \vec{m} (μ_0 is the permeability of free space) is computed according to

$$\vec{B}(\vec{r}) = \frac{\mu_0}{4\pi} \left(\frac{3\vec{m} \cdot (\vec{r} - \vec{r}')}{|\vec{r} - \vec{r}'|^5} (\vec{r} - \vec{r}') - \frac{\vec{m}}{|\vec{r} - \vec{r}'|^3} \right). \quad (1)$$

B. Static reconstruction approach

In the conventional static approach, the information on sensor positions and grid sources is merged to the leadfield (sensitivity) matrix L . To find the optimal dipole magnitude

vector \vec{m}_r , the difference between the forward computed field and the measurement vector \vec{b} has to be minimized:

$$\vec{m}_r = \arg \min_{\vec{m}} (L \cdot \vec{m} - \vec{b}) \quad (2)$$

\vec{m}_r can then be determined by a minimum norm estimation [5] using a Truncated Singular Value Decomposition (TSVD) method [6] neglecting singular values of L that are smaller than the regularization parameter σ_r :

$$\vec{m}_r = L_r^+ \cdot \vec{b} = (U \Sigma V^T)_r^+ \cdot \vec{b} = \sum_{i=0}^r \frac{\vec{u}_i^T \vec{b}}{\sigma_i} \vec{v}_i \quad (3)$$

C. Spatio-temporal reconstruction approaches

A simple model to approximate the temporal characteristics of MRX signals is the logarithmic decay [7], with the amplitude a and the relaxation time constant τ :

$$f(t) = a \cdot \ln\left(1 + \frac{\tau}{t}\right) \quad (4)$$

To incorporate this information in the inverse solution, three approaches were implemented:

- 1) Fit of measurement data channels to the model function (4) followed by minimum norm estimation on fitted amplitudes (3)
- 2) Static minimum norm estimation for every sample (3) followed by fit of estimated dipole magnitudes to the model function (4)
- 3) Spatio-temporal minimum norm estimation

For the last approach, the static forward model and therewith the leadfield matrix is expanded following Darvas et al. [8]. The spatio-temporal leadfield matrix L_T is computed as the Kronecker product of $f_T = (f(t_1), f(t_2), \dots, f(t_T))^T$ and L :

$$L_T = f_T \otimes L \quad (5)$$

Replacing L by L_T and \vec{b} by $\vec{b}_T = (\vec{b}(t_1), \vec{b}(t_2), \dots, \vec{b}(t_T))^T$ in (2) and subsequently applying the same TSVD method results in an estimated optimal relaxation amplitude for each dipole.

III. SIMULATIONS

For the evaluation of the performance of the spatio-temporal reconstruction techniques and the comparison to the conventional static approach, we perform simulations varying relevant parameters. We employ the setup of a 16 channel micro SQUID sensor system located at the BIOMAG centre Jena for our simulations, since this system has been involved in spatially resolved MRX experiments. The 16 sensors of the system are arranged in a rectangular area of 32 x 32 mm.

With respect to the low spatial resolution of the sensor setup, the simulated source is formed by a single dipole positioned 10 mm off the centre in both directions and 20 mm

below the sensor plane. The magnitude of the dipole decays following (4) with $\alpha=1 \text{ nAm}^2$ and $\tau=10 \text{ ms}$, which is consistent with measurement values. White Gaussian noise leading to different signal-to-noise ratios (SNR) is added to the simulated data and 50 simulation runs with different noise realizations are conducted. The added noise is realized independently to channels and samples, respectively. The goodness-of-fit (GOF_{nn}), i. e. the root mean square error between the field of the estimated sources and the respective noise-free input data, is selected as the figure of merit in this study.

IV. RESULTS

All spatio-temporal methods yield nearly identical results in the performed simulations with the given setup. Thus, in the following only the results of the third approach and the static approach are compared, respectively. Fig. 1 shows sample results of static and spatio-temporal reconstruction.

Fig. 1. Sample reconstructions for the static (left) and spatio-temporal (right) approach (SNR of input data: 20 dB; $\sigma_r = 0.05$). The \square identifies the position of the source dipole. All units are mm, step between isolines: $0.25 \cdot 10^{-12} \text{ Am}^2$.

The influence of the regularization parameter σ_r on the reconstruction quality is displayed in Fig. 2. Generally, the values are significantly higher for the spatio-temporal methods. Both spatio-temporal and static approach show the best values for $\sigma_r = 0.05$.

Fig. 2. Mean GOF_{nn} values for different values of the regularization parameter σ_r (SNR of input data: 10 dB; 50 simulation runs, $\text{SD} < 1.5$).

To quantitatively evaluate the sensitivity of the compared approaches towards noise, GOF_{nn} values for different SNRs in the simulated data are investigated (see Fig. 3). For all examined noise levels, the GOF_{nn} of the spatio-temporal approach is above 97 % and significantly larger than the value of the static approach. With increasing SNR, the difference between both methods decreases.

Fig. 3. Influence of noise on the reconstruction quality: Mean GOF_{nn} values for simulated data with different SNRs ($\sigma_r = 0.05$).

We also investigated the influence of the selection of the relaxation time constant in the model function of the spatio-temporal methods. As Fig. 4 shows, the GOF_{nn} decreases with the increasing deviation of the time constants of the inverse model function and the simulated data.

Fig. 4. Mean GOF_{nn} value for different time constants τ in the simulated data spatio-temporally reconstructed with a model function time constant of $\tau = 10 \text{ ms}$; the static approach is invariant to the temporal model function (SNR of input data: 10 dB; $\sigma_r = 0.05$; 50 simulation runs, $\text{SD} < 0.5$).

V. CONCLUSION

Our simulations show that the integration of temporal information in the reconstruction of magnetic nanoparticle distributions from MRX measurements considerably improves the reconstruction quality, regardless of the regularization parameter. The robustness against noise significantly increases. Even with slight deviations between the time constants in the inverse model function and the data, the spatio-temporal approaches still show better results than the conventional static approach.

Planned work comprises intensive studies on the properties of the spatio-temporal reconstruction approaches with respect to more complex model functions accounting for different relaxation processes and the size distribution of the particles.

Abstract—Electrical Resistance Tomography (ERT) is a body of methods and techniques aimed to reconstruct the spatial distribution of the conductivity of a material starting from the knowledge of boundary measurements such as, for instance, the Neumann-to-Dirichlet map. This inverse problem is ill-posed and nonlinear and, therefore, its solution require a considerable computational effort. In this paper we discuss three fast non-iterative reconstruction methods for locating inclusions in an otherwise homogeneous material. These methods, potentially, are candidate for near real-time applications.

I. INTRODUCTION

This paper is focused on the Electrical Resistance Tomography (ERT) to detect inclusions in conducting materials by non-iterative methods. Non-iterative methods have attracted a lot of interest because they provide a test for evaluating if a point of the domain (or a subregion) is part or not of the anomaly, regardless other points (or subregions). The test is usually very cheap from the computational viewpoint. On the other hand iterative methods, representing the most common approaches to inverse problems, update iteratively the current estimate of the spatial distribution of the conductivity. At each step of the algorithm at least one forward problem has to be computed thus, the computational cost is an issue and, moreover, the solution can be trapped in false solutions.

In ERT a major role is played by the Neumann-to-Dirichlet map that is the operator Λ mapping the boundary (applied) currents f into the boundary (measured) voltages $u|_{\partial\Omega}$, i.e. $\Lambda: f \rightarrow u|_{\partial\Omega}$ where

$$\begin{cases} \nabla \cdot \sigma \nabla u = 0 & \text{in } \Omega \\ \sigma \partial u / \partial \nu = f & \text{on } \partial\Omega \end{cases} \quad (1)$$

Ω is the conducting domain under investigation and ν is the outward normal on $\partial\Omega$.

It is well known (see [1]–[5]) that the inverse problem of reconstructing the conductivity σ from the knowledge of Λ has an unique solution when the conductivity satisfies some assumptions. In particular, here we face the reconstruction of piecewise smooth conductivities (for the uniqueness see [1]).

Here we assume a constant background conductivity constant conductivities into each inclusion. In addition, each inclusion occupies a simply connected domain with enough smooth boundary. The union of all inclusion is the set $B \subset \Omega$.

In this paper we are going to show three fast and non-iterative algorithms that we have implemented and a comparison of the related performances.

II. NON-ITERATIVE IMAGING METHODS

A. First method

The first algorithm is based on the factorization method proposed by Bruhl and Hanke in [6]. This method requires the knowledge of the background Neumann-to-Dirichlet map Λ_0 (i.e. the map when no anomalies are present in Ω) and the measured map Λ corresponding to the domain with defects.

In [6] and references therein, it is shown that a point $z \in \Omega$ belongs to an inclusion if and only if the boundary value $g_{z,d} = G_{z,d}|_{\partial\Omega}$ is in the range of $(\Lambda - \Lambda_0)^{1/2}$, i.e.:

$$\sum_{k=1}^{+\infty} \langle g_{z,d}, v_k \rangle^2 / \lambda_k < +\infty \quad (2)$$

where the v_k 's and λ_k 's are the eigenfunctions and eigenvalues of $\Lambda - \Lambda_0$, respectively and $G_{z,d}$ is the solution of:

$$\begin{cases} \Delta G_{z,d} = \Delta D_{z,d} & \text{in } \Omega \\ \partial G_{z,d} / \partial \nu = 0 & \text{on } \partial\Omega. \end{cases} \quad (3)$$

In (3) $D_{z,d}$ is the dipole potential:

$$D_{z,d}(x) = \frac{(z-x) \cdot d}{2\pi|x-z|^n}, \quad x \neq z \quad (4)$$

and d is a fixed but otherwise arbitrary unit vector.

B. Second method

The second method is an algorithm based on the Multiple Signal Classification method (MUSIC) that has been shown to be closely related to the Factorization method if small inclusions are considered [7]. The MUSIC algorithm has been developed by Devaney [8] to locate point scatterers from multistatic measurements in wave propagation inverse problems. The same principle can be applied to small cavities that can take the role of the point scatterers. If each inclusion centered in z_k is surrounded by a circle of radius εr_k , it is possible to show [7] that the Neumann-to-Dirichlet map Λ_ε converges to Λ_0 as $\varepsilon \rightarrow 0$ and that the range of the difference $\Lambda_\varepsilon - \Lambda_0$ is finite dimensional. In the limit for small ε , a point z is in the inclusion if and only if the function $g_{z,d}$ of II.B is in the range of $\Lambda_\varepsilon - \Lambda_0$. Therefore, the MUSIC algorithm constructs the spatial map:

$$\cot\theta(z) = \frac{\|Pg_{z,d}\|}{\|(I-P)g_{z,d}\|} \quad (5)$$

where P is the orthoprojector operator in the range of $\Lambda_\varepsilon - \Lambda_0$ and θ represents, geometrically, the angle between $g_{z,d}$ and the range of $\Lambda_\varepsilon - \Lambda_0$. By construction $\cot\theta(z)$ is very large when z is inside an inclusion because $g_{z,d}$ has a vanishing projection in the subspace orthogonal to range of $\Lambda_\varepsilon - \Lambda_0$, i.e. $(I-P)g_{z,d}$ is very small. In the presence of noise having level δ the orthoprojector P is reduced from the range of $\Lambda_\varepsilon - \Lambda_0$ to the linear space spanned by the first Ritz vectors of $\Lambda_\varepsilon - \Lambda_0$ whose Ritz values are greater than δ .

C. Third method

The third method is based on an imaging method developed by the authors in [9]. The method relies on the idea that inclusions with higher electrical resistivity increase the boundary voltages in some sense [10]. In particular, is possible to demonstrate the following monotonicity for the Neumann-to-Dirichlet map:

$$B_1 \subseteq B_2 \Rightarrow \Lambda_2 - \Lambda_1 \geq 0 \quad (6)$$

where \geq means positive semi-definite and Λ_k is the Neumann-to-Dirichlet map corresponding to anomalies occupying region B_k . The inversion algorithm [9] is based on:

$$\Lambda - \Lambda_{\text{test}} \geq 0 \text{ false} \Rightarrow \Omega_{\text{test}} \not\subseteq B \quad (7)$$

that follows directly from (6) where Ω_{test} is a generic test anomaly used to reconstruct the unknown anomaly B .

The imaging method checks (7) for different trial anomalies, for instance those obtained by partitioning the domain Ω in non-overlapped subsets (see figure 1). Then, it is possible to establish if a generic subset of this partition is part or not of the unknown anomaly B . Then, the reconstruction is the union of the subset that, through test (7), result to be included in B .

Test (7) can be performed by evaluating the sign of the eigenvalues of $\Lambda - \Lambda_{\text{test}}$. In order to avoid false negative due to the presence of noise that can alter the eigenvalues closer to zero, we associate to the test anomaly in subdomain k the following quantity (sign index):

$$s_k = \sum_j \lambda_{k,j} / |\lambda_{k,j}| \quad (8)$$

where $\lambda_{k,j}$ are the eigenvalues of $\Lambda - \Lambda_k$ and Λ_k is the Neumann-to-Dirichlet map related to test domain k . Then, the spatial map $1/(1 - s_k)$ reveals the presence of anomalies in the peaks.

III. NUMERICAL EXAMPLE

This preliminary numerical example is related to an almost rectangular inclusion embedded in a circle with a radius of 1cm. The defect has a resistivity that is 100% larger than those of the background. The synthetic data have been obtained by

an in-house FEM code. Random noise has been added to the numerically Neumann-to-Dirichlet map in order to avoid the inverse crime.

In the full paper we will give further details of the methods and we will propose an exhaustive comparison between these methods.

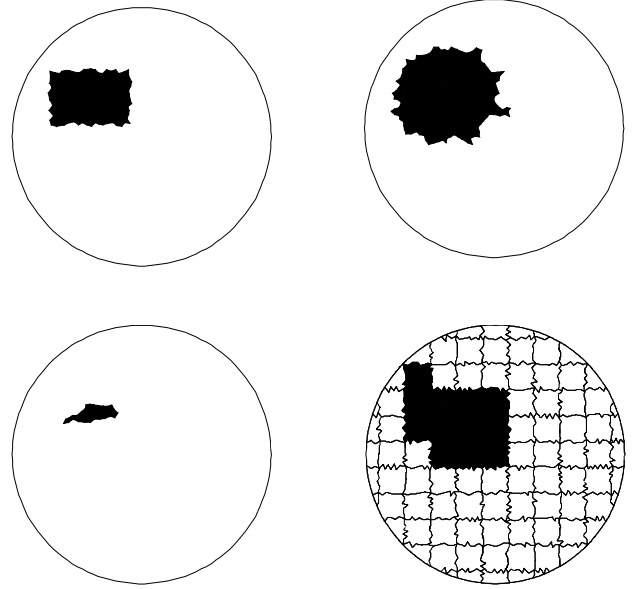

Fig. 1: Top: the real inclusion (left) and the reconstruction obtained by the factorization method (right). Bottom: the reconstruction obtained by MUSIC (left) and by the monotonicity method (right). The grid of the subdivision in test subdomains is also shown (bottom, right).

Abstract— This paper presents a new MRAM using perpendicular magnetic tunnel junction device about shape optimization for high capacity. Conventional MRAM need more increasing current power as smaller size for high capacity. It is critical problem that need more increasing current power. As a solution, we propose a new MRAM that has two additional high permeable poles in this paper. Proposed new MRAM has a strong switching field owing to two poles added on both sides of the free layer, just like perpendicular magnetic recording heads. For high Gb/Chip, by change of shape design, new MRAM can have a strong switching field on the same injected current. We show results that are variation of a switching field owing to two poles added on both sides of the free layer by thickness of the free layer and cell square size, injected current density. So we present an optimization design of new MRAM for high Gb/Chip. This research was done using three dimensional FEM with injected current density of $5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$.

I. INTRODUCTION

Partly because conventional MRAM has a faulty structure using a simple write current injection system, magnetoresistive random access memory (MRAM) is reducing its expectation as a commercial non-volatile memory. For downsize scalability, the major problem that is the mere write current is required at the smaller bit size should be solved with a new design [1]-[2]. STT MRAM technology has advantages conventional (toggle) MRAM on injected current and cell size. STT writing technology, by directly passing a current through MTJ, overcomes these hurdles with much lower switching current, simpler cell architecture which results in a cell that can be as small as 6F2 (for single-bit cells) and reduced manufacturing cost, and more importantly, excellent scalability to future technology nodes [3].

In this paper, we presents a new technology that has advantages conventional MRAM on injected current and cell size. It is Pole Type Perpendicular MRAM (PTP MRAM). PTP MRAM uses perpendicular magnetic field in order to change the state of the free layer in a perpendicular magnetic tunnel junction (pMTJ) [4]-[5]. PTP MRAM uses two high permeability poles on both sides of the free layer in order to enhance switching field. Switching filed of conventional MRAM generated by injected current is equally distributed on the space but most of the field in PTP MRAM passes through the additional poles with high permeability. PTP MRAM has downsize scalability and is expected to be utilized usefully as a commercial memory with high capacity for having the enhanced switching field. Also PTP MRAM solves thermally assisted self-demagnetizing problem because this system is able to use high coercivity free layer.

We show results that are variation of a switching field owing to two poles added on both sides of the free layer by thickness of the free layer and cell square size, injected current density. So we present an optimization design of new MRAM for high Gb/Chip. This research was done using three dimensional FEM with injected current density of $5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$.

II. THE PTP MRAM CELL

Fig. 1 shows a schematic drawing of the PTP MRAM element. PTP MRAM element has two poles added on both sides of the free layer. The material of these poles has high permeability and then this system is able to have enhanced switching field. We call bit pole for the one on top of the free layer and word pole for the other beneath the free layer. Both poles have a single current line at the side. PTP MRAM has pMTJ on the bottom of the word pole. Fig. 2 (a) ~ (c) describes the write process of PTP MRAM. Memory status is “0” in fig. 2 (a) because having same direction of magnetization in the free layer and the fixed layer. When bit current and word current are injected. Magnetization of the free layer is changed rapidly by the switching field assisted by the bit pole and word pole as fig. 2 (b). Finally the state of the free layer is changed like fig. 2 (c) and then the cell has the status “1”. Usually the name of pMTJ stands for a set of free layer, fixed layer and junction but in this paper pMTJ shows only junction part like fig. 2 (d).

Fig. 1. Schematic drawing of the PTP MRAM cell. PTP MRAM has a two high permeability poles added on both sides of free layer, named bit pole on top of free layer and word pole beneath the free layer. This system has the pMTJ beneath the word pole and fixed layer is poisoned beneath the pMTJ.

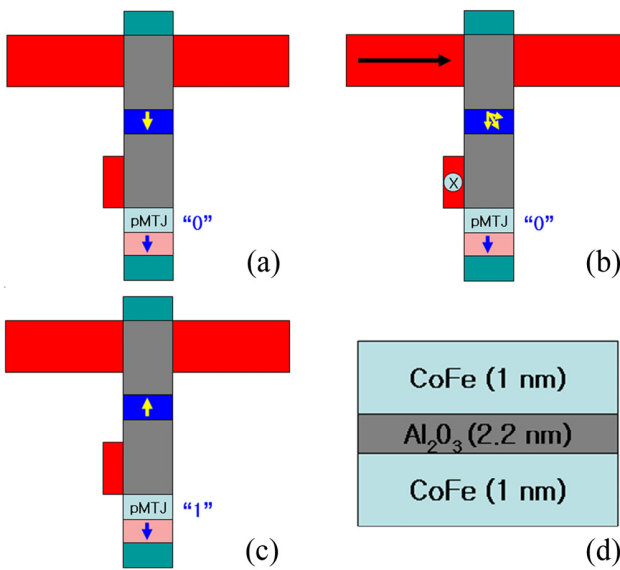

Fig. 2. . Write process of the PTP MRAM and structure of the pMTJ. (a) shows "0" status. When direct current is injected in bit and word line, status of free layer is changed like (b). Finally status of the free layer is stabilized to be "1" status as (c). (d) shows the structure of the pMTJ.

III. RESULT AND DISCUSSION

The PTP MRAM has superior magnetic field efficiency than conventional MRAM because this novel system has additional high permeability poles, which are expected to generate stronger switching field than conventional MRAM system. So this system has downsize scalability and high coercivity magnet can be used in the free layer. Figure 3 shows magnetic field intensity on the center of the free layer in PTP MRAM and conventional MRAM with direct current densities $I = 5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$. Clearly the stronger switching field is generated in PTP MRAM than in conventional MRAM at the same direct current.

Fig. 4 shows a result that is magnetic field intensity by changing free layer thickness on the center of the free layer of PTP MRAM with a direct current densities factor $I = 5 \times 10^6 \text{ A/cm}^2$. We can know that switching field will be strong for decreasing free layer's thickness of the PTP MRAM. But to

Fig. 3. Comparison of magnetic field intensity on the center of the free layer of PTP MRAM and conventional MRAM with a direct current densities factor $I = 8 \times 10^7 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$. Clearly the graph shows PTP MRAM has a stronger field than conventional MRAM on the same current density injected.

TABLE I
MAJOR SPECIFICATIONS USED FOR CALCULATIONS

	Single Current Type
Cell Square Size	50 nm (W) X 50 nm (H)
pMTJ Thickness	2.2nm
Fixed Layer Thickness	30 nm
Free Layer Thickness	10 ~ 30 nm
Metal Contact Thickness	30 nm
Pole Length	400 nm
Cell Gap	50 nm
Current Line Cross-section	50 nm (W) X 400 nm (H)
Current Range	$5 \times 10^6 [\text{A/cm}^2]$

Fig. 4. Results of magnetic field intensity by changing free layer thickness on the center of the free layer of PTP MRAM with a direct current densities factor $I = 5 \times 10^6 \text{ A/cm}^2$.

Free layer's thickness increases the coercivity.

IV. CONCLUSION

We present an optimization design of new MRAM for high Gb/Chip. This research was done using three dimensional FEM with injected current density of $5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$. Next time, research will more be optimizing the switching field and injection current.

Brain source localization: a MILP approach

Fabio Freschi

Department of Electrical Engineering

Politecnico di Torino, Italy

Email: fabio.freschi@polito.it

Abstract—The purpose of this work is to propose and test a mixed integer linear programming formulation for the problem of brain source localization. Such technique allows the localization of the minimum number of currents that are able to reconstruct potentials recorded at the scalp. The algorithm makes use of binary variables in order to be less sensible to noise on input data. Some preliminary simulation results show that the algorithm is effective in source localization and robust with respect to errors on measurement data.

I. INTRODUCTION

The localization problem of brain sources from scalp potential recordings is a key problem in computational bioelectromagnetism, and its solution is an active research field [1]. Primary sources are generally modeled as ideal point current dipoles.

In the up-to-date literature the source location inverse problem from the knowledge of scalp potentials is commonly solved by Nelder-Mead simplex method [2]. The functional to be minimized is a suitable norm of the reconstruction error. The main disadvantages of the simplex method is that it requires multi-start and it can fail when the nodes of the simplex fall inside a single element. It is possible to overcome these drawbacks with a proper formulation of the problem. In fact, there are classes of problems, *e.g.* convex problems, that can be solved with deterministic techniques, that guarantee the reaching of the global solution in a finite number of steps.

This work describes a mixed integer linear programming (MILP) formulation of the brain localization problem and some results on a simulation test case are presented and discussed.

II. IDENTIFICATION ALGORITHM

A. Direct problem

When modeling neural sources, it is widely adopted the static approximation of current conduction equation (displacement currents are usually neglected). Under the hypothesis of stationary field, the problem can be described by the Poisson equation in terms of electric scalar potential φ :

$$\nabla \cdot (\sigma \nabla \varphi) = \nabla \cdot \vec{J}_s \quad (1)$$

where \vec{J}_s are the source current densities. In this work, (1) is discretized by means of the cell method [3]. The algebraic counterpart of stationary current field Poisson equation, is:

$$\tilde{\mathbf{D}}\mathbf{M}_\sigma\mathbf{G}\varphi = \mathbf{A}\varphi = \tilde{\mathbf{D}}\mathbf{i}_s. \quad (2)$$

\mathbf{G} is the discrete gradient operator (edge-to-node incidence matrix), \mathbf{M}_σ is the conductance constitutive matrix (diagonal when hexahedral discretization is adopted), $\tilde{\mathbf{D}} = -\mathbf{G}^T$ is the discrete (dual) divergence operator, \mathbf{i}_s the source current vector. It is worth noting that the number of elements in \mathbf{i}_s equals the number of edges in the mesh.

B. Lead field matrix

The solution of the inverse problem requires the definition of the so called *lead field matrix* \mathbf{L} [4], the linear operator that maps the source vector to the vector of scalp potentials. If \mathbf{A}^{-1} is a suitable factorization of the stiffness matrix (*e.g.* obtained by Cholesky factorization), potentials can be calculated by:

$$\varphi = \mathbf{A}^{-1}\mathbf{G}^T\mathbf{i}_s. \quad (3)$$

Since the reconstruction problem starts from the knowledge of potentials in a subset $\hat{\varphi}$ of surface potentials that belong to electrodes, a projection matrix \mathbf{P} is defined, such that:

$$\hat{\varphi} = \mathbf{P}\varphi. \quad (4)$$

In addition the localization problem can be appropriately guided by some *a-priori* information on the localization of brain sources, *e.g.* coming from functional magnetic resonance imaging [1]. From a mathematical point of view, it is possible to define an interpolation matrix \mathbf{Q} that expands the restricted vector of current sources to the complete vector of sources:

$$\mathbf{i}_s = \mathbf{Q}\mathbf{i}_r. \quad (5)$$

By collecting (3), (4) and (5) the reconstruction problem can be formulated as:

$$\hat{\varphi} = \mathbf{P}\mathbf{A}^{-1}\mathbf{G}^T\mathbf{Q}\mathbf{i}_r = \mathbf{L}\mathbf{i}_r. \quad (6)$$

The system (6) is under-determined, since the number of electrodes is typically smaller than the number of possible current sources.

C. Mixed integer linear programming

In this work the attention is focused on a single current dipole lying parallel to one of the coordinate axes. Under this hypothesis it is possible to formulate the source localization problem as a MILP.

The vector of unknowns is made by a current value i_k (continuous) and a binary value δ_k for each edge k . These variables are linked by the relation:

$$-I_{\max}\delta_k \leq i_k \leq I_{\max}\delta_k. \quad (7)$$

TABLE I
GEOMETRY AND TISSUE PROPERTIES

tissue	outer radius	conductivity
	cm	S/m
scalp	9.2	0.43478
skull	8.74	0.00625
CSF	8.28	1.538
gray matter	7.82	0.3334
white matter	7.37	0.1428

Variable δ_k defines the on/off status of the k th edge current. The novelty of the proposed algorithm is to impose the identification of electrode potentials as constraint and not as objective. To be less prone to measurement uncertainties on scalp potentials, (6) is reformulated as inequality constraint¹:

$$(1 - \alpha) \hat{\varphi}^{\text{meas}} \leq \mathbf{L}\mathbf{i}_r \leq (1 + \alpha) \hat{\varphi}^{\text{meas}} \quad (8)$$

where $\alpha > 0$ is an estimation of measurement uncertainties and $\hat{\varphi}^{\text{meas}}$ are the measured potentials. When noise is present, a common problem in reconstruction algorithms is the raise of spurious sources that compensate the potential fluctuations with respect to the exact values. These undesired effects are mitigated by the definition of the objective function. The linear algorithm should minimize the number of sources, that can be formulated as a linear combination of the binary variables:

$$\min \sum_k \delta_k \quad (9)$$

By the definition of objective (9) and constraints (7), (8), the MILP algorithm searches for the minimum number of currents that matches the recorded potentials with the desired precision.

III. CASE STUDY

The test case is a modified five-layer spherical model (Fig. 1(a)), whose geometrical and material parameters are reported in Table I. The discretization is characterized by 61565 hexahedra and 67368 nodes. 17 electrodes are regularly placed on the upper half of the outer sphere (Fig. 1(b)), while a current dipole of $100 \mu\text{Am}$ is randomly placed on the outer surface of gray matter. This corresponds to have 8068 possible locations for currents. In order to prove the robustness of the algorithm with respect to measurement errors, a random white noise is added to scalp potentials. Noise amplitude is progressively increased from 0% to 25% of the signal values. In all cases the algorithm is capable of detecting a single source and locating the exact position of the current dipole, with a maximum error on current magnitudes lower than 8% (Fig. 2). The average computational times of the different MILP phases for this case are: LP relaxation 27 sec, generation of cuts 16 sec, branch and bound 184 sec. Search is performed by Xpress-IVE software [5] on a Intel Core 2 Duo, 2.4 GHz with 4 GB of RAM.

¹Equation (8) holds when $\hat{\varphi}^{\text{meas}} > 0$, otherwise inequality signs must be reversed.

Fig. 1. Geometry: (a) vertical cut showing 5 tissues and (b) position of electrodes.

Fig. 2. Error on current magnitude for different random noise on scalp potential measurement.

IV. DISCUSSION AND FUTURE WORK

The proposed method is effective in reconstructing scalp potential due to a single dipole. By suitably using binary variables, the algorithm has proved to be robust with respect to noise on input data. It has been shown the possibility of introducing some knowledge in the search by an appropriate definition of the interpolation matrix \mathbf{Q} .

These promising preliminary results will be extended in the full paper, where a more accurate simulation protocol will be followed. In particular there will be shown how the algorithm can be extended to sources with arbitrary orientation, by the definition of nodal currents. Moreover, the scalability of the algorithm with respect to the number of sources and the model resolution will be analyzed. Finally some simulations will be performed on a realistic head model in order to verify the effects of complex geometries on the algorithm performances.

A Hybrid Design of Distribution Transformers Using 2D-FE and a Conventional Method

M.A. Arjona, *IEEE Senior Member*, C. Hernández, *IEEE Member*

Instituto Tecnológico de la Laguna, División de Estudios de Posgrado e Investigación

Blvd Revolución y Calz. Cuauhtemoc, 27000, México

Abstract— Integrating Finite Elements into the design procedure of electromagnetic devices has always been a challenge for researchers and design engineering community. This paper presents the application of a hybrid method that involves the application of conventional design methodology and two-dimensional finite elements. The optimization is carried out using a Genetic Algorithm which allows finding the global minimum and then a determinist algorithm is used to find the final solution. The methodology is illustrated in the design of a 1500 kVA distribution transformer.

I. INTRODUCTION

The necessity of being competitive in global marketing has led transformer manufacturers to require computing systems with the capacity to produce rapidly: optimal, reliable and feasible transformer designs. These systems constitute a powerful tool for manufacturers that are willing to have in their design departments in their constant search for: (a) saving experimented engineering-design man-hours, (b) increasing their design capacity, (c) reducing the delivery cycle and (d) optimizing the use of materials. This is particularly true in cases where the reduction of fabrication costs and the payment of specialized engineer salaries may define the survival of a small factory.

Traditional design methods consist of calculating losses, leakage impedance and magnetizing current with approximate formulae which most of the cases are derived from empirical knowledge owned by the experimented designers. With the appearance of numerical methods, as the Finite Elements (FE), the electromagnetic performance of transformers can be predicted with higher accuracy. Using FE models in optimization has always been a challenge for the electromagnetic analysts, being the computation time one of the main obstacles.

This paper uses both approaches, i.e. traditional methodology and FE models, which when properly combined; it can lead to better designs. A Genetic Algorithm (GA) is used firstly with the conventional-design equations; this allows finding an approximate global solution. Afterwards, a deterministic method uses the obtained design model and employs FE models for calculating iron and winding losses, leakage reactance and magnetizing current. The hybrid methodology is tested in the design of a 1500 kVA, 13.2/0.22 kV three-phase distribution transformer.

II. TRADITIONAL DESIGN METHODOLOGY

The general problem of design may be defined as that of determining the most suitable form of the transformer [1],[2].

An optimal design is not obtained simply by the solution of a set of equations; it requires iterations. The sinusoidal induced voltage, V , in any transformer winding is given by:

$$V = 4.44NfB_m A_c \quad (1)$$

where N represents the number turns, f the frequency (Hz), B_m is the amplitude of sinusoidal flux density (Teslas) and A_c denotes the net cross section area (m^2) of the iron carrying the sinusoidal flux.

The transformer has different voltage levels; therefore it is needed to determine the electric clearances of windings, coils, core and yoke to avoid insulation failure due to high electric field stresses. Dimensions of ventilation ducts between groups of coils are also taken into account at this stage, which will be dependant on the type of transformer. The total number of calculated turns must be accommodated in the transformer window area, thus an initial distribution of windings must be computed. A distribution transformer must satisfy a set of design constraints to avoid penalized costs from the customer. These constraints are: a) efficiency, b) percentage of leakage impedance, and c) no-load current. In addition, the designer must guarantee the specified electrical power of the unit. The dc resistance loss of a single winding was calculated with the following equation

$$P_R^w = \frac{J^2 \rho m_{cu} \times 10^9}{\rho_{d,cu}} \quad (2)$$

where J stands for the current density (A/mm^2), ρ denotes the conductor resistivity ($\Omega\text{-mm}$), m_{cu} is the copper weight (kg) and $\rho_{d,cu}$ is the density of cooper (kg/m^3). The copper weight can be computed with

$$m_{cu} = \rho_{d,cu} N l_m s \quad (3)$$

where l_m is the length of mean turn (m) and s is the cross-sectional area of a conductor (m^2). It must be recalled that total joule loss is three times the joule loss of a phase (low and high voltage windings).

The total winding loss is

$$P_{cu} = P_R + P_{eddy} \quad (4)$$

where P_R and P_{eddy} denotes total joule and eddy current winding losses, respectively.

$$\%R = P_{cu} \times 100/S \quad (5)$$

$$\%X = fIN \left(s_0 + \frac{s_1 + s_2}{3} \right) \cdot 8 \times 10^{-5} / (hE/N) \quad (6)$$

$$\%Z = \sqrt{(\%R)^2 + (\%X)^2} \quad (7)$$

$$\eta = \left[1 - \frac{(P_{fe} + P_{cu})}{(S \cdot PF + P_{fe} + P_{cu})} \right] \times 100 \quad (8)$$

where S stands for the rating transformer power (VA), s_{0-2} (mm^2) denote mean turn diameters multiplied by the gap of between windings and thickness of primary and secondary windings respectively. P_{cu} represents the total winding losses, PF denotes the power factor and P_{fe} is the no-load loss (W) obtained from the magnetizing curve and core flux density data. Although a transformer is a simple device, its numerous, highly interrelated and heterogeneous design parameters make a closed-form solution to the design problem impossible.

III. HYBRID DESIGN OPTIMIZATION

The hybrid design consists in using stochastic optimization with conventional design procedures, as briefly explained in the last section, and deterministic optimization with FE models as it is illustrated in Fig. 1. The improved design calculations employing FE models are: leakage reactance, magnetizing current, eddy losses and no-load losses. Leakage reactance and winding eddy current loss are calculated using an asymmetric model of the transformer. No load losses are obtained with a voltage fed cartesian FE model without load, the same model is used for estimating the magnetizing current. The summary of equations needed for making the above calculations are [3]:

$$\frac{\partial}{\partial z} \frac{v}{r} \frac{\partial(rA)}{\partial z} + \frac{\partial}{\partial r} \frac{v}{r} \frac{\partial(rA)}{\partial r} + \frac{j\omega\sigma}{r}(rA) = J_s \quad (9)$$

$$\begin{bmatrix} S + j\omega N & -P \\ j\omega Q & R + j\omega L \end{bmatrix} \begin{bmatrix} A \\ I_w \end{bmatrix} = \begin{bmatrix} 0 \\ V_e \end{bmatrix} \quad (10)$$

where S is the FE stiffness matrix, P and Q are weighting winding matrices, R is the external resistance, L external inductance, I_w a vector of winding currents, V_e denotes the external potential sources, A represents a vector of complex potentials, ω is the angular frequency, v stands for the reluctivity, r is radius, J_s is the source complex current and σ is the electric conductivity.

A GA was used to solve the equation related to the conventional design. A GA is a stochastic method that employs probabilistic and non-local search heuristics that simulate natural evolution, which works on the chromosomes [4]. When the convergence is reached, an optimization with the Gauss-Newton method is launched where FE models are used. The proposed methodology was applied to the design of a 1500 kVA, 13.2/0.22 kV three-phase distribution transformer and the achieved results are shown in Table I.

IV. CONCLUSIONS

This paper has presented a novel approach that combines the conventional design method of transformers with 2D-FE models to improve calculations. Firstly, a Genetic Algorithm is used until a solution is found using the conventional model and then the optimization is switch to the Gauss-Newton. By using this approach, better designs results in a shorter period

of time are achieved because finite element models are employed in the last step of the optimization process.

TABLE I
HYBRID OPTIMIZATION DESIGN RESULTS

Design variable	Optimization	
	GA Conventional	Gauss-Newton FE-Conventional
Efficiency (%)	98.963	98.952
No load loss (%)	0.154	0.154

Inverse Magnetic Field Calculation For Underground Grid Condition Monitoring

S. Salon, MVK Chari, J. Braunstein, J. Selvaggi
 ECSE Department RPI
 Troy, NY 12180-3590
 salon@rpi.edu

Abstract— This paper illustrates the methods which were developed to diagnose and evaluate the condition of the grounding grid used in electric substations. The grid is made of copper conductors which are buried to a depth of typically up to 2 meters. The safety of the substation depends on the continuity of the grounding grid where direct visual inspection of the grounding grid is not possible. RPI has developed an inverse method which can be used to detect breaks in the underground grid as well as the location of the buried conductors. We have performed forward and inverse calculations and have made field measurements on a simulated grid and at a substation.

I. INTRODUCTION

A schematic of a substation grounding grid is shown below in Figure 1. The substation equipment such as transformers, switchgear, towers, etc is grounded and to ensure a low resistance ground a grid of copper conductors is buried underneath the substation. Each piece of equipment and tower is connected to this grid, which in turn is connected to grounding rods down into the water table. Since the safety and security of the substation depends on the proper operation of this grid, we must insure that it has not degraded over time or the welded connection have broken [1]-[3].

Figure 1: Schematic of Substation

II. ANALYSIS

The grid is usually set out in a rectangular pattern with allowance made for the location of the substation equipment. In the initial phase of the investigation we solved the forward problem [4]. This was to insure that a good signal could be

picked up at the surface. Current was injected into the grid at one corner and removed at the other. The current distribution was found including resistive and inductive effects and the skin effect in each of the conductors. The grid is shown in Figure 2.

Figure 2: Test Grid

The results (magnitude of the Flux Density) at 200 mm above the grid is shown in Figure 3. We see that the shape and size of the grid are clearly visible and the magnitude of the field was in a range that is easily measured. In the case of a healthy grid, the signature is symmetric.

Figure 3: Flux Density for Healthy Grid

We explored various faults and excitation patterns which will be detailed in the full paper. The case of the excitation of Figure 2 with 3 faults is shown in Figure 4.

Figure 4: Results with 3 Faults

The indentation for subheadings is 0.1 in.

III. INVERSE PROBLEM

We now turn to the inverse problem. If we assume a set of loop currents in the grid, we can find the influence functions that give the flux density at the field points in terms of the unknown currents. If we have breaks in the grid, the currents in the affected branches will naturally be zero.

Figure 5: Set-up For Inverse Problem

After much algebra (included in the full paper) we obtain

$$\begin{Bmatrix} B_1 \\ \vdots \\ B_n \end{Bmatrix} = \begin{pmatrix} a_{11} & \dots & \\ \vdots & \ddots & \vdots \\ & \dots & a_{nn} \end{pmatrix} \begin{Bmatrix} i_1 \\ \vdots \\ i_n \end{Bmatrix}$$

We solve this full matrix for the loop currents and then convert this to branch currents. Results from this method confirm that the currents can accurately be found from good measurements.

Another type of inverse problems allows us to take surface measurement and then locate the path of the conductor. Figure 6 shows actual flux density measurements taken at a substation and the final path computed by our algorithm. In this case, the current in the conductor is known and the algorithm finds the path. The development will be given in the full paper.

Figure 6: Measured Flux Density and Calculated Conductor Location

IV. CONCLUSIONS

We introduce the idea of using surface field measurements to diagnose the integrity of the grounding grid. The forward problem shows that we can diagnose problems with the grounding grid. We illustrate 2 types of inverse problems. In the first one we take field measurements with an assumed geometry and show that we can find the branch currents. In the second example we take real data and locate the path of the underground current. The indication is that field measurements can be a valuable technique to diagnose problems in the grounding grid.

Abstract— This paper presents a practical methodology of finding a robust optimal solution for a multi U-slot PIFA(Planar Inverted F-Antenna) structure with triple bands of 433 MHz, 912 MHz and 2.45 GHz. Using evolutionary strategy, a global optimum is first sought out in terms of the lengths and widths of the slots and the shorting strip. Then the optimized values are modified by Taguchi quality method in order to obtain robustness against the change of material constant and feed position. To verify the method, the performance of the antenna is accurately predicted by general-purpose electromagnetic software and optimized results are thoroughly examined compared to the initial design.

I. INTRODUCTION

The success of wireless communication service is heavily dependent on the development of reliable RF components. As a core of RF components, the antenna should satisfy various demands for small size as well as versatile functions. Especially, multi-band function is needed to provide the RF systems with flexibility and mobility in wide use. Up to date, intensive research has been carried out to find an efficient and reliable structure of multi-band RFID antennas, which works well regardless of standard frequencies used. As part of the efforts, U-slots are adopted to get multi-band characteristic, where a parametric study is conducted to seek proper design parameters starting with the approximated formula on resonance frequency [1]. In other works, a U-slot based PIFA structure is used but it usually requires a lot of computing time because of the three-dimensional (3D) structure itself [2].

This paper proposes a practical methodology of finding a robust optimum for a U-slot based PIFA structure with triple bands 433MHz, 912 MHz and 2.45 GHz. To achieve this, Taguchi quality method (TM) is complemented with evolution strategy (ES) algorithm. An initial design starts with two U-slots in the metal patch on the substrate located above the ground. The lengths and widths of the two U-shaped slots and position of the shorting vertical strip are selected for design parameters during ES optimization[3]. The optimized design yields better performance than the initial one alone with 3D electromagnetic simulation. However, it cannot give a guarantee of the optimized design because there are fabrication errors in real world that may deteriorate good performance predicted

Therefore the optimized values from ES should be modified to become insensitive to possible changes in the coaxial feed position (FP) and the permittivity of the substrate (PS), which are uncontrollable factors in reality. Applying TM to the design optimized by ES, robust optimal values are obtained to take into account the noise factors of FP and PS.

From results, it is confirmed that the final design produces satisfactory performances especially in terms of robustness to the noise factors.

II. PRACTICAL APPROACH TO ROBUST DESIGN

This paper proposes a practical approach to achieving a robust optimal solution of triple-band antenna structure, where Taguchi method (TM) is complemented with evolution strategy (ES) algorithm. In general, it is difficult in seeking out an optimal solution in infinite design space only by Taguchi method because of its restriction on the number and level size of design parameters. To overcome the drawback, (1+1) evolution strategy is first utilized in order to find a global optimum for an initial design considered. Then the robust optimization by Taguchi method is executed with the optimal design values previously obtained from the evolution strategy. After all, the proposed method can give a robust design target around the global optimum while keeping the product performance insensitive to the effects of noise factors that may appear in manufacturing process. The procedure of the robust optimization proposed involves four main stages.

- 1) Defining design parameters and objective function and executing evolution strategy algorithm for searching a global optimum.
- 2) Selecting sensitive parameters based on the above as well as noise factors.
- 3) Setting the optimal solution as an initial design and executing numerical experiments according to orthogonal array.
- 4) Using analysis of mean (ANOM) and variance (ANOVA) techniques to obtain optimal setting of parameters for robust design.

Then, the robust optimal solution is investigated in terms of the concepts of signal-to-noise (SN) ratio and loss function

III. RESULTS

A. Analysis model

The geometry of the problem is illustrated in Fig. 1 where a metalized patch lies on top of the substrate located above the ground plane. The metal patch is connected to the ground plane by means of the shorting strip and the coaxial feed. Such the PIFA resonates around certain frequencies suggested by the approximate formula presented in [1] and [2]. Here the initial geometry of the patch is decided for 433 MHz resonance. Then the initial lengths and widths of the U-shaped slots are roughly determined for the radiation at 912 MHz and 2.45 GHz. To accurately predict the performance of the

antenna, the 3D EM simulation technique in the time-domain, FIT are used with the perfect matched layers (PMLs).

Fig. 1. Configuration of the triple-band PIFA structure

B. Size optimization using evolution strategy

Among 6 design parameters shown in Fig. 1, four crucial parameters, W2, L2, W3 and L3, forming U-shaped slots are selected for size optimization using (1+1) ES. The design goal is to obtain optimal slot dimensions for triple-band PIFA at frequencies of 433, 912 and 2,480 MHz. To achieve this, the multi-objective function with constraints is defined as:

$$\text{Minimize } F = \sum_{i=1}^3 \alpha_i (|f_i - f_{oi}|)^2 \quad (1)$$

subject to $S_{11}(f_i) \leq -15$ dB

where α_i is weighting factor, f_i band frequency computed at each design iteration, f_{oi} target frequency value and S_{11} reflection coefficient. For saving computing time, the design parameters are forced to be selected from finite integer sets.

The initial and optimized design values are presented in Table I and the reflection coefficient values are compared in Fig. 2. From the results, it is observed that the performance of the optimized design coincides well with the design goal even though only the integer values are permitted for design parameters. But, at this stage, we have no idea of how robust the optimum is.

TABLE I. DESIGN PARAMETERS AND PERFORMANCE

Parameter	Unit	Initial values	Optimal values
W2	mm	41	50
L2	mm	41	43
W3	mm	15	13
L3	mm	15	16
Frequency / S_{11}	MHz	439.5/-25.15	430/-40.82
	dB	981.5/-15.90	910.5/-27.22
		2,563/-7.13	2458.5/-16.24

Fig. 2. Comparison of reflection coefficient before and after EV optimization

C. Robust optimization using Taguchi method

Starting with the optimized design by ES, robust optimization is carried out by Taguchi method in order to find a new optimal solution insensitive to noise factors. For the four design parameters, the x and y coordinates of feeding point and substrate permittivity are considered as noise factors.

Based on the number of design and noise parameters and the settings considered in Table II, a standard orthogonal array $L9(3^4 \times 3^4)$ was selected for the matrix numerical experiments, where the parameters are assumed to be mutually independent.

For the “nominal the best characteristic” case, which resembles the minimization of the performance (1), the SN ratio can be calculated by

$$\text{SN ratio} = -10 \log(\bar{y}_i^2 / V_i) \quad (2)$$

where \bar{y} and V denote the mean and variation of performance values, respectively and the subscript i belongs to the i th row of the orthogonal array used. Through the somewhat routine process of Taguchi quality control, an optimal setting of the design parameters can be determined. It is revealed that the performance deviation (i.e. robustness) predicted from the setting improved by more than 70% compared to the optimized design in ES. Fig. 3 compares the reflection coefficient profiles before and after robust design procedure.

TABLE II. DESIGN AND NOISE PARAMETERS FOR THE FIRST SETUP

Type	Parameter	Level		
		1	2	3
Control Factor	W2 (mm)	49.8	50	50.2
	L2 (mm)	12.9	13	13.1
	W3 (mm)	42.8	43	43.2
	L3 (mm)	15.9	16	16.1
Noise Factor	Feeding point x coordinate	-0.1	0	0.1
	Feeding point y coordinate	-0.1	0	0.1
	Substrate permittivity (ϵ_r)	4.36	4.4	4.44

Fig. 3. Comparison of reflection coefficient before and after robust optimization

IV. CONCLUSION

A practical approach to robust optimization of triple-band antenna structure is proposed, where TM is complemented with ES algorithm. From results, it is referred that the final design is insensitive to noise factors and also nearly close to the global optimum. Our extended paper will include comparison of experimental and simulated data.

Abstract — Patterned ground shield of on-chip spiral inductor is designed using deterministic optimization method. Separation between inductor and ground strip is modified during design process, as well as widths of ground strips and slots. For sensitivity analysis, approximate adjoint variable method is used. Significant increase in Q -factor is observed in final design while reduction of inductance is minimal.

I. INTRODUCTION

On-chip spiral inductors are widely used in a variety of radio frequency integrated circuits (RF IC's). For spiral inductors in silicon-based RF IC's, substrate loss at high frequencies can degrade quality factor (Q). Also, noise coupling may appear at gigahertz frequencies. One of the popular design techniques to alleviate this problem is to insert a patterned ground shield (PGS) to block inductor electric field from entering the silicon [1]. Patterned slots on the PGS cut off the path of induced loop current, hence reducing disturbance of inductor magnetic field.

When designing spiral inductor with PGS, many parameters should be considered including widths of ground strips and slots, separation between spiral and ground shield, and number of overlap turns between ground strip and inductor. So far, these design variables were determined by trial and error in most cases, resulting in high design cost and time.

In this paper, deterministic optimization method is applied to the optimal design of PGS of on-chip spiral inductor. Design goal is to maximize Q -factor while keeping inductance reduction minimal. Sensitivity analysis of objective function is performed by approximate adjoint variable method.

II. DESIGN OF SPIRAL INDUCTOR WITH PGS

Fig. 1 explains improvement of Q -factor of spiral inductor with PGS. Electric field of inductor in substrate direction is blocked by a ground shield and dissipation loss is reduced. Magnetic field disturbance is small because eddy current on ground shield is suppressed by patterned slots.

L_s and R_s denote inductance and resistance of the line and coupling capacitance between overlapping lines are written as C_s . Capacitance of oxide layer between silicon board and line is modeled by C_{ox} , and parasitic capacitance and resistance of silicon board are modeled by C_{si} and R_{si} , respectively [2].

Electromagnetic simulation of inductor will significant error compared to the measurement if the material parameters are

entered inaccurately. In order to obtain EM simulation result similar to the TSMC process, accurate electric conductivity of the inductor substrate is determined by evolution strategy (ES).

(a) Picture of Spiral inductor with patterned ground shield

(b) Equivalence circuit of Spiral inductor

Fig. 1. Schematic picture of spiral inductor with patterned ground shield.

The objective function F is expressed by a function of Q -factor and inductance, where Q is given by

$$Q = 2\pi \times \frac{\text{magnetic energy stored}}{\text{energy loss in one cycle}}. \quad (1)$$

Sensitivity of objective function F with respect to design variable p is calculated using approximate adjoint variable method [2] and written as

$$\frac{\partial F}{\partial p_n} \approx \frac{\partial^e F}{\partial p_n} - \int_0^{T_{\max}} \iiint_{\Omega} (\hat{E}_x)_n \cdot \Delta_n R(\bar{E}_x) d\Omega dt \quad (2)$$

where

$$\Delta_n R(\bar{E}_x) = (\Delta_n \mathcal{L}) E_x - (\Delta_n \alpha) D_t E_x - \Delta_n (\beta D_t J_x). \quad (3)$$

\mathcal{L} is a finite-difference operator, α and β are coefficients defined by grid size and time step, and $D_t J_x$ is a difference of current density at $t + \Delta t/2$ and $t - \Delta t/2$ [3]. The design variables are explained in Fig. 2.

6. OPTIMIZATION(B)

Fig. 2. Design variables for PGS optimization.

III. DESIGN RESULTS

A. Analysis model using evolution strategy

Fig. 3. Spiral inductor of TSMC process

For the inductor structure used in EV simulation with ES, the number of the coil turns is 5.5, width of the top metal $6 \mu\text{m}$, and radius of inner coil $98.04 \mu\text{m}$ as shown in Fig. 3.

The design parameters are set as electric conductivity of each layer of the substrate, named pass2, pass, IMD, ILD, FOX, Sub (Fig. 3). The main characteristics of inductor are inductance and Q-factor, and the objective function is defined as a function of them:

$$\text{Minimize } F = \sum_{i=1}^{12} \alpha_i (|L_i - L_{oi}|)^2 + \sum_{i=1}^{12} \beta_i (|Q_i - Q_{oi}|)^2 \quad (4)$$

where α_i and β_i are weighting factors for inductance L_i and Q-factor Q_i from EM simulation, and L_{oi} , Q_{oi} are target values of inductance and Q-factor obtained from equivalent circuit analysis.

Design result and optimized values are shown in table I and II. Also, inductance and Q-factor results are compared in Fig. 4 and 5.

TABLE I. DESIGN PAMETERS

Parameter	Unit	Initial values	Optimal values
Pass3	S/m	0	0.5
Pass	S/m	0	0.5
IMD	S/m	0	0.002
ILD	S/m	0	0.002
FOX	S/m	0	0.002
Sub	S/m	0	14

TABLE II. PERFORMANCE

Performance	Unit	1GHz	2GHz	3GHz	4GHz	5GHz
Inductance	nH	12.582/	13.512/	15.483/	19.538/	29.705/
Initial/Optimal		12.568	13.810	16.503	21.797	28.973
Q-factor		7.062/	11.706/	13.083/	11.785/	8.505/
Initial/Optimal		6.037	7.435	5.546	3.116	1.165

Fig. 5. Comparison of Q-factor before and after EV optimization

B. PGS optimization

Optimization was performed for 2 target frequencies (1 and 2.5 GHz). In Table III and Fig. 6, Q-factor and inductance of spiral inductor with optimized PGS is compared with those with no PGS and with solid ground shield. Significant drop in both inductance and Q-factor is observed for inductor with solid ground shield because of eddy current in ground shield, whereas for optimized PGS, Q-factor is improved by as much as 16.6% while inductance reduction is small.

TABLE III. Q-FACTOR AND INDUCTANCE COMPARISON

Frequency (GHz)	Inductance		Q-factor	
	1	2.5	1	2.5
Non-PGS	12.568	14.927	6.037	6.701
Solid ground shield	3.712	3.895	2.115	4.274
PGS	11.928	14.258	5.967	7.439

Fig. 6. Comparison of Q-factor Non-PGS and PGS

Detailed optimization procedure which is implemented in our study will be expressed in details on Compumag conference. Also, we will show effectiveness of our approach by comparing with the conventional one.

Optimization of perfectly matched layer parameters for finite element modeling of grounding systems

Luiz Lebensztajn, Viviane Cristine Silva, Lucas Blattner Martinho

Universidade de São Paulo LMAG/PEA

Av. Prof. Luciano Gualberto, T3 N.158, 05508-900, São Paulo SP Brazil, leb@pea.usp.br, viviane@pea.usp.br

Abstract — An approach to estimate perfectly matched layers parameters for finite-element modeling of grounding systems is proposed. It is based on two optimization techniques, namely Kriging models and Multiobjective Evolutionary algorithm. Results are compared with both theoretical and experimental data.

I. INTRODUCTION

In the finite element analysis (FEA) of grounding systems, a suitable mesh truncation scheme is needed in order to delimit the unbounded three-dimensional domain. Perfectly matched layers (PML) have been efficiently used for this purpose in the numerical solution of 2D problems governed by Laplace equation [3]-[5]. Nevertheless, the parameter estimation of PML has proved to be problem dependent. This is also true in the case of 3D FEA of grounding systems [4].

Here, an attempt is made to develop guidelines for their selection by firstly parameterizing the PML in terms of the relevant dimensions of a grounding system and then to determine these values with the aid of optimization techniques. A previous, similar attempt has been reported in [5] for Electrostatics in 2D.

In this work, a Multiobjective Evolutionary algorithm [7] is used to find a set of PML parameters that provides a highly accurate solution. Kriging models replace the numerical solution to evaluate the relevant quantities and therefore to save computing time [6].

II. PROBLEM DESCRIPTION

The proposed strategy is firstly tested in a canonical example, composed of a single, vertically buried electrode. Although a 2D problem in nature, it is solved in 3D, since both theoretical and experimental data are available for this configuration [1]-[2]. The case of a 32-m bare copper stake [2], buried in a soil with a resistivity of 450 $\Omega\cdot\text{m}$, is used as test case. The quantities to be analyzed are low-frequency ground impedance, R , and surface potential, V , computed at a distance of 1.0 m from the electrode.

The parameters involved in the construction of a PML are (see Fig. 1): a) thickness of the buffer region, d_{buff} ; b) thickness of the absorbing layers, d_{PML} ; c) material coefficient, a . As a first attempt, the thicknesses, d_{buff} and d_{PML} , are parameterized in the geometrical model of the ground system as:

$$d_{\text{buff}} = 2h + \alpha L \quad \text{and} \quad d_{\text{PML}} = n\beta h, \quad (1)$$

where h is a distance taken as 1.0 m, $0 \leq \alpha \leq 5.0$ and $1.0 \leq \beta \leq 10.0$ are dimensionless, real values; n is the number of absorbing layers ($1 \leq n \leq 10$), and L is the electrode length. The material

coefficient, a , was initially restricted to the range [1,50]. Therefore, the actual parameters chosen to be optimized are all dimensionless values: α , β , n and a .

Fig. 1 3D model of a single-wire grounding system showing PML parameters.

III. METHODOLOGY

Quantities R and V , which are relevant in the low-frequency performance of grounding systems, are computed and the corresponding error compared with their theoretical values is to be minimized.

First, let the errors, e_R and e_V (associated, respectively to the grounding resistance and the surface potential) be defined as follows:

$$e_R = (R_{th} - R_{num})/R_{th} \quad \text{and} \quad e_V = (V_{th} - V_{num})/V_{th}, \quad (2)$$

where the subscripts th and num indicate theoretical and numerical values, respectively. The optimization problem can be written as:

$$\min \begin{cases} e_R^2 \\ e_V^2 \end{cases}, \text{ with respect to } \alpha, \beta, n \text{ and } a. \quad (3)$$

The errors are squared in order to enhance absolute low-valued errors. This corresponds to an unconstrained, multiobjective optimization problem, which will provide a set of rules to build an efficient PML for the grounding system problem scenario.

The minimization is performed with a multiobjective genetic algorithm, as proposed in [7]. The algorithm stores both dominated and non-dominated solutions. In order to obtain faster convergence, only the non-dominated solutions, as well as the ones close to the Pareto set, enter the selection process. A clearing technique in the parameter space, associated to a niche approach in the objective space, is performed so as to avoid similarities between solutions. In both cases a specific criterion is used to penalize one of the individuals.

In order to construct inexpensive approximations of computationally expensive engineering analyses and simulations (such as FEA), Kriging models [6] are adopted. The design of the computer experiment was based on Latin hypercubes [8] in order to fill the space of the input data. These procedures are used to derive some relationships between pairs of PML parameters, which are expected to lead to lower errors in both R and V .

IV. RESULTS

Fig. 2 presents the Pareto set, achieved after minimization of both e_R^2 and e_V^2 . Fig. 3 shows histograms of PML parameters associated to that Pareto set, i.e., those parameters which lead to the lowest errors. Fig. 4 illustrates histograms for some ratios between pairs of PML parameters, which are useful as a guidance to choose the more appropriate values for the test case described in II.

With the aid of Figs. 3 and 4, the following parameters might be selected: $d_{buff} = 135$ m, $a = 47$, $n = 10$ and $d_{PML} = 30$ m. By adopting these values, the FEA of the problem depicted in Fig. 1 yielded the results summarized in Table I.

Some results in Figs. 3 are shown in absolute values (m) for clarity, although the optimization schemes were applied in the dimensionless variables of (3).

Fig.2 Pareto set after minimization of e_R^2 and e_V^2 .

TABLE I
NUMERICAL \times THEORETICAL RESULTS

	Theoretical[1]	FEA	$e_{R,V}$ (%)
Ground resistance (Ω)	20.98 (Exp. 21 [2])	21.25	1.2
Surface Potential (V) ¹	9309	9092	2.3
Electric Field (V/m) ¹	2237	2097.4	6.2

¹ at 1.0 m of the stake

V. CONCLUSION

The proposed optimization strategy to determine PML parameters for FE modeling of grounding systems was based only on geometrical parameters in this preliminary approach. A more complete analysis should include other significant variables in (3), such as soil resistivity, discretization refinement, as well as other grounding grid configurations, e.g. horizontal electrodes. These additional issues are intended to be addressed in the paper's extended version

Abstract — We present here an original application linking an electrochemical phenomenon and the computational aspect of electromagnetic fields to provide a corrosion diagnosis of a protected underwater steel structure. This is possible with the pairing of a numeric method, the BEM, and the study of inverse problems. After a defined operating time, it is mandatory to check an underwater steel structure. Sadly, current examinations techniques require immobilize the structure for a long time and are less efficient. The purpose of this paper is to replace this checking by a series of close electrical measurements in the electrolyte which provides a corrosion diagnosis of the structure. The new method introduced ensures a great time-saving but also an accuracy never reached before. This paper presents this method and its checking through real measurements on a frigate mock-up.

I. INTRODUCTION

During its operating life, an underwater structure suffers from corrosion. This phenomenon starts when iron paint defects appear on its surface, electrically linked to noble metals (propellers in Bronze and Nickel for example). This reaction, called galvanic coupling, makes the iron an anode and bronze a cathode. To fight against this reaction, two main methods have been developed:

- The Sacrificial Anode Cathodic Protection (SACP): some less noble elements than iron (Zinc, Aluminium, etc...) are placed on the structure to protect it. They are going to be corroded instead of the iron of the structure itself, becoming the new anode of the reaction.
- The Impressed Current Cathodic Protection (ICCP): Platinum anodes are distributed on the structure, injecting currents in the seawater. This places the iron in its passivation zone and protects it.

These two protections lead to a circulation of currents in the seawater, inducing the presence of a varying electromagnetic field. The first step of the study is to predict this electromagnetic field from the electric boundary conditions. Then, the problem will be inversed and a corrosion diagnosis will be deducted, starting from near electric field measurements and leading to the corroded areas localization. This paper, based on electric fields and applied to real measurements on a mock-up, extensively improves a method previously introduced [1].

II. FORWARD MODELING

As said before the forward modeling aims to predict the electric potential and the electromagnetic field from physic

boundary conditions. Trying to achieve to diagnosis tool, the numeric method used must directly link the boundary conditions to the measurement locations, advantage provided by the Boundary Elements Method. Moreover, this method permits a simple modeling of the infinity region [2] [3].

Starting from the Laplace equation, the principle is to use the third Green's identity to write an integral equation on the Γ boundaries of the problem:

$$h(M).\varphi(M) + \oint_{\partial\Gamma} \varphi(P) \cdot \frac{\partial}{\partial n_q} G(M,P) dl - \oint_{\partial\Gamma} G(M,P) \cdot \frac{\partial}{\partial n_q} \varphi(P) dl = 0 \quad (1)$$

where φ is the electric potential and $\partial\varphi/\partial n$ the opposite of the normal current density, within the conductivity σ factor. P is the integration point on the boundary and M the point where the computation is made. $h(M)$ is the solid angle seen by M and G is the Green function $1/r$, where r is the distance [MP].

After the surfaces have been meshed, a point matching approach of (1) at the barycenter of each element can be provided, leading to a matrix system..

$$[A_{Green}] \begin{bmatrix} \varphi \\ \partial\varphi/\partial n \end{bmatrix} = 0 \quad (2)$$

Making such an approximation is known as not very precise, but, as the main goal is the development of an inverse method, it is acceptable for us. Of course, this system has more unknowns than equations. To solve it requires the introduction of boundary conditions. At the last step of this forward modeling, we get a non linear system due to the form of the polarization law ($\partial\varphi/\partial n = f(\varphi)$) introduced by the presence of polarizable steel on the boundaries. This system is then usually solved by an iterative Newton-Raphson process.

The electric field anywhere in the domain is then available thanks to the gradient of (1):

$$\mathbf{E}(M) = \frac{1}{4\pi} \oint_{\partial\Gamma} \varphi(P) \left(-3 \cdot \frac{(\mathbf{r}\cdot\mathbf{n})\mathbf{r}}{r^5} + \frac{\mathbf{n}}{r^3} \right) + \frac{\partial\varphi(P)}{\partial n} \cdot \frac{\mathbf{r}}{r^3} dl \quad (3)$$

If the electric field is expressed in several points, the last equation can be represented by the following system:

$$[A_{Measurement}] \begin{bmatrix} \varphi \\ \partial\varphi/\partial n \end{bmatrix} = E \quad (4)$$

III. INVERSE METHOD AND IMPROVEMENTS

The main goal is, from real electromagnetic measurements contained in the E vector and the construction of the system (4), to find the X vector. This problem is very ill posed, due to a different number of unknowns and equations, numeric approximations and measurements error. It leads to a very bad

condition number for (4) and a direct inversion provides a good mathematical results but with no physic behavior.

An original method to get a better condition number is to add the Green equations from (2) linking all unknowns on the boundaries. This ensures to have a physical result and permits to reduce the number of measurements to make. This first step permits a real facilitation of the inversion [1]:

$$\begin{bmatrix} A_{Measurement} \\ A_{Green} \end{bmatrix} \begin{bmatrix} \varphi \\ \partial\varphi/\partial n \end{bmatrix} = \begin{bmatrix} E \\ 0 \end{bmatrix} \quad (5)$$

In a second time a regularization technique is needed to get the best solution of (5). The one chosen is Tikhonov's method, its principle being to find a solution minimizing [4]:

$$\min(\|A.X - B\| + \lambda\|L.X\|). \quad (6)$$

The L matrix is called the regularization matrix: a 0-order regularization (L is the identity matrix) privileges solutions with minimum norm; a 1-order one favors continuous solutions and a 2-order one accentuates this continuous behavior. In our study, a 2-order method is chosen. The λ choice, image of the importance given to this regularization (symbolizing the compromise between solution precision and regularization effect) is made thanks to the well-known L-curve technique.

IV. METHOD CHECKING WITH REAL MEASUREMENTS

To check the diagnosis method explained before, real measurements are employed: a composite 1/40th mock-up of a frigate has been equipped with an adapted ICCP, electrically linked to iron plates (simulating the paint defects) disposed on the hull. The mock-up is then placed in a salted water with a controlled conductivity (5,16 S/m).

Fig. 1. 1/40th mock-up set in measurement conditions

When the ICCP is running, some electric field measurements are made on lines at different depths.

Fig. 2. Real electromagnetic measurements on a 1/40th mock-up

These measurements have been made in the Physical Scale Modeling (PSM) facility of the US Naval Research Laboratory (NRL) located in Key West (Florida). In fact, 640 measurements are made: 320 Ex and 320 Ez, no one made on the y (transverse) axis. The complex meshing of the structure gives 3103 elements, making the system under determined.

By adding the 3103 Green equations through A_{Green} , the new system gets a better condition number. An interpolation is finally made from the electric field measurements, to get a sufficient number of equations and make the problem over determined.

The current density on each anode is known (in the range of the hundred A/m²) as an evaluation of the mean value of the current density on the propellers. The previous improved inverse method gives the following results on the hull:

Fig. 3. Current density on the boundaries in A/m²

Current density results are only shown, because of their visibility, but potentials are also obtained. The scale is negative as we want to see the currents going back to the hull, which are the corroded ones. These parts correspond to the less potential areas. The result matches the real location of the iron plates, giving a good diagnosis, with less than 5% of error. The method guarantees good results with a complex geometry and real measurements.

V. CONCLUSION

This diagnosis method succeeds in locating the corroded areas of an immersed part of a hull with real electric field measurements. But some other structures can be studied, as pipelines, offshore platforms, etc... Potential measurements can also be the basis but the use of electric field sensors is more widespread. Moreover, the numerical tools used here can be applied to other scientific domains, such as heat problems for example.

²Depto de Computação, Universidade Federal de Ouro Preto, Ouro Preto, 35400-000, Brazil.

This paper presents a Multiobjective Clonal Selection Algorithm (MCSA) with dynamic variation of its main parameters. The method performs a somatic hypermutation step using different probability distributions, balancing the search in the algorithm. In order to illustrate the efficiency of the MCSA, we compare its performance with the Nondominated Sorting Genetic Algorithm II (NSGA-II), and illustrate its application in an industrial electromagnetic design.

Index Terms—Multiobjective optimization, clonal selection algorithm.

I. INTRODUCTION

The solution of real-world engineering design problems can be, in some cases, translated into optimization problems that involve multiple, often conflicting, objectives. For these multiobjective optimization problems, there is not a single optimal solution, but a set of trade-off solutions, known as Pareto-optimal solutions, in which each point represents different degrees of importance for the objectives. Multiobjective algorithms try to find an estimate set that best approximates the Pareto-optimal set, allowing the designer to consider alternative solutions for the design problem.

To deal with these multiobjective optimization problems, many evolutionary approaches have been proposed since the 1990's, including algorithms based on artificial immune systems (AIS), which have presented very promising results [1]. See [2] for an overview on multiobjective algorithms based on AIS.

As the AIS-based methods have a special ability in solving multimodal functions, mapping the best local solutions, some further mono-objective works have employed these systems to perform high computational cost optimization problems, see for instance [3] and [4]. In order to investigate the efficiency of these algorithms for multiobjective optimization, we extended the ideas presented in our previous work [4] to the multiobjective clonal selection algorithm (MCSA). Although this approach has presented useful results, it requires the adjustment of many initial parameters. In this paper, we propose an enhanced version of the MCSA, with a dynamic control of its parameters. The algorithm is compared with the nondominated sorting genetic algorithm (NSGA-II). In addition, we illustrate an application of the MCSA to an industrial electromagnetic design.

II. DESCRIPTION OF THE ALGORITHM

The algorithm is essentially defined by four main steps, namely affinity evaluation, cloning, affinity maturation and

replacement. The N_{pop} candidate solutions are evaluated over all objective functions, and each point receives an affinity value according to the fast nondominated sorting with crowding distance assignment.

The n_{sel} best solutions are selected for cloning and each one of these points receives a number of clones given by:

$$N_C^i = \left\lceil nc \times \frac{\xi_i}{\sum_{i \in n_{sel}} \xi_i} \right\rceil \quad (1)$$

in which $\xi_i \in [0, 1]$ is the normalized crowding distance and nc is the total number of clones produced.

The maturation of the immune response is implemented by the somatic hypermutation and receptor editing operators. Given the population of clones, the hypermutation consists of adding different kinds of perturbations to them [4], in which the best n_{dN} copies are perturbed using a Gaussian distribution, and the n_{dC} remaining are perturbed using a Chaotic distribution, such that $n_{dN} + n_{dC} = 1$.

In this paper, the mutation radius $\gamma \in [0, 1]$ and the relation between n_{dN} and n_{dC} are adjusted dynamically. In this way, while the population evolves, the value of γ decreases and the value of n_{dN} increases, intensifying the local refinement in the algorithm towards the end of the optimization process. These parameters are stated next:

$$\begin{aligned} \gamma(n_{eval}) &= (\gamma_o - 0.05) \exp(-\lambda_1 n_{eval}) + 0.05 \\ n_{dN}(n_{eval}) &= 1 - ((\epsilon_o - 0.1) \exp(-\lambda_2 n_{eval}) + 0.1) \end{aligned} \quad (2)$$

in which n_{eval} represents the current number of evaluations, $\gamma_o = 0.40$, $\epsilon_o = 0.50$, $\lambda_1 = 5/n_{eval}^{max}$ and $\lambda_2 = 3/n_{eval}^{max}$.

The receptor editing operator can be viewed as a special kind of mutation employed by a simple differential evolution (DE) algorithm. Here, we adopt a similar procedure to the best n_{sel} antibodies, producing new solutions v_i , $i \in [1, n_{sel}]$, according to (3), with random and different indexes $r1, r2, r3 \in [1, n_{sel}]$ and $\omega = 1$.

$$v_i = x_{r1} + \omega(x_{r2} - x_{r3}) \quad (3)$$

In order to maintain the diversity of the solutions, the replacement operator generates $N_{pop} - n_{sel}$ new random points within the search region.

Algorithm 1: The Multiobjective Clonal Selection Algorithm

```

1 begin
2    $\mathcal{P}_t \leftarrow$  Generate the initial  $N_{pop}$  solutions;
3    $\Phi_t \leftarrow$  Evaluate the points in  $\mathcal{P}_t$ ;
4   while Not stop criterion do
5      $\mathcal{F}_t \leftarrow$  Classify the solutions ( $\mathcal{P}_t, \Phi_t$ );
6      $\mathcal{S}_t \leftarrow$  Select the best  $n_{sel}$  solutions ( $\mathcal{F}_t$ );
7      $\mathcal{C}_t \leftarrow$  Perform the cloning process ( $\mathcal{S}_t$ );
8      $\mathcal{Q}_t \leftarrow$  Perform the affinity maturation ( $\mathcal{S}_t, \mathcal{C}_t$ );
9      $\mathcal{R}_t \leftarrow$  Replacement and diversity generation;
10     $\mathcal{P}_{t+1}, \Phi_{t+1} \leftarrow (\mathcal{F}_t^1 \cup \mathcal{Q}_t \cup \mathcal{R}_t)$ ;
11     $t \leftarrow t + 1$ ;
12  end
13 end

```

All new solutions produced by the hypermutation, editing and replacement operators are classified into nondominated fronts, and the first one is stored in an archive whose maximum size is \mathcal{L} . The best N_{pop} points, i.e., the less dominated ones with greater crowding distance, are selected for the next iteration. The previous steps are summarized in the Alg. 1.

III. RESULTS

A. Analytical Problems

The MCSA parameters have been chosen as $N_{pop} = 30$, $n_{sel} = 0.90$ and $nc = 70$. The NSGA-II has been set with simulated binary crossover (SBX) and polynomial mutation. A population archive of $\mathcal{L} = 100$ has been adopted for both methods.

We have selected three benchmark problems with three objectives: DTLZ6, DTLZ7 and DTLZ8. These problems allow to investigate the ability of the methods (i) to converge to a degenerated curve (DTLZ6), (ii) to identify disconnected Pareto-optimal regions in the search space (DTLZ7), and (iii) to deal with constraint functions (DTLZ8).

The results presented in the Fig. 1 have been estimated using the S-metric. By considering that the hypervolume calculated should increase as generations evolve, the progress of the median of the S-metric gives a picture of the convergence speed of each algorithm. In this case, the MCSA has outperformed the NSGA-II in all DTLZ problems. The algorithms were executed 30 times with a stop criterion of 50,000 function evaluations.

Fig. 1. Statistic values of convergence speed.

B. Microwave Heating Device

The microwave heating device has applications in sterilization processes where it is used to heat a water layer. Its structure consists of six dielectric layers (l_1, \dots, l_6) which receive microwave power from both sides, see Fig. 2.

The design is described by 09 variables, which are the six layers, the power density sources (P_1, P_2), and the position of P_2 (d). As stated next, the optimization problem consists of the maximization of the quantity of water and the minimization of the spent energy, ensuring a water temperature between 100°C and 121°C:

$$\begin{aligned} \min F = & \begin{cases} f_1(\vec{x}) = -l_3 \\ f_2(\vec{x}) = (P_1 + P_2)\Delta t_h \end{cases} \\ \text{subject to } & \begin{cases} g_1(\vec{x}) = -T + 100^\circ\text{C} \leq 0 \\ g_2(\vec{x}) = T - 121^\circ\text{C} \leq 0 \end{cases} \end{aligned} \quad (4)$$

in which Δt_h is the spent heating time.

Regarding the same MCSA parameters, we have attained an estimated Pareto-optimal in a single run of the method, with a stop criterion of 16,000 function evaluations. For the decision-making process, we have selected the point which corresponds to the most efficient device, in which the energy efficiency (eff) is the relation between the coupled and the reflected energy. The solution achieved by the MCSA presents an efficiency gain of 26% when compared with the SPEA-II.

Method	$f_1(\vec{x})$	$f_2(\vec{x})$	eff	CPU Time
MCSA	-0.0558	0.0252	0.68%	830 min ¹
SPEA-II	-0.0400	0.0204	0.54%	990 min ²

Abstract—The electroencephalogram (EEG) is one of the techniques that is used for the non-invasive diagnosis of patients suffering from epilepsy. EEG source localization identifies the neural activity, starting from measured EEG. This numerical localization procedure has a resolution, which is difficult to determine due to uncertainties in the EEG forward models. More specifically, the conductivity values of brain and skull in the head models are unknown. In this paper, we propose the use of non intrusive probabilistic methods for quantifying the possible errors introduced by the uncertain head conductivity values. This paper illustrates the accuracy and computational advantages of the non intrusive method for EEG source analysis. We validate the presented method with Monte Carlo simulations.

I. INTRODUCTION

Neurological disorders, such as epilepsy, can be diagnosed by the use of the electroencephalogram (EEG). The EEG measures potentials on the scalp of the patient under study by means of electrodes over a period of time. These potentials are the result of electrical activity produced by the brain. The number of electrodes may vary, but typically 20 to 40 electrodes are placed on the scalp of the patient. The malfunctioning region in the brain needs to be identified using the EEG. To this end, EEG measurements can be coupled to a numerical procedure in order to identify the neural sources, in a so-called *EEG source analysis*. For EEG source analysis, two subproblems need to be solved: a forward and an inverse problem.

The EEG forward problem consists in simulating the EEG potentials for a given neural electrical activity. For this, the following needs to be provided: a head model, i.e. a model that incorporates the anatomy of the head with the different brain tissues, and a source model, i.e. a physical and mathematical model for the brain activity. By solving the EEG inverse problem, sources are determined which correspond with the measured EEG potentials. These sources can be identified with good temporal resolution, contrary to other biomedical imaging techniques, but fail to have a high spatial resolution. The need exists for quantifying the errors that are made when recovering the neural sources when using a certain inverse numerical procedure. In the head model, the geometry can

give rise to errors [1] but through the use of accurate Magnetic Resonance Images, these errors can be limited. Large uncertainties however are introduced with model parameters that are difficult to determine: the conductivity values of the brain and the skull. We propose to use so-called *non intrusive probabilistic algorithms* to quantify the uncertainties on the location of the neural sources, which only assume the conductivity to be of finite variance [2], [3].

II. INCORPORATION OF STOCHASTIC UNCERTAINTY IN EEG SOURCE ANALYSIS

A. Definition of the problem

The EEG forward problem starts from the location and orientation of neural sources, where conductivity values of the brain and skull need to be provided, and calculates the EEG electrode potentials. We assume for simplicity of analysis that the neural activity is represented by a single electrical dipole with a given location $\mathbf{r} = [r_x, r_y, r_z]^T$ and orientation. This is a widely used approximation of the neural activity of patients suffering from epilepsy. The brain to skull ratio of the conductivity X is the important model parameter when solving the EEG forward problem. Since we want to propose a method that takes into account the uncertainty on the conductivity and where the error due to geometrical modelling is not considered, we employ a coarse approximation of the head: the spherical head model. This model is a widely-used approximation of the head where the head is represented by three spheres: the inner sphere represents the brain, the intermediate layer represents the skull and the outer layer represents the scalp (cf. Fig. 1a). In this case a semi-analytical expression exists for the computation of the EEG potentials [4]. In our numerical tests we always use a standard configuration of 27 electrodes.

Spreading out the uncertainty from the conductivity to the position of the dipole is an inverse problem. To solve this inverse problem we use the Nelder-Mead simplex method in combination with a non intrusive stochastic approach based upon a chaos polynomial decomposition of both the conductivity and the dipole position [2]. The only assumption on the conductivity is that it is a random variable of finite variance. We do not make any assumption on the shape of the probabilistic distribution of the position of the dipole.

This work was supported by the Belgian Science Policy under grant IAP P6/21 and by NSF under grant DMS-0609824.

Fig. 1. (a) Three-shell spherical head model and (b) larger mean error for dipoles for which the potential is very sensitive to the conductivity.

B. Non intrusive method for EEG source analysis

Assuming that the conductivity is a random variable of finite variance, we can expand it as a truncated series of order p_{in} of Hermite polynomials of a random gaussian variable $\xi_i(\omega)$, known as *Hermite chaos polynomials* [2]:

$$X(\omega) = \sum_{i=0}^{p_{in}} X_i h_i(\xi(\omega)), \quad (1)$$

where h_i is the polynomial of Hermite of order i and ω is random coordinate.

The inverse deterministic problem allows us to compute the value of the position of the dipole from the value of the conductivity (X). This process can be seen as a “blackbox” such as $\mathbf{r} = \mathbf{r}(X(\xi(\omega)))$. Hence the dipole position along the spatial direction x (resp. y or z) belongs to a space that can be spanned by the polynomials $h_i(\xi(\omega))$, and can thus be written as a truncated series at an order p_{out} :

$$\mathbf{r}_x(\omega) = \sum_{i=0}^{p_{out}} \mathbf{r}_x^m h_i(\xi(\omega)). \quad (2)$$

To compute the value of the unknown real coefficients \mathbf{r}_x^m , we use the orthogonality properties of the Hermite polynomials:

$$\mathbf{r}_x^m = \frac{E(\mathbf{r}_x(\omega) h_m(\xi(\omega)))}{E(h_m(\xi(\omega))^2)}, \quad (3)$$

where $E(\cdot)$ is the mathematical expectation. The denominator can be computed analytically. To compute the numerator (which is an integral) we use a Hermite Gauss integration scheme with d integration points [2]:

$$E(\mathbf{r}_x(\omega) h_m(\xi(\omega))) \approx \sum_{i=1}^d w_i \mathbf{r}_x(X(t_i)) h_m(t_i), \quad (4)$$

where t_i is the i -th Gauss point and w_i the associated weight. This only requires to compute the inverse deterministic problem d times, with the conductivity evaluated through (1) with $\xi(\omega) = t_i$, $i = 1, \dots, d$.

III. RESULTS AND DISCUSSION

We performed computations using the Monte Carlo (MC) and the non intrusive (NI) methods for several test cases corresponding to dipoles located increasingly farther from the center of the head (Case 1 to 4). In all cases the Monte Carlo simulations were performed using a sample size of 2000 and the non intrusive method used $p_{in} = 13$, $p_{out} = 6$ and $d = 10$. The brain to skull conductivity ratio X is chosen as a uniform

TABLE I

MEAN OF THE POSITION OF THE DIPOLE (MM) FROM THE CENTER IN THE x , y AND z -DIRECTION FOR SEVERAL TEST CASES.

Case	Method	\bar{r}_x (mm)	\bar{r}_y (mm)	\bar{r}_z (mm)
Case 1	MC	7.72	7.72	7.73
	NI	7.72	7.72	7.73
Case 2	MC	23.54	23.34	23.65
	NI	23.52	23.32	23.64
Case 3	MC	31.75	31.62	31.73
	NI	31.72	31.60	31.71
Case 4	MC	39.49	40.07	39.33
	NI	39.46	40.03	39.31

TABLE II

STANDARD DEVIATION OF THE POSITION OF THE DIPOLE IN DIFFERENT CASES.

Case	Method	σ_{r_x} (mm)	σ_{r_y} (mm)	σ_{r_z} (mm)
Case 1	MC	0.53	0.53	0.53
	NI	0.54	0.54	0.53
Case 2	MC	1.38	1.50	1.31
	NI	1.40	1.51	1.33
Case 3	MC	1.63	1.70	1.64
	NI	1.65	1.72	1.66
Case 4	MC	2.17	1.91	2.26
	NI	2.19	1.85	2.28

random variable between $1/40$ and $1/9$. A fixed orientation (y -direction) of the dipole is assumed, and its location is measured from the center of the head model.

The results in Table I show the mean obtained by MC and NI for the four different EEG data sets. The results obtained using both methods are in very good agreement. The computational time required by the Monte Carlo method is about 8000 seconds on a $2.26GHz$ personal computer, whereas non intrusive method requires only 40 seconds.

Table II shows that for increasing distances from the center of the head, larger standard deviations are observed. This means that the uncertainty on the spatial position of the source increases when the source approaches the electrodes. This is due to the fact that the sensitivity of the potentials to the conductivity becomes larger when the source is farther from the center (cf. Fig. 1.b). Here again, one can note the good agreement between both numerical methods.

The full paper will provide additional details on the non intrusive probabilistic method and compare this method with classical techniques used in the EEG community, such as the Cramer-Rao boundary method.

The EMC Method Applied to the Design of Local and Asymmetric Gradient Coils for MRI

Hector Sanchez Lopez, Michael Poole, Feng Liu, Stuart Crozier
School of Information Technology and Electrical Engineering, University of Queensland, Australia
hsanchez@itee.uq.edu.au

Abstract—The design of local, asymmetric gradient coils is of great importance for magnetic resonance imaging (MRI). Such local coils promise increased gradient strengths and slew rates that have the potential to acquire image data with increased spatial and/or temporal resolution. Conventional coil design techniques are limited to specific geometries (e.g. cylindrical, planar) by their mathematical formulation. In order to more closely surround the sample of interest a symmetry-free, inverse boundary element method (BEM) was employed to design local gradient coils without relying on symmetry to parameterize and simplify the mathematical problem. With several examples we illustrate the versatility of this approach and the superiority of the performance of local gradient coils.

I. INTRODUCTION

High performance gradient coils are critical for the ever increasing demands of new techniques in magnetic resonance imaging (MRI). Many methods for designing gradient coils have been presented [1, 2] with the aim of tailoring the wire pattern of the coil to generate linear axial magnetic field gradients in a region of interest (ROI) with high efficiency (η , field gradient per unit current measured in T/m/A) and low stored magnetic energy (low inductance L , μH). It is known that reducing the coil size and re-designing the wire pattern accordingly increases the coil performance [3], often measured as the ratio η^2/L [1]. However, conventional coil design methods based on the target field approach [1] were developed for specific geometries such as cylinders and are difficult to apply to local gradient coil. Employing a symmetry-free gradient coil design method allows us to tailor the shape of the gradient coil to more closely conform to the ROI. Such a boundary element method (BEM) was first presented for gradient coil design by Pissanetzky [4] and has been extended [5] and applied to more complex design problems [6]. An alternative approach was used in this study that employs the equivalency between a magnetized volume and a surface current density, which we have therefore termed the “equivalent magnetization current” (EMC) method [7]. The versatility of the EMC method is demonstrated by the design of asymmetric, high-performance, local gradient coils. It is illustrated that conforming the coil design surface to the sample shape increases the performance of the resulting gradient coil

II. MATERIALS AND METHODS

The EMC method considers an isotropic, rigid, non-hysteretic, arbitrary volume, V , of thickness h , bounded by the

surface S ($S \in \mathfrak{R}^3$) that possesses a magnetization, $\mathbf{M}(\mathbf{r}')$, normal to S . A volume of “well-behaved” magnetization $\mathbf{M}(\mathbf{r}')$ can be considered as equivalent to a uniform current density on its surface [8]. If h is small and $\mathbf{M}(\mathbf{r}')$ is piecewise-linear throughout the thin volume, V , it can be shown that (See Eqs. (1)-(9) in [7])

$$\mathbf{M}(\mathbf{r}')h = \psi(\mathbf{r}') \cdot \hat{\mathbf{n}}(\mathbf{r}'), \quad \mathbf{r}' \in S, \quad (1)$$

where $\psi(\mathbf{r}')$ is the scalar piecewise-linear stream-function of the current density flowing on S and $\hat{\mathbf{n}}(\mathbf{r}')$ is the normal vector to S at \mathbf{r}' . The arbitrarily-shaped surface is discretized into triangular elements with N nodes defining the corners of each boundary element. $\psi(\mathbf{r}')$, can be expressed as a sum of unknown nodal stream-function values, s_n , and basis-functions, $\Psi_n(\mathbf{r}')$; $\psi(\mathbf{r}') = \sum_{n=1}^N s_n \hat{\psi}_n(\mathbf{r}')$ [7], for which $\hat{\psi}_n(\mathbf{r}')$ is linear in each triangle and can be expressed as:

$$\hat{\psi}_n(\mathbf{r}') = \begin{cases} 1 - \frac{(\mathbf{r}' - \mathbf{r}_n) \cdot \mathbf{d}_{ni}}{|\mathbf{d}_{ni}|^2} \hat{u}(\mathbf{r}'), & \hat{u}(\mathbf{r}') = \begin{cases} 1, & \mathbf{r}' \in \Delta_{ni} \\ 0, & \mathbf{r}' \notin \Delta_{ni} \end{cases} \end{cases} \quad (2)$$

for $i = 1, \dots, O$, where \mathbf{d}_{ni} is the perpendicular distance vector from \mathbf{r}_n to the far side of each triangle Δ_{ni} , associated with the n^{th} node and O is the number of triangles associated with the node n . Equation (2) simply ensures that $\hat{\psi}_n(\mathbf{r}')$ in each triangle has value of one at the node n and falls linearly to zero at the edge opposite to the node n . In the rest the conducting surface ($\mathbf{r}' \notin \Delta_{ni}$) $\hat{\psi}_n(\mathbf{r}')$ is zero. The flux density of the magnetic field, \mathbf{B} , produced by a magnetized thin volume was deduced by applying the curl operator to the magnetic vector potential, \mathbf{A} , Eq. (5.103), pg 197 in [8]. Substituting the product $\psi(\mathbf{r}') \cdot \hat{\mathbf{n}}(\mathbf{r}')$ for the magnetization-thickness function, $\mathbf{M}(\mathbf{r}')h$, the magnetic flux density can be written as:

$$\mathbf{B}(\mathbf{r}) = -\frac{\mu_0}{4\pi} \sum_{n=1}^N s_n \sum_{i=1}^O \nabla_{\mathbf{r}} \int_{A_{ni}} \hat{\mathbf{n}}_{ni}(\mathbf{r}') \cdot \hat{\psi}_n(\mathbf{r}') \cdot \nabla_{\mathbf{r}'} \left(\frac{1}{R} \right) dA_{ni} \quad (3),$$

where A_{ni} is the area of the triangle i associated with node n . The stored magnetic energy, force and torque can be calculated assuming an equivalent surface current density, \mathbf{J} , flowing in the surface of the triangle that belongs to the node n . The axial component of (3) $B_z(\mathbf{r})$ is linear with respect to s_n , as are the net torque and net force generated by the coil in the intense, uniform background magnetic field, $B_0 \mathbf{z}$. The stored magnetic energy is quadratic with respect to s_n . The optimization was therefore stated as a quadratic programming (QP) problem in the present work. The *quadprog* function, provided in MATLAB's[®] optimization toolbox, was employed

9. Numerical Techniques

to solve the QP problem. The solutions, s_n , are the stream-function values corresponding to the gradient coil with minimum inductance that satisfies the constraints placed upon the net torque and net force and the inequality constraints of the linearity of $B_z(\mathbf{r})$. Equally-spaced contours of $\psi(\mathbf{r}')$ were generated to approximate the continuous current density by an arrangement of discrete current-carrying wires [6].

III. RESULTS AND DISCUSSIONS

For comparison, a figure of merit (FoM) given by η^2/L , was used to characterize performance of the coils. The maximal deviation from the target flux density in the ROU was calculated using Eq. (6) in [6].

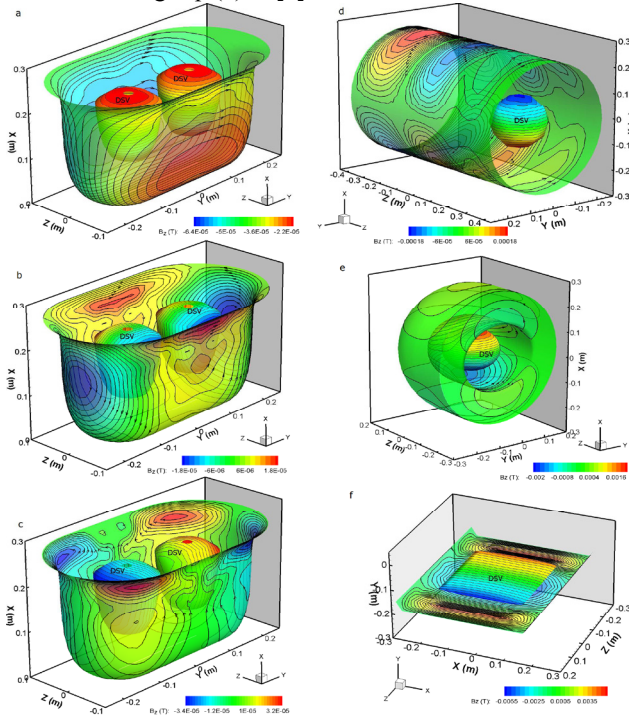

Fig. 1. The three axis local x-,z-,y- gradient coils for breast imaging (a,b,c). Asymmetric torque balanced transverse x-gradient coils for head imaging (d,e). The uniplanar insertable z-gradient coil. The arrow in the coil pattern represents the sense of the current. Contour line at the DSV represents the values of the axial magnetic field component (units in Tesla).

A three-axis (x, y, z) gradient coil for breast imaging was designed using the EMC approach. Figs. 1 (a, b, c) show the wire pattern of each coil and the two ROIs used to specify the target linear magnetic field. The proposed coils would permit imaging of both breasts simultaneously. The FoM of the designs resulted $11.113 \cdot 10^{-4} \text{ T}^2 \cdot \text{m}^{-2} \cdot \text{A}^{-2} \cdot \text{H}^{-1}$, $10.5 \cdot 10^{-4} \text{ T}^2 \cdot \text{m}^{-2} \cdot \text{A}^{-2} \cdot \text{H}^{-1}$ and $9.04 \cdot 10^{-4} \text{ T}^2 \cdot \text{m}^{-2} \cdot \text{A}^{-2} \cdot \text{H}^{-1}$ for the x-, y- and z-gradient coils, respectively. If one large ROI is used instead of two smaller ones, the coil FoM decreases by as much as 0.7 times, the resistance increases dramatically and the gap between wires is reduced from 1 mm to 0.0001 mm producing a complex and an impractical design. The FoM of the local gradient coils can be up to 130 times larger that the same value produced by standard whole body gradient coil. A second

design was two torque-balanced, asymmetric gradient coils for head imaging. Figs. 1. (d, e) shows the wire patterns of the transverse x-gradient coils. The pattern in Fig. 1 (d) shows the ROI shifted towards one end for patient access. However, this feature is obtained with detriment of coil performance; the FoM is reduced 4.6 times from the original value and the resulting torque is minimized 1000 times from an unbalanced coil. Providing shielding for such a coil would make it easier to torque balance as the shield wires flow with opposite sense to the primary wires. Fig. 1 (e), presents an ultra-short head x-gradient coil with a similar target ROI. Due to the shape of this structure the resulting FoM was 120 times larger than the same value produced by the coil Fig. 1 (d). A minimal torque of $0.0001 \text{ N/m} \cdot \text{A} \cdot \text{T}$ along the y-direction would be generated by the coil when immersed in a homogenous magnetic field. A uniplanar, open structure was also studied using the EMC method. This coil could be used for spinal imaging, for example. Due to the closeness to the sample, high gradient strengths could be generated. The efficiency of this design was $\eta = 0.34 \cdot 10^{-3} \text{ T/m}$ (approximately one order higher than the standard local coils), the resistance was expected to be $66 \cdot 10^{-3} \Omega$ using a maximal copper strip width of 1.4 cm and the minimal value was 3.5 mm with a 1 mm of gap between strips.

IV. CONCLUSIONS

Several examples of local gradient coil with increased performance over whole body coils have been presented. This was made possible by employing a symmetry-free coil design to optimally tailor the shape of the coil to more closely conform to that of the imaging region. The use of two ROIs instead of one large one simplifies the coil current pattern and hence superior coil performance is obtained.

Abstract—To perform parameter and shape optimization, an initial topology is required which affects the final solution. Topology optimization methods have the advantage to release this constraint. They are based on a splitting of the design space into cells, in which they attempt to distribute optimally some given materials.

Several convexity issues were already highlighted in topology optimization of electromagnetic devices. The optimization algorithm gets trapped in local minimizers and the final solution differs according to the initial conditions. In this paper, two main causes of this lack of convexity are studied. The first one is linked to the handling of intermediate materials, especially those that are a combination of windings and iron. The second one appears when the optimization objective is computed by a difference of magnetic energy between different positions of the rotor.

The methods proposed to manage these convexity issues focus on the shape of the optimization domain of each cell, in terms of materials. They are based on the use of parameterized hyperbolic functions to define the boundaries of the optimization domain and to modify them during the optimization process.

I. INTRODUCTION

Optimization methods differentiate themselves from the design parameters on which they are performed. Parameter optimization is concerned with some dimensions of the drive topology, such as the length of a tooth. However, the range of solutions that may be obtained is limited by the topology fixed initially. Shape optimization experiences the same issue at a lower level.

In topology optimization, the design space is split into cells. The method is then concerned with distributing predefined materials into the cells, such as air, copper or iron [1]–[4]. The design parameters are thus the electric and magnetic properties in each cell, i.e. the current density and the permeability. The main advantage of this approach is that no initial topology is required and that the design parameters enable any topology to be represented. However, this problem often turns out to lack of convexity, which has already been experimented in [5], [6].

In this paper, two complementary methods are suggested to affect the convexity. The first one is related to cells containing a combination of iron and copper, for which the current density and the permeability must be adjusted carefully. The second method concerns problems where the objective function is computed by the difference of magnetic energy between

TABLE I
ELECTRIC AND MAGNETIC PROPERTIES OF THE MATERIALS

Material	Permeability (μ)	Current Density (j)
Air	μ_0	0
Iron	$\mu_0\mu_r$	0
Copper	μ_0	J

different rotor positions. The two methods are explained on the basis of the three materials described in Table I.

II. CONVEXITY ISSUES RELATED TO INTERMEDIATE MATERIALS

The development described in this section is based on Fig.1, which illustrates the optimization domain in a cell. The three black points represent the three possible materials. The horizontal and vertical boundaries are easily delimited, respectively for a material moving between air and iron and air and copper. However, when a cell is moving between copper and iron, we must determine the maximum allowable values for the current density and the permeability.

There are two extreme choices for this boundary. If we allow the electromagnetic properties to move in the whole rectangle (boundary 1 on Fig.1), we can expect a convex shape for the objective function. Indeed, a cell can then be filled with an intermediate material having the maximum permeability and current density at the same time and thus more valuable than copper or iron alone, as illustrated on Fig.1(b). The other extreme is motivated by the fact that eventually, the cells should contain a unique material and not a combination of them. We could thus reduce the domain to the horizontal and the vertical segments (boundary 5). In this case, there is no combination of iron and copper anymore, a cell must be emptied of copper before being filled with iron.

At the beginning of the optimization, we want the problem to be convex in order to avoid the algorithm to be trapped in local minimizers. Since the cells must eventually be filled with a unique material, we have to reduce progressively the optimization domain. In order to modify the domain boundaries, we suggest the use of hyperbolic functions, which is illustrated by the boundaries 2, 3 and 4.

Fig. 1. (a) Optimization domain in a cell for the design variable μ and j (b) Illustration of the convexity evolution

Fig. 2. (a) Mapping between the permeability μ and the design variable p (b) Optimization domain in a cell for the design variable p and j

In the literature, the topology optimization is usually performed on a design variable p linked to the permeability by a given mapping, rather than on the permeability itself. Here, a mapping could also be used to simplify the optimization. Indeed, the shape of the optimization domain is complex because of its hyperbolic boundary. Thanks to the following mapping, the optimization can be performed on the triangular domain represented on Fig.2:

$$\mu = \mu_0 \frac{1 + (\mu_r - 1)(1 - a)p}{1 + (\frac{1}{\mu_r} - 1)ap}, \quad (1)$$

where $a \in [-\infty, \frac{\mu_r}{\mu_r - 1}]$ is a parameter. When p stays in the triangular domain, the set of possible values for the permeability and the current density change according to the parameter a . Increasing progressively its value is similar to a progressive reduction of the optimization domain using a hyperbolic boundary in terms of μ and j .

III. CONVEXITY ISSUES RELATED TO THE DIFFERENCE OF MAGNETIC ENERGY

In a finite element model, the torque of an actuator can be computed in different ways. One of them is to compute the difference of magnetic energy between two rotor positions. However, we observe that using a difference as an objective function creates convexity issues. A solution is then to allow having different rotor shapes for the two positions at the beginning of the optimization.

We define p_1 the permeability of a cell in the rotor position 1 and p_2 the permeability of the corresponding cell in position 2. The idea is to allow these two permeabilities to be different at the beginning of the optimization and to reduce progressively the difference between them. This can be achieved by using the optimization domains shown on Fig.3: the boundaries are defined by hyperbolic functions and the domain is reduced during the optimization to become eventually a straight line.

Fig. 3. Optimization domain for the rotor part

Fig. 4. Optimal topology of a reluctant actuator

IV. APPLICATION

The two methods described in this paper were applied for the optimization of a reluctant actuator. The optimization result is illustrated on Fig.4.

V. CONCLUSION

In conclusion, the two methods presented along this paper are based on the utilization of hyperbolic boundaries for the optimization domain in the cells. They allow reducing significantly the issues linked to convexity for the topology optimization of electromagnetic drives.

Abstract— The development of optimization techniques for multiobjective problems in electromagnetics has been flourishing in the last decade. This paper proposes an improved multiobjective particle swarm optimization (PSO) approach and applies it to the multiobjective version of TEAM workshop problem 22. Simulation results show that improved multiobjective PSO finds a better Pareto-optimal front with respect to more classical PSO methods while maintaining a better spread of nondominated solutions along the front.

Index Terms— TEAM workshop benchmark problem 22, particle swarm optimization, electromagnetic optimization, multiobjective optimization.

I. INTRODUCTION

Recent literatures suggests that multiobjective approaches based on meta-heuristics can serve as a more exploratory and effective tool in solving multiobjective optimization problems than traditional optimizers in electromagnetics optimization. In this context, recent work has presented the effectiveness of multiobjective particle swarm optimization (MOPSO) [1]. Particle swarm optimization (PSO) is a meta-heuristic technique developed by Eberhart and Kennedy in 1995 [2], inspired by social behavior of bird flocking or fish schooling. PSO has been successfully used to solve single-objective optimization because of its high convergence speed and relative simplicity. These features motivated researchers to extend PSO to multiobjective problems. Recently, a considerable number of MOPSO algorithms have been proposed [3].

This paper evaluates a MOPSO, based on [4], which is improved by social and cognitive time-variant factors and an operator of velocity updating based on truncated Gaussian distribution (G-MOPSO). G-MOPSO is tested on the multiobjective version of TEAM benchmark problem 22.

II. FUNDAMENTALS OF PSO, MOPSO AND G-MOPSO

The PSO algorithm uses a number of particles which constitute a swarm. These particles fly with a certain velocity and, at each iteration, adjust their velocity vector, based on their momentum and the influence of their own best position (*pbest*) as well as the best position of their neighbors (*gbest*). In other words, the swarm direction of a particle is defined by

the set of particles neighboring the particle and its history experience.

A. MOPSO

Moore and Chapman proposed the first extension of the PSO strategy for solving multi-objective problems in 1999 [5].

However, the high speed of convergence in MOPSO approaches often implies a rapid loss of diversity during the optimization process. [4] proposes a MOPSO incorporating the concept of nearest neighbor density estimator for selecting the global best particle and also for deleting particles from the external archive A of nondominated solutions. This approach uses the mutation operator proposed in [6] in such a way that it is applied only during a certain number of generations at the beginning of the process. Finally, the authors adopt the constraint-handling technique from the NSGA-II [7].

The implementation of MOPSO given in [4] is based on following fundamental steps (obvious ones are omitted):

- i) Initialize a swarm with random positions and velocities
- ii) Evaluate the particles and store nondominated ones in A ;
- iii) Compute the crowding distance of each member of A ;
- iv) Sort A in descending crowding distance order;
- v) Randomly select the global best for the swarm from a specified top portion (e.g. top 10%) for the sorted A and store its position in *gbest*.
- vi) Update velocities and positions according to:

$$v_i(t+1) = w \cdot v_i(t) + c_1 \cdot ud \cdot [p_i(t) - x_i(t)] + c_2 \cdot Ud \cdot [p_g(t) - x_i(t)] \quad (1)$$

$$x_i(t+1) = x_i(t) + \Delta t \cdot v_i(t+1) \quad (2)$$

where w is the inertia weight; $v_i = [v_{i1}, v_{i2}, \dots, v_{in}]^T$ stands for the velocity of the i -th particle, $x_i = [x_{i1}, x_{i2}, \dots, x_{in}]^T$ stands for the position of the i -th particle of population, and

$p_i = [p_{i1}, p_{i2}, \dots, p_{in}]^T$ represents the best previous position of the i -th particle. Positive constants c_1 and c_2 are the cognitive and social factors, respectively, which are the acceleration constants responsible for varying the particle velocity towards *pbest* and *gbest*, respectively. Index g represents the index of the best particle among all the particles in the swarm. Variables ud and Ud are two random numbers [0,1].

- vii) Perform the mutation operation proposed in [6];
- viii) Evaluate the particles in swarm;
- ix) Insert all new nondominated solution into A if they are not dominated by any of the stored solutions. All dominated solutions in A . If the archive is full, the solution to be replaced is determined by: a) compute the crowding distance values of each nondominated solution in the archive A ; b) sort the nondominated solutions in A in descending crowding distance values, and iii) randomly select a particle from a specified bottom portion (e.g. lower 10%) and replace it with the new solution;
- xi) Return to Step (iii) until a criterion is met, usually a sufficiently good fitness or a maximum number of iterations, t_{\max} . In this work, the t_{\max} value is adopted.

B. The proposed G-MOPSO approach

The proposed G-MOPSO approach uses social and cognitive time-variant factors [8] and a velocity update operator based on truncated Gaussian distribution [9]. In particular the updating of c_2 is given by [8]:

$$c_2 = (c_{2f} - c_{2i}) \frac{t}{t_{\max}} + c_{2i} \quad (3)$$

where c_{2i} and c_{2f} are constants. In this work, the adopted values are suggested by [10] and given by $c_{2i} = 0.4$ and $c_{2f} = 2.05$.

III. OPTIMIZATION RESULTS

TEAM workshop problem 22 consists in determining the optimal design of a superconducting magnetic energy storage (SMES) device in order to store a significant amount of energy in the magnetic field with a fairly simple and economical coil arrangement which can be rather easily scaled up in size.

The multiobjective version of TEAM workshop problem 22 [10] is a continuous, constrained, eight-parameter benchmark with two conflicting objectives: the attainment of a required stored energy and the minimization of the stray field along two given lines. The setup of the MOPSO and G-MOPSO methods involved binary tournament selection, population size $P=30$, and stopping criterion $t=200$ generations. In the MOPSO, a unitary value was adopted in c_1 and c_2 , and w with linear decreasing of 0.9 to 0.4 during the generations, while in G-MOPSO equation (7) is used to update the c_1 and c_2 values.

Simulation results for 30 runs (Figs. 1 refers to the Pareto front obtained by G-MOPSO) show that the non-dominated solutions obtained by G-MOPSO dominate the solutions obtained by MOPSO. Furthermore, it can be observed that in terms of spacing metric [11] the solutions obtained by G-MOPSO are more uniformly spaced than MOPSO approach. The spacing obtained using MOPSO was 133.8798 and in the case of G-MOPSO was 2.1843.

IV. CONCLUSIONS

PSO is becoming very popular due to its simplicity of implementation and ability to quickly converge to a reasonably good solution.

Fig. 1. Pareto front obtained by G-MOPSO.

Furthermore it can be quite easily extended to multiobjective problems. In this paper the performance of a variant of MOPSO is tested on the multiobjective version of TEAM benchmark problem 22 with good results. In the extended version of the paper a thorough comparisons of the fronts obtained by MOPSO and G-MOPSO will presented together with a detailed description of the algorithmic details of G-MOPSO.

Abstract — A Magnetic Fluid Hyperthermia (MFH) inductor design using multiobjective evolution strategy techniques has been proposed. Uniformity of the magnetic field and solution sensitivity are the objective functions chosen for the selection of the inductor geometry .

I. INTRODUCTION

MFH provides the heating of cancer lesions until a temperature that can damage tumoral tissues. In this therapy nanoparticles, injected in the human tissues, are heated by means of an AC magnetic field which should be as much as possible uniform in the treatment area [1]. Such a kind of equipment was installed e.g. at the Charité hospital in Berlin [2]. The field source is a coil with a ferrite yoke which is able to guarantee, in a cylinder with diameter of 20 cm a magnetic field strength with a uniformity of 90 % [2]. In the paper, the synthesis of an iron-free magnetic field source, inspired by Loney solenoid system [3], is proposed. The aim is to synthesize a uniform field in the treatment region, insensitive to small variations of coil system parameters.

Actually, in various applications of bioengineering, the generation of uniform magnetic fields is required. For instance, in magnetic resonance imaging (MRI) [3], as well as in magnetic induction tomography (MIT) [7], the field synthesis problem is characterized by a small size of the controlled region and a high degree of uniformity (in the order of ppm). Instead, in MFH the controlled region size is one order bigger than in MRI and MIT systems, because the anthropometric dimensions should be taken into account; this, in turn, has a consequence in terms of the degree of field uniformity achievable in practice.

Scope of the paper is to propose an automated optimal-design procedure of inductors for MFH clinical treatment of cancer lesions, with the final aim of providing a control in the uniformity of magnetic field and hence a uniform therapeutic temperature in wide body regions. In particular, an air-cored solenoid system, which offers a possible advantage in terms of reduced size due to the lack of ferromagnetic material is considered. The design problem is formulated in terms of a multiobjective problem [4].

II. THE DEVICE

In Fig. 1 an half of the longitudinal section of the device, with the controlled region Ω , and design variables, is sketched. L_1 and L_2 are the lengths of main and correcting coils, respectively, x_1 is the radius of main coil, dx the gap between main and correcting coil, z_1 the distance of the main coil from

the z axis, dz is the shift of the correcting coil with respect the main one. The square at the system centre, with side L_x , is the area where the field uniformity is to be controlled. In Table I the variation ranges of design variables and the fixed values of parameters are reported.

Fig. 1: geometry of the system

TABLE I
VALUES OF THE PARAMETERS

	R1[m]	dr[m]	Z1[m]	dz[m]	L1[m]	L2[m]	I1[A]	I2[A]
Min	0.25	0.05	0.15	-0.05	0.2	0.15	1000	500
Max	0.5	--	0.4	0.45	--	--	--	--

III. DIRECT PROBLEM

The magnetic field has been computed using a semi-analytical model, i.e. superposing the field generated by each turn composing a coil. To this end, a classical formula [5] that involves the evaluation of elliptic integrals has been used. This method has been chosen for its computational speed in repeated field analyses, and in view of an optimization procedure.

A. Field analysis

The inhomogeneity function, f , is defined as follows:

$$f = \frac{H_{\max} - H_{\min}}{H_{\text{mean}}} \quad (1)$$

where H_{\max} , H_{\min} , and H_{mean} are maximum, minimum and average value of the magnetic field in the controlled region Ω , respectively; numerically, inhomogeneity has been computed in a set of $N=231$ points, located in Ω .

B. Sensitivity evaluation

An inexpensive evaluation of sensitivity is possible when a set of $n_p \gg 1$ points discretizing the search space is available. Each point of the set is considered as the centroid of a hypercube ω composed of all the other points which distance

from the given one is less than a threshold [6]. Then, sensitivity s is approximated as :

$$s(\tilde{g}) \equiv [f(\tilde{g})]^{-1} [\sup_g f(g) - \inf_g f(g)], \quad g \in \omega \quad (2)$$

where \sup and \inf are computed within ω , and $f(\tilde{g})$ is the inhomogeneity function value at the hypercube centroid \tilde{g} . In

Fig. 2 sensitivity versus inhomogeneity function. Points in the lower left and upper right corner are good and bad solutions, respectively.

Fig. 2, sensitivity s is plotted as a function of inhomogeneity f . The cloud of points has been obtained after sampling the three-dimensional search region formed by variables x_1 , z_1 and dz . In particular, z_1 and dz have a practical significance because they have to be adjusted during the set-up phase of therapy equipment, and their setting depends on the patient size. The sampling is based on a random search governed by a uniform probability density function, and is composed of 1,000 points.

IV. DESIGN PROBLEM

The aim of the magnetic system is to generate a field uniform enough in the controlled region Ω . The shape design of the system has been performed using a multiobjective formulation. Ensuring the maximum homogeneity of the magnetic field in a prescribed volume was the main target of the design. In fact, a uniform magnetic field is a preliminary condition for an uniform power density and then for an almost uniform heating of human body tissues. On the other hand, since the opening of the system has to be adjusted depending on the anthropometric sizes of the patient, the sensitivity of configurations minimizing the field inhomogeneity should be evaluated. This way, among all feasible solutions, the ones exhibiting both low inhomogeneity and sensitivity will be selected. Therefore, the design problem has been cast as a two-objective optimization problem: find the set of feasible solutions x such that both $f(x)$ and $s(x)$ are minimum, according to Pareto optimality [4].

V. RESULTS

In Fig. 3a and 3b two feasible geometries are shown: the former is an example of good solution, the latter of bad solution. The first one represents a optimum case and the second one a not-optimal case. In Fig. 4 the percentage variation of the H field is shown; the maximum of the magnetic field H is close to 15000 A/m. The maximum has been evaluated as the global one along three directions (d_1, d_2, d_3), defined inside the controlled region (Fig. 1). It can

be noted that between 2 and 20 cm from the axis system the field uniformity is higher than 95%.

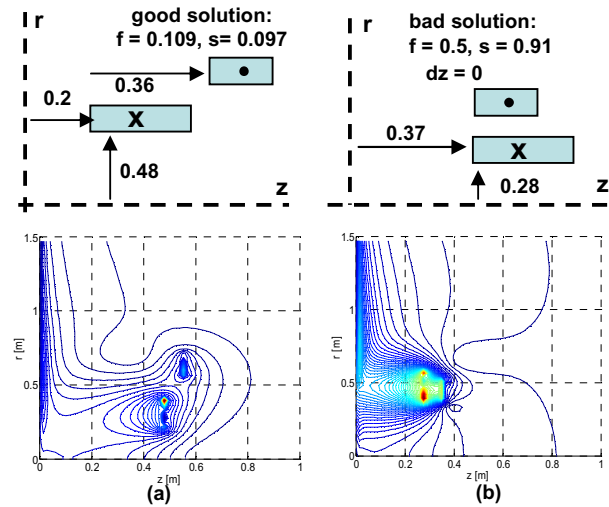

Figure 3: geometry and H field lines for a (a) good and a (b) bad solution.

Fig. 4: percentage variation of H field.

In the full-length paper the Pareto front of the problem will be identified by means of an optimization procedure based on evolutionary computing. Eventually, for assessing the optimization results, a finite-element based thermal analysis of a human tissue subject to the synthesized magnetic field will be developed.

Abstract — The approaches to process the process variations in the parasitic extraction of interconnects are still indigent and how to implement spectral stochastic finite element method (SSFEM) is still a little ambiguous. In this paper, the clear flow of SSFEM is detailed and three important points such as the stochastic field, the post-processing for calculation of capacitance, are emphasized.

I. INTRODUCTION

During this ultra-deep submicron and nanoscale integrated circuit technology era, it's irrefutable that the process variations have become pivotal issues in integrated circuit design and verification, and an ample solver to handle the variability shall be a crucial goal in EDA. Of all types of variations [1], material parameter variations, especially at the interconnect structure level are studied in this paper.

In brief, the stochastic analysis in numerical computation was firstly applied in the structural mechanics and gradually extended to the field of electromagnetic [2]-[3]. Usually, the finite element method (FEM) is used to analyze material variations [4] while the integral equation method (IEM) and the boundary element method (BEM) are utilized to discuss geometric variations [5]-[6]. Ideas of SSFEM and polynomial chaos (PC) are practiced in [2], but some key procedures of SSFEM for electromagnetism computation are not appropriately explained and practices in analyzing interconnects parasitic are not yet made.

In this paper, based on the scheme of stochastic finite element methods and stochastic field theory, we will show clearly the overall flow of SSFEM and introduce the way to analysis the material properties with correlation functions which becomes probable requirements henceforth.

II. STOCHASTIC FINITE ELEMENT METHODS

Neumann expansion stochastic FEM (NSFEM) traced here is usually used to solve randomness problems.

For FEM's matrix system $\mathbf{K}\Phi = \mathbf{b}$, given $\mathbf{K} = \bar{\mathbf{K}} + \Delta\mathbf{K}$, $\mathbf{P} = \bar{\mathbf{K}}^{-1}\Delta\mathbf{K}$, according to Neumann series expansion [2],

$$\mathbf{K}^{-1} = (\bar{\mathbf{K}} + \Delta\mathbf{K})^{-1} = (\mathbf{I} + \bar{\mathbf{K}}^{-1}\Delta\mathbf{K})^{-1} \bar{\mathbf{K}}^{-1} \quad (1)$$

$$= (\mathbf{I} + \mathbf{P})^{-1} \bar{\mathbf{K}}^{-1} = (\mathbf{I} - \mathbf{P} + \mathbf{P}^2 - \mathbf{P}^3 + \dots) \bar{\mathbf{K}}^{-1}$$

$$\Phi_0 = \bar{\Phi} = \bar{\mathbf{K}}^{-1}\mathbf{b}, \quad \Phi_i = -\bar{\mathbf{K}}^{-1}\Delta\mathbf{K}\Phi_{i-1}, \quad i \geq 1, \quad \Phi = \sum_{i=0}^{\infty} \Phi_i \quad (2)$$

III. PROBLEMS

Parasitic extraction of interconnects is readily an electrostatic field problem or a steady electric field problem:

$$\text{div}(\varepsilon \cdot \text{grad } \varphi) + \rho = 0, \quad \text{or} \quad \text{div}(\sigma \cdot \text{grad } \varphi) = 0 \quad (3)$$

Let us consider a small domain spatial D or an element Ω_e with random permittivity. If the permittivity is supposed to be uniform within D , we call it *constant distribution*, while if the distribution obeys some correlation function, we call it *field distribution*. If ε is random, but its variance is finite in real space, it can be expressed as a stochastic field,

$$\varepsilon(\mathbf{x}, \theta) \equiv H(\mathbf{x}, \theta)\varepsilon(\mathbf{x}) \quad (4)$$

A. Stochastic field

Karhunen-Loève expansion (K-L) and orthogonal series expansion (OS) are usually used to discrete stochastic field into expressions in random space. For example, the K-L expansion of stochastic field $H(\mathbf{x}, \theta)$ is shown as

$$H(\mathbf{x}, \theta) = \mu(\mathbf{x}) + \sum_{i=1}^{\infty} \sqrt{\lambda_i} \varphi_i(\mathbf{x}) \xi_i(\theta) \quad (5)$$

In the above, $\mu(\mathbf{x})$ is the mean of the whole domain D , $\xi_i(\theta)$ is a standard normal variable (SNV), λ_i and $\varphi_i(\mathbf{x})$ are value pairs of eigenvalues and eigenfunctions relative to the correlation function of the stochastic field. Under a certain condition, we can get the closed form solution, while under other conditions, we can choose another orthogonal functions set [2]. In constant distribution, $\varphi_i(\mathbf{x}) \equiv 0$, $\lambda_i \equiv 1$ equivalently.

Then the element coefficient matrix and ensemble coefficient matrix can be re-written as,

$$\mathbf{k}^e(\theta) = \mathbf{k}_0^e(\theta) + \sum_{i=1}^{\infty} \mathbf{k}^e(\theta) \xi_i(\theta) = \mathbf{k}_0^e(\theta) + \sum_{i=1}^{\infty} \xi_i(\theta) \sqrt{\lambda_i} (\quad (6)$$

$$\int_{\Omega_e} \varphi_i(\mathbf{x}) \varepsilon_0 \text{grad} w \mathbf{J}^{-T} \cdot \mathbf{J}^{-1} \text{grad} w \det(\mathbf{J}) d\Omega_e)$$

$$\left[\mathbf{K}_0 + \sum_{i=1}^{\infty} \mathbf{K}_i \xi_i(\theta) \right] \cdot \Phi(\theta) = \mathbf{b} \quad (7)$$

B. Governing equation of stochastic response

Expand equation (7) via Neumann method, then

$$\Phi(\theta) = \sum_{k=0}^{\infty} (-1)^k \left[\sum_{i=1}^{\infty} \mathbf{K}_0^{-1} \cdot \mathbf{K}_i \xi_i(\theta) \right]^k \cdot \Phi_0 \quad (8)$$

With the growing of k as well as the amount of constant distribution domains, the product of $\xi_i(\theta)$ -s becomes increasingly complex.

C. Polynomial chaos

The complex items of $\xi_i(\theta)$ -s can be mapped to another normalized orthogonal basis set $\{\Psi_j(\theta)\}_{j=0}^{\infty}$, such as Hermite polynomial, Legendre polynomial and *etc* in space L^2 . Of course $\{\Psi_j(\theta)\}_{j=0}^{\infty}$ is well-defined by $\{\xi_k(\theta)\}_{k=1}^{\infty}$, so each stochastic response quantity $\phi_i(\theta)$ can be expressed as

$$\phi(\theta) = \sum_{j=0}^{\infty} \phi_j \Psi_j(\theta), \quad \text{while } \Psi_{\mathbf{a}}(\theta) = \prod_{i=1}^M h_{\alpha_i}(\xi_i(\theta)) \quad (9)$$

The number of M -dimension and p -order polynomial items is $P = \sum_{k=0}^p C_{M+k-1}^k [2]$ -[3].

D. General stochastic coefficient matrix

Based on equations (7-9), the matrix items are truncated at advisable dimensions and series degree to form a residue,

$$\text{err}_{M,p} = \left[\sum_{i=0}^M \mathbf{K}_i \xi_i(\theta) \right] \cdot \left[\sum_{j=0}^{P-1} \Phi_j \Psi_j(\theta) \right] - \mathbf{b} = \sum_{i=0}^M \sum_{j=0}^{P-1} (\mathbf{K}_i \xi_i(\theta)) \cdot \quad (10)$$

$$\Phi_j \Psi_j(\theta) - \mathbf{b} = \sum_{i=0}^M \sum_{j=0}^{P-1} \mathbf{K}_i \cdot \Phi_j \xi_i(\theta) \Psi_j(\theta) - \mathbf{b}$$

Set $c_{ijk} = E[\xi_i \Psi_j \Psi_k]$, $\mathbf{b}_k = E[\Psi_k \mathbf{b}]$, $\mathbf{K}_{jk} = \sum_{i=0}^M c_{ijk} \mathbf{K}_i$, and

implemented by Galerkin scheme, the general stochastic coefficient matrix is approximately formed as

$$\begin{bmatrix} \mathbf{K}_{00} & \cdots & \mathbf{K}_{0,p-1} \\ \vdots & & \vdots \\ \mathbf{K}_{p-1,0} & \cdots & \mathbf{K}_{p-1,p-1} \end{bmatrix}_{\substack{(N \times P) \\ \times \\ (N \times P)}} \cdot \begin{bmatrix} \Phi_0 \\ \vdots \\ \Phi_{p-1} \end{bmatrix}_{\substack{(N \times P) \\ \times \\ (1)}} = \begin{bmatrix} \mathbf{b}_0 \\ \vdots \\ \mathbf{b}_{p-1} \end{bmatrix}_{\substack{(N \times P) \\ \times \\ (1)}} \quad (11)$$

Then we get the stochastic response,

$$\Phi(\theta) = \sum_{j=0}^{P-1} \Phi_j \Psi_j(\theta) \quad (12)$$

The above method is so called SSFEM, and it's a *real* one in the case of *field distribution*.

E. Post-processing

Using equation (12), we can obtain statistics moments and probability distribution conveniently for Ψ_j is determinate functions of SNV. Calculation of capacitance can be referred to the electric flux surrounding a conductor

$$F = \int_{\Omega_{\Sigma}} \varepsilon(\theta) \mathbf{k} \cdot \text{grad} v d\Omega \quad (13)$$

where Ω_{Σ} is a closed *thick* surrounding surface. Finally the capacitance is also a function of Ψ_j .

Particularly, we use Latin hypercube sampling (LHS) method instead of direct Monte Carlo sampling method to verify the validity and effectiveness of SSFEM; LHS turns out to be more efficient and credible.

IV. EXEMPLIFICATION

A simple example (Fig 1) is drawn to validate the idea of interconnects parasitic extraction with SSFEM.

Homogeneous permittivity and $M=2$ -dimension are assumed, for that the variations is quite small, choose $p=5$, then $P=21$. The FEM matrix is 898×898 while SSFEM matrix is 18858×18858 .

Fig. 1. Sketch of example of multi-domains with probability distribution.

Results are shown in Table I, the unit of capacitance is $fF/\mu\text{m}$, unit of time is s . We can find that if field distribution is under consideration, the time consumption booms sharply and the error is also notably fluctuated.

TABLE I. COMPARING SSFEM AND FEM USING LHS

Type	Value	SSFEM	LHS
Nominal mean		0.014310	
Constant distribution	mean	0.01428	0.01430
	std	0.002721	0.002796
Field distribution	time	326	1,226
	mean	0.01483	0.01526
(correlation function of exponential type)	std	0.003230	0.005045
	time	472	1931

V. CONCLUSION AND OUTLOOK OF SSFEM

Three points during the detailed steps of SSFEM are emphasized: the NSFEM procedure, the stochastic field distribution, and the capacitance formula as the function of PCs. But it's still not known clearly which distribution are the actual one, which perhaps strictly obeys some physical processes; and the orthonormal functions we select as the space basis maybe cannot exactly keep the characteristics of the original field. More efforts to in-depth research in stochastic field are required.

SSFEM explodes the amount of calculation and memory needed, so high efficiency algorithms is another key point. Adverting to the current programs, the techniques of multi-core CPU, GPGPU, *etc* are surely worthy of attention.

Abstract — This paper describes the applicability of a kriging assisted method to the design of a synchronous generator with a high temperature superconducting (HTS) rotor winding. The derived algorithm provides pareto optimal fronts maximising the air-gap flux density while minimising the length of YBCO tapes.

I. INTRODUCTION

The prospect of reducing the size and weight of a machine through using HTS windings is very appealing, especially for applications such as offshore wind power generation. Until recently the performance of such machines was somewhat hampered by the limited capabilities of the available BiSCCO tapes. Now that the second generation (2G) HTS tapes have become commercially available [1], with improved tolerance to the perpendicular component of the magnetic field, the possibility of building much smaller and lighter electrical machines is becoming a reality. The design of such devices requires substantial simulation effort; structural and thermal as well as electromagnetic requirements may require modelling. The cost is greatly increased if optimisation is required.

II. THE SPECIFIC OPTIMISATION PROBLEM

As an example, we consider a 6-pole arrangement with a 2G HTS rotor winding which may be used to demonstrate the principle of a high torque slow rotating multi-pole machine working in applications such as wind power generation. The objective is to maximise the air-gap flux density using the shortest possible length of the HTS tape

There are a number of possibilities regarding the rotor configuration (Fig.1). Although a coreless rotor is clearly the best choice to achieve the substantial mass reduction required to justify the use of a HTS winding in a full size machine, use of some iron may be warranted in a demonstrator. The choice of rotor configuration is a compromise between obtaining a high air-gap flux density and making the small demonstrator as similar as possible to the full-size machine. Similarity to the full size machine is not easily quantified; each configuration was therefore optimised separately, allowing the final choice to be informed by the results of these optimisations.

Each of the arrangements of Fig. 1 has two possible stator configurations: ‘slotted’ and ‘slotless’. In a conventional machine, the stator teeth are required to help raise the air-gap flux density by providing a low-reluctance flux path through the stator winding. The high current densities available in a HTS field winding may allow a high air-gap flux density to be obtained without the aid of teeth, suggesting that they are not required; hence they could be removed to save weight.

Fig. 1. Rotor configurations chosen for the design study: a) fully cored, b) inner core and coil core, c) inner core, d) fully coreless.

Moreover, the high flux density may saturate the teeth, reducing their effectiveness. It has also been found that modulation of the air-gap field by the stator teeth can induce quite substantial tooth ripple losses in the rotor. While these considerations favour the removal of the teeth, it should be noted that the teeth provide mechanical support for the winding and a radial thermal conduction path to help cool the winding. If they are removed, alternative arrangements must be sought to ensure support and cooling of the winding.

Optimising the design of an electrical machine is a computationally expensive process requiring repetitive use of finite element models. An added complication arises from the use of HTS windings. Since the critical current density of the HTS tape depends on the magnetic field that impinges on it, the critical current is a function of the current in the winding. This implies that for any configuration to be analysed the critical current density needs to be found iteratively, further increasing the computational cost. An efficient algorithm is therefore required, which should minimise the number of evaluations for which finite-element modelling is required. In this work we propose a methodology based on surrogate modelling using kriging [2, 3] to improve the efficiency of the optimization process.

III. SURROGATE MODELLING

The response surface methodology fits an approximation function to data obtained from the computationally expensive objective function at a small number of points. This response surface can then be used to predict the value of the objective function at intermediate positions in the search space. After constructing the response surface from an initial set of data points (off-line learning), it is used to guide the optimiser in selecting a new design vector for evaluation. As each new point is added, the surface fitting is repeated to take advantage of the new data point (on-line learning).

Kriging is a form of response surface modelling based on the principle of maximum likelihood and, in addition to providing a response surface that passes through all the data points, provides a meaningful estimate of the uncertainty of its predictions. Using these two values it is possible to estimate

the expected improvement that may be obtained by adding a new data point to the existing set. Using this measure to determine where the next point should be added greatly reduces the risk of the optimiser getting trapped in a local minimum. However, this technique is not foolproof; the algorithm may still fail to find the global minimum if the kriging function significantly underestimates the uncertainty in this region of the search space.

The goal of this study is to find a design which will give the highest possible air-gap flux density while using the least amount of superconducting tape. Due to the anisotropy of the tape both magnitude and direction of the magnetic flux density need to be considered. The manufacturer's data for the dependence of the critical current of the YBCO tape on the field, in both the perpendicular and parallel directions, has been incorporated into the command script executing in the finite element package. The critical current is taken to be the lower of the value estimated from the maximum normal component of B and that estimated from the maximum parallel component of B . The critical current is found by repeatedly solving the model and changing the assumed current in the superconductor towards the minimum value given by the graphs of $I_c(B)$ until satisfactory convergence is obtained. The fundamental D-axis component of the air-gap flux density predicted by the model is then returned to the optimisation algorithm written in MATLAB.

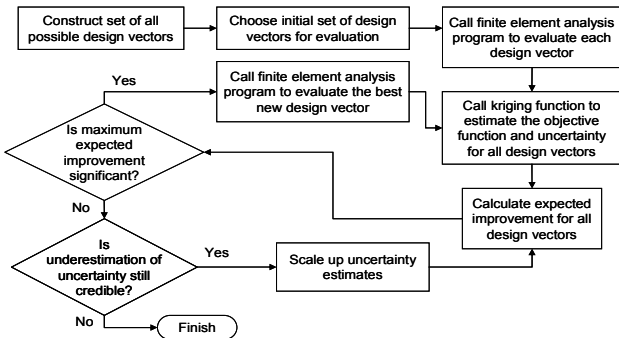

Fig. 2. Optimization algorithm.

A simplified illustration of the algorithm is presented in Fig. 2. The optimizer varies the following parameters: the number of turns in the largest coils, the number of coils and the number of coils that have reduced number of turns to leave space between adjacent poles. A constraint was imposed on the minimum bend radius at the ends of the HTS coils.

A set of 16 points is first chosen using the Latin sampling cube [4]. After evaluating these points and fitting a surface the algorithm finds the maximum of the expected improvement

$$E[I(x)] = (f_{\min} - y)\Phi\left(\frac{f_{\min} - y}{s}\right) + s\phi\left(\frac{f_{\min} - y}{s}\right) \quad (1)$$

and evaluates the objective function at the new point. In (1) f_{\min} is the minimum value of the objective function at the sampled points, y is the predicted value at point x , s is the square root of the expected square error at point x predicted by the surrogate model, ϕ is the standard normal distribution function and Φ is its integral. This equation is easily obtained by integrating the product of the improvement and the estimated (assumed normal) probability density function.

Use of the expected improvement to drive the algorithm seems reasonable, but it has its limitations. First, as noted previously, it is likely that the values of expected square error predicted by the kriging function are under-estimated; hence the algorithm could stop after finding a good local minimum but fail to find the global minimum. Secondly, maximising the expected improvement for each new point is a short-term objective and places no value on the knowledge gained by adding new data points. Scaling up the uncertainty estimates as proposed in Fig. 2 should overcome the first problem, although the method of deciding whether under-estimation of uncertainty is still credible needs further consideration. While the optimiser can be encouraged to explore more widely by deliberately over-estimating the uncertainty, the expected value of the information obtained from a new data point is difficult to estimate. More discussion about exploration versus exploitation and enhanced formulations will be provided in the extended paper. Figure 3 shows the pareto optimal front obtained for a coreless rotor at 40K in a slotless stator.

Fig. 3. Pareto optimal front for one of the considered configurations.

IV. CONCLUSIONS

The paper demonstrates the use of surrogate modelling and kriging assisted optimisation in the context of the design of a synchronous generator having a superconducting rotor winding made of YBCO tapes. The necessary repetitive use of finite element models makes the design process computationally expensive but is helped by efficient use of the response surface methodology. The criterion of expected improvement is applied but the balance between exploitation and exploration needs to be carefully controlled.

The advantage of using a surrogate-assisted optimization algorithm is the small number of finite element evaluations. A surrogate-assisted optimization algorithm, called Multiobjective Efficient Global Optimization, suited for grid computing is presented in this paper. The surrogate model used by the algorithm is the Kriging model. An application to the Superconducting Magnetic Energy Storage (SMES) system of Team benchmark problem 22 is presented. The Pareto optimality front, representing the trade-off curve between objectives is obtained at low cost. At the end of the optimization process, the surrogate model and the finite element model are very close to each other in the subspace around the Pareto front.

Index Terms—surrogate-assisted optimization, multiobjective optimization, Kriging surrogate model, grid computing, optimal design, SMES, Team benchmark problem 22.

I. INTRODUCTION

In the design optimization process, analytical models are usually used in order to simulate the behavior of the designed product. The Finite Element Analysis (FEA) is used in the later stages of product development, in order to validate the obtained design.

The recent trend is to integrate the Finite Element Analysis in the early stages of the product development cycle, allowing this way a significant reduction of the product development delay. Even though the computing resources have developed exponentially during the last decade, the FEA still remains time consuming, and its direct integration in the optimization process remains marginal. This is due to the great number of function calls of an optimization algorithm. The surrogate-assisted optimization strategies appear a promising approach [1], allowing the integration of high fidelity models, such as FEA, in the optimization process, and with a reasonable time cost. The application to the optimal design of an electrical machine using multiphysic model including FEA can be found in [2]. Some extensions to the multiobjective optimization case have been developed recently [3].

Real design engineering problems are complex, presenting many conflicting objectives and constraints. The trade-off curve between objectives (called Pareto optimality front) obtained through multiobjective optimization helps engineers in the difficult task of decision making. In this paper a new multiobjective surrogate-assisted optimization algorithm is presented. A new infill criterion, called Pseudo distance, suited for the multiobjective optimization case is presented. The Kriging surrogate models developed by the algorithm through the optimization process present the particularity of being very close to the FEA model in the subspace around the Pareto front. The algorithm was applied to the Team benchmark problem 22, which deals with the optimization of a superconducting magnetic energy storage system (SMES).

II. SURROGATE-ASSISTED OPTIMIZATION

This section describes the Surrogate-Assisted Optimization strategy. The algorithm presented in this paper is based on [2], which was adapted for the multiobjective case, and suited for grid computing. The surrogate models used by the algorithm are Kriging models.

A. Kriging Surrogate Model

In the Kriging model formulation, an unknown function $y(x)$ can be expressed as a sum of two terms: one that gives the global trend of the function, called the regression or polynomial model, and another one that gives the local deviations from the global trend. The correlation function controls the smoothness of the model. The Gaussian correlation function between points i and j is:

$$R(x^{(i)}, x^{(j)}) = \exp \left[- \sum_{k=1}^{n_k} \theta_k |x_k^{(i)} - x_k^{(j)}|^2 \right] \quad (1)$$

where x is the design variable vector, θ_k represents the unknown correlation function parameter vector.

The Kriging model predicts the estimated response value \hat{y} . The Mean Square Error (MSE) is the expected value of difference between the true response and the estimated one. Since Kriging interpolates the data, MSE is zero at the sampled points. At unknown points, MSE should be minimized in order to obtain a good approximation.

Fig. 2 presents a one dimensional example. The Kriging model is constructed using 5 sample design points. At the sample points the standard error is zero and higher in the gaps between sampled points. This tells us that the Kriging model gives the exact value at the sample points (interpolation model) and may have some error at other design vectors. This important information is used by the infill criteria to locate the infill point to be added.

Fig. 2 – One dimensional illustration example showing the true model, Kriging prediction and its standard error.

B. Algorithm

The algorithm starts by sampling the initial points using the Design Of Experiments (DOE) method. The set of initial points is then evaluated using the high fidelity model, such as FEA model. A Kriging surrogate model is fitted for each objective and constraint function individually. A new infill point selection criterion was developed in order to generate a set of infill points instead of a single point. This allows the distribution of the FEA model evaluations over each available CPU. Each of these points is then validated against accept conditions and if these conditions are met, it will be added to the improvement solution set. In both cases, the point is added to the sample data set. If the prescribed stopping criteria are met, the algorithm ends, obtaining the non-dominated solutions forming the Pareto front. Otherwise, it goes back and uses the new obtained infill points to fit new Kriging models.

More details on the algorithm will be given in the full paper.

C. Infill Point Selection Criteria

In this paper a new infill criterion, called *pseudo distance* is proposed for the multiobjective optimization case. It is based on the non-dominate concept. The pseudo distance is composed of two terms: the dominate distance D_d , and the neighboring distance D_n , presented in (2)-(4).

$$D_{pseudo}(x) = D_n(x) + D_d(x) \quad (2)$$

$$D_n(x) = \sum_{i=1}^m \left(\left(\frac{f_i^{(s_i)} - \hat{f}_i(x)}{f_{i,max} - f_{i,min}} \right) \cdot \hat{\delta}_i(x) \right) \quad (3)$$

$$D_d(x) = \sum_{j=1}^{n_{dom}} \sum_{i=1}^m \left(\left(\frac{f_i^{(s_j)} - \hat{f}_i(x)}{f_{i,max} - f_{i,min}} \right) \cdot \frac{1}{\hat{\delta}_i(x)} \right) \quad (4)$$

An example is given in Fig. 3 to explain the concept.

Fig. 3 – (a) Dominate distance, (b) Neighboring distance

D_d gives a design vector with the smallest estimated standard error (small $\hat{\delta}$), i.e. accurate Kriging predictions that will dominate with the greatest distance the existing non-dominated front (NF). Starting from a non-dominated front $NF_1=[S_1, S_2, S_3, S_4, S_5]$, from the previous iteration, the point T_1 will be preferred to another point T_2 , due to its greater dominate distance, as presented in Fig. 3a.

On the contrary, the D_n will focus to the neighborhood of the trial point. It will give a design vector with a high standard error (high $\hat{\delta}$), i.e. the greatest distance between the trial point and its neighboring non-dominated points. It sacrifices prediction accuracy in order to spread the points along the front, filling up the largest gap between two existing non-dominated points, as shown in Fig. 3b. This time, the point T_3 will be preferred to T_4 , because of the greater D_n .

The next design vector is located by maximizing (2), using a mono objective optimization algorithm. This step is repeated until a prescribed number of infill points are obtained, depending on the number of available CPUs.

III. APPLICATION TO TEAM WORKSHOP PROBLEM 22

The algorithm was applied to the eight-parameter multiobjective Team workshop problem 22. The obtained results are presented in Fig. 4. The non-dominated front is obtained through 300 FEA model evaluations (220 infill points and 80 initial points using Latin hypercube sampling). The problem was formulated as follows:

$$\min \begin{cases} f_1 = B_{stray}^2 / B_{norm}^2 \\ f_2 = |E - E_{ref}| / E_{ref} \end{cases} \quad (5)$$

with $E_{ref}=180\text{MJ}$, $B_n=200\mu\text{T}$ and subject to quench condition.

The presented algorithm allows obtaining the Pareto non-dominated front with low number of FEA evaluations.

Abstract — A hybrid algorithm based on the combination of the Flock of Starlings Optimization (FSO) and the Bacterial Chemotaxis Algorithm (BCA) is presented for multimodal optimization tasks. In particular the FSO, that is a modification of the well known Particle Swarm Optimization, is a powerful instrument for exploring the whole space of solutions, whereas the BCA, that virtually emulates the motion of a real bacterium looking for food (i.e. fitness function), shows its better performances in local search. The present approach uses the FSO to explore the solution space and the BCA for refining solutions. A parallel strategy is implemented: the FSO is permanently running, and any time it found a possible solution, the BCA is launch, and so on. Test on general optimization benchmark and on the TEAM22 problem are shown.

I. INTRODUCTION

In this paper is presented a hybrid algorithm based on the combination of two heuristics inspired from Artificial life: the Flock of Starlings Optimization (FSO) [1] and the Bacterial Chemotaxis Algorithm (BCA) [2]. The approach is particularly suitable for multimodal optimization tasks. The FSO as described in [1] is a modification of the well known Particle Swarm Optimization (PSO) [3] by adding a topological rule to the metric rules typical of the PSO. In fact, the FSO is inspired to recent naturalistic observation about the real starling flights [4]. As it is shown in [1], the FSO is particularly suitable for exploration and multimodal analysis. On the other hand, the BCA virtually emulates the motion of a real bacterium looking for food (i.e. fitness function). It is a heuristic that shows its better performances in local search [5]. The present approach uses the FSO to explore the solution space and the BCA for refining solutions. Moreover, a parallel strategy is implemented: the FSO is permanently running, and any time it found a possible solution, the BCA is launch, and so on. Test on general optimization benchmark and on the TEAM22 problem are shown.

II. THE APPROACH

A. The FSO

The classical PSO algorithm [3] is based on the control of the velocity shown by particles moving into the solution space. The updating at the (t+1)-th calculation step of the k-th component of the velocity vector, $v_{kPSO}^j(t+1)$, of each j-th particle is ruled by the following expression:

$$v_{kPSO}^j(t+1) = \omega^j v_{kPSO}^j(t) + \lambda^j (p_{bestk}^j - x_k^j(t)) + \gamma^j (g_{bestk} - x_k^j(t)) \quad (1)$$

where $k = 1 \dots \Delta$, and Δ is the dimension of the solution space of the x variables; ω^j , λ^j and γ^j are the so-called *inertial*, *cognize* and *social* coefficients respectively (often governed by the random (0,1) function) [3]; g_{bestk} is the coefficient global best of the whole swarm, while p_{bestk}^j is the personal best of each j-th particle.

The FSO algorithms add to (1) a new term due to the observation [4] that in real flock each generic h-th bird controls and follows the flight of a number, N_{crl_birds} , no matter what are their positions inside the flock: $\delta^j \cdot Mccb_k^j$; where δ^j is the so-called *topological coefficient* [1]. Finally, the updating at the (t+1)-th calculation step of the k-th component of the velocity vector, $v_{kFSO}^j(t+1)$, of each j-th particle is ruled by the following expression:

$$v_{kFSO}^j(t+1) = v_{kPSO}^j(t+1) + \delta^j \cdot Mccb_k^j \quad (2)$$

where: $Mccb_k^j = \frac{1}{N_{crl_birds}} \sum_{h=1}^{N_{crl_birds}} v_{FSO}^{h,j}$ is the mean value of the

k-th velocity components, $v_{kFSO}^j(t+1)$, of each h-th controlled starling of the flock by the j-th birds. The values g_{bestk} and $g_{bestk} \forall j, k$ are evaluated at each step t. These best values are computed by a suitable fitness function that estimates the goodness of the actual solution. As it has been proof in [1] for the case of identification of hysteresis models, the FSO can find a solution even if the dimension of the solution space is very high and moreover it is particularly suitable for multimodal optimization tasks.

B. The BCA

The BCA [5] takes inspiration by the motion characteristics of particular micro-organisms (bacteria) that is due to the different chemical properties encountered in the habitat (bacterial chemotaxis). A real bacterium differently reacts to the gradients of nutritive substance concentration (fitness) or of harmful substances. A mathematical description of the bacterium motion can be developed by the determination of suitable probabilistic distributions referred both to the motion duration and to the velocity vector (speed and direction) of the bacterium. For space reason, we invite to refer to [2] for a detailed description of the algorithm. More details will be given in the extended version of this paper.

C. The Hybridization and Parallelization

The present approach is hybrid since when the FSO finds a possible optimum, the BCA is launched to refining this

solution. But the FSO does not stop his search and goes on looking for other possible solutions. For implementing this approach we use 20 PC dual-cores. One of this is the Master on which the FSO runs; one is used to store the found solutions; whereas the other 18 units manage the BCAs. In this way it is possible to combine the high exploration capability of the FSO with the high fastness of the BCA in local search.

III. VALIDATION ON GENERAL BENCHMARKS

Let us apply the proposed algorithm to a 2D famous benchmark: the *bird function* which is expressed by $f(x, y) = \sin(x)e^{(1-\cos(y))^2} + \cos(y)e^{(1-\sin(x))^2} + (x-y)^2$. Into the range $x, y \in [-2\pi, +2\pi]$, it shows several local minima and two global minima equal to $f_{\min} = -106.7645367$ (approximation by limiting to 7 digits the decimal point precision) for two different pairs of coordinates: $(-1.58214, -3.13024)$ and $(4.70104, 3.15294)$. By comparing PSO, FSO and hybrid FSO+BCA we found the following results: the FSO found each minimum with good accuracy without to be launched more than one time: $(-1.58, -3.14)$ with $f_{\min} \approx -106.72$ and $(4.64, 3.13)$ with $f_{\min} \approx -106.24$; the PSO was entrapped into the closest global minimum encountered (depending on initialization of guess values) but showing the same level of accuracy of FSO; FSO+BCA improve the accuracy of the single FSO: it found both the global minima achieving the same value of $f_{\min} = -106.7645367$ for both minima.

IV. VALIDATION ON TEAM PROBLEM 22

The goal of the Team problem 22 [6-8] is to optimize the performance of the considered superconducting magnetic energy storage device systems consisting of two superconducting solenoid coils of rectangular cross section carrying opposite currents. This system has to be optimized in terms of its geometrical dimensions and currents carried, taking care that the magnetic stray field should be minimized without reducing the stored energy value. Consequently the target energy stored is fixed to 180 MJ, while the stray flux density should be as small as possible; in addition the maximum magnetic field within conductors must not exceed a certain critical value (in the present test, all the used optimization constrains are those reported in [8]). The optimization problem consists of finding all or a subset of the 8 parameters: $R_1, h_1, d_1, J_1, R_2, h_2, d_2, J_2$ (see Fig. 1). In this optimization problem we use as performance indices both the energy target and the stray field, i.e. the magnetic flux density RMS value measured along the two lines shown in Fig. 1 (for this evaluation we have considered 22 equally spaced points):

$$\xi = \frac{1}{22} \left(\frac{\sum_{i=1}^{22} |B_{stray,i}|^2}{B_{norm}^2} \right) + \frac{|Energy - E_{ref}|}{E_{ref}} \quad (3)$$

where E_{ref} is 180 MJ and B_{norm} is 3 mT. The magnetic flux density, B , can be easily obtained by using the Biot-Savart law, whereas the energy can be computed by considering the system in term of mutually coupled inductors. The self and

mutual inductances have been evaluated according to [9][10]. The present test is referred to the 3-parameter optimization. We have fixed $(h_1, R_1, d_1) = (3.0916, 2.8071, 0.1162)$ [m] and the current densities $(J_1, J_2) = (23.3809, -19.5511)$ [MA/m²]. Random guess values have been used for FSO which found a solution in $(h_2, R_2, d_2) = (1.56, 2.34, 0.39)$ [m] returning $\xi = 0.026$ by (3). Then, the FSO values have been used for initializing the BCA that found a refined solution in $(h_2, r_2, d_2) \approx (1.56101, 2.34240, 0.39395)$ [m] (just 5 decimal digits of 16 are here reported) corresponding to $\xi \approx 2.16 \cdot 10^{-4}$ that is a significant result [8].

Two-level refined direct method for electromagnetic optimization and inverse problems

Guillaume Crevecoeur, Ahmed Abou-Elyazied Abdallah, and Luc Dupré

Dept. of Electrical Energy, Systems & Automation, Ghent University, Sint-Pietersnieuwstraat 41, B-9000 Ghent, Belgium

Abstract—Electromagnetic optimization and inverse problems require a large number of evaluations in numerical forward models. These computer models simulate complex problems through the use of numerical techniques, and hence the evaluations need a large computational time. Two-level methods have been developed that include a second model so to accelerate the inverse procedures. Contrary to existing two-level methods, we propose a scheme that enables acceleration when the second model is based on the initial numerical model with coarse discretizations. This paper describes the proposed refined direct optimization scheme and validates the method onto algebraic test functions. Finally, we apply the method for solving an electromagnetic inverse problem.

I. INTRODUCTION

THE classical equations of Maxwell can be solved when the geometry, material characteristics and sources are specified. Using efficient numerical techniques, electromagnetic computer models can be built, which solve the so-called forward problem. Optimization and inverse problems on the other hand, need to identify a priori unknown parameter values by starting from an objective or electromagnetic measurements. Traditional direct optimization procedures strive towards the minimization of a predefined cost function by the use of one forward model. These methods have an update scheme that is based on the responses and eventual first and second order derivatives of the forward model. However, when dealing with complex problems where a single evaluation of the numerical forward problem is very time demanding, it is possible that solving optimization and inverse problems becomes difficult, time demanding and not practical.

In this perspective, so-called two-level optimization methods, e.g. space mapping [1], manifold mapping [2], etc., were conceived which accelerate the optimization procedure by incorporating an additional coarse model in the procedure. These methods propose an iterative scheme that includes a coarse model (low accuracy, time efficient) and a fine model (high accuracy, very time demanding), but fail to converge in a computationally efficient way when the computational time of the coarse model is not sufficiently smaller than the computational time of the fine model [2]. This is for example the case when the coarse model is based on the initial fine numerical model with coarse discretizations. Indeed, when dealing with complex electromagnetic problems, it is not always possible to build a very fast analytical model that is similar to the fine model. Therefore, we propose an alternative method that enables to solve optimization problems in a more efficient way, when including such a coarse model. This paper describes this so-called refined direct optimization scheme

in detail and implements the scheme with the Nelder-Mead simplex method and non-linear least squares methods. In order to validate the method, we apply the method onto algebraic test functions and an electromagnetic inverse problem.

II. REFINED DIRECT OPTIMIZATION (RDO) SCHEME

The computational effort in existing two-level schemes can become high because the coarse model is sequentially optimized with different objective values. In this paper, we carry out only one optimization of a surrogate-based model, that is iteratively refined during the optimization itself. The basic idea of the RDO scheme is to alter the optimization of the cost \mathcal{Y} , e.g. least-squares difference between measurements and simulations, of the fine model \mathbf{f} :

$$\mathbf{x}_f^* = \arg \min_{\mathbf{x}} \mathcal{Y}(\mathbf{f}(\mathbf{x})) \quad (1)$$

to the optimization of the cost of the surrogate model: $\mathbf{x}_s^* = \arg \min_{\mathbf{x}} \mathcal{Y}(\mathbf{s}(\mathbf{x}))$. Metamodels can be used as surrogate models within optimization schemes. These models are built by interpolating response data, obtained by evaluating the model $\mathbf{f}(\mathbf{x}_i)$ for a certain set of sample points \mathbf{x}_i , $i = 1, \dots, N$ in the design space. N is the number of design points. When dealing with complex problems, N needs to be large in order to obtain a sufficiently accurate metamodel. Here, we use metamodels for interpolating the coarse model response data to the fine model response data. The relation between coarse model response and fine model response is less complex and less difficult to determine. In this way, N can be reduced. The surrogate model, used in the RDO scheme has the following form: $\mathbf{s}(\mathbf{x}) = \mathbf{c}(\mathbf{x}) + \mathbf{e}(\mathbf{x})$ with error function $\mathbf{e}(\mathbf{x})$ that is determined using metamodels. In this paper, we use the Kriging metamodel, see e.g. [3], for making the interpolation. The surrogate model $\mathbf{s}(\mathbf{x})$ is refined during the optimization procedure by performing a limited number of fine model evaluations. The number of updates depends on how accurate the coarse model is, compared to the fine model. The proposed method has the same features as the traditional direct optimization method, i.e. start value, stopping criteria, etc., where the internal parameters of the RDO method are self-tunable. The method uses a trust-region strategy for updating the surrogate model. An outline of the algorithm is given:

Step 1: N design points are generated around start value $\mathbf{x}^{(0)}$ within the trust region radius $\Delta^{(0)}$: $\mathbf{x}_i^{(0)}$. Here, the latin hypercube sampling method is used. Evaluations are then carried out in the coarse and fine model.

Step 2: Construction of surrogate model $\mathbf{s}^{(0)}$ by determining $\mathbf{e}(\mathbf{x})$. We initialize $m = 0$.

Fig. 1. (a) Minimization of \mathcal{J}_1 , and (b) of \mathcal{J}_2 .

Step 3: Partial run of direct optimization method using surrogate model $\mathbf{s}^{(m)}$. Updates $\mathbf{x}^{(k)}$, $k = 1, \dots, K$ are carried out, depending on the used direct optimization method. The partial run of direct optimization method is stopped when $\mathbf{x}^{(K)}$ is near the trust region boundary. $\mathbf{x}^{(m)}$ becomes $\mathbf{x}^{(K)}$.

Step 4: Update of surrogate model: $\mathbf{s}^{(m+1)}$ in region $\Delta^{(m)}$. A limited number of evaluations are carried out in the fine model, so to refine the surrogate model in the next trust region.

Step 5: Determine the accuracy of the surrogate model so to determine the new trust region $\Delta^{(m+1)}$. The accuracy of the previous surrogate model $\mathbf{s}^{(m-1)}$, depends on the fidelity of the coarse model $\mathbf{c}(\mathbf{x})$ and the accuracy of the error function $\mathbf{e}(\mathbf{x})$. The accuracy is determined as follows:

$$\rho^{(m)} = \frac{\mathcal{Y}(\mathbf{f}(\mathbf{x}^{(m-1)})) - \mathcal{Y}(\mathbf{f}(\mathbf{x}^{(m)}))}{\mathcal{Y}(\mathbf{s}^{(m-1)}(\mathbf{x}^{(m-1)})) - \mathcal{Y}(\mathbf{s}^{(m-1)}(\mathbf{x}^{(m)}))}. \quad (2)$$

On the basis of $\rho^{(m)}$, we determine $\Delta^{(m+1)}$, similar to [4].

Step 6: If the termination criteria of the direct optimization method are not satisfied, then go to step 3, and set $m = m + 1$.

III. RDO APPLIED ONTO ALGEBRAIC TEST FUNCTIONS AND AN ELECTROMAGNETIC INVERSE PROBLEM

We compared the RDO method with the traditional direct optimization scheme. Firstly, we applied the RDO onto the following algebraic function: $\mathcal{J}_1(\mathbf{f}(\mathbf{x})) = -\exp(-(x_1^2 + x_2^2))$ with $\mathbf{x}_f^* = [0, 0]^T$. The implemented coarse model is similar to the fine model but where output and input are altered with optimal value $\mathbf{x}_c^* = [1, -1]^T$. Fig. 1a shows the points $\mathbf{x}^{(k)}$ that are updated in the traditional Nelder-Mead simplex method in order to obtain \mathbf{x}_f^* and \mathbf{x}_c^* . The figure shows the alternative path followed by the RDO algorithm in order to achieve convergence to $\mathbf{x}_s^* = \mathbf{x}_f^*$. The path followed by the iterates differ from the fine model one, but convergence is obtained with a limited number (20) of evaluations in the fine model.

Secondly, we applied the RDO onto the minimization of the two-dimensional Rosenbrock test function, with fine model: $\mathcal{J}_2(\mathbf{f}(\mathbf{x})) = 100(x_2 - x_1^2)^2 + (1 - x_1^2)$. The coarse model is again, seriously altered in input and output space. Fig. 1b compares the convergence history of the traditional method with cost $\log(\mathcal{Y}(\mathbf{f}(\mathbf{x}^{(k)})))$ with the RDO method with cost $\log(\mathcal{Y}(\mathbf{s}(\mathbf{x}^{(k)})))$ in each k -th iteration.

Finally, we applied the RDO method on the identification of the anhysteretic B - H characteristic of a magnetic ring core. The magnetic ring core, shown in Fig. 2a, is partially excited with an excitation angle 230° , where the introduced air gap is approximately 1 mm. This geometry is a simplified

Fig. 2. (a) Configuration of the partially excited magnetic ring core with air gap. (b) Recovered BH-characteristics using RDO and actual B - H characteristics.

magnetic circuit of an electromagnetic device. Due to the lack of extra samples to perform measurements with e.g. the classical single sheet tester, the B - H characteristics remain unknown. Therefore, we identify the material properties on the magnetic circuit itself, using a coupled experimental-numerical inverse approach based on the RDO technique. The results are compared with a traditional least-squares non-linear method.

The fine and coarse models are three-dimensional numerical models based on the finite element method (FEM), with fine and coarse mesh respectively. The FEM model solves the non linear quasi-static Maxwell's equation with non-linear permeability. The single-valued nonlinear constitutive relation of the magnetic material, is modelled by means of three parameters $[H_0, B_0, \nu]$:

$$\frac{H}{H_0} = \left(\frac{B}{B_0}\right) + \left(\frac{B}{B_0}\right)^\nu. \quad (3)$$

The inputs of the forward problem are the excitation currents and the magnetic material parameters for well known ring core dimensions. However, the output is the magnetic induction at specific position, e.g. position 2, as shown in Fig. 2a. On the other hand, the inputs of the inverse problem are the measured excitation currents and the measured local magnetic induction, e.g. at position 2. The output of the inverse problem is the magnetic material parameters. The identified material characteristics are depicted in Fig. 2b, where the recovered material characteristics approximate the actual B - H characteristic. The result is obtained in a computational efficient way with 20 % acceleration compared to the traditional optimization method.

IV. CONCLUSION

This paper proposes a method that decreases the computational time that is needed when optimizing or solving electromagnetic inverse problems. The results show that such problems can be solved with considerably improved acceleration as compared to the traditional inverse solutions.

Abstract— This paper describes the application of multivariate adaptive regression splines (MARS), one of the response surface methodologies, for reducing the calculation cost in electric machine design. Some numerical examples are reported for confirming the validity and effectiveness of MARS. And then, we also apply the proposed optimization method with MARS to a practical optimization problem.

I. INTRODUCTION

Recently, the practical application of design optimization method has been gradually spread. However, increasing calculation cost remains as an essential issue. Then, in this paper, we propose the adoption of multivariate adaptive regression splines (MARS), one of the response surface methodologies (RSM), for reducing the calculation cost in electric machine design. MARS adequately decomposes the search domain into some sections with basis functions so as to hold the abundant expressiveness and versatility. This paper reports some numerical examples, e.g., mathematical and benchmark models, to demonstrate the effectiveness of the proposed optimization approach with MARS.

II. MULTIVARIATE ADAPTIVE REGRESSION SPLINES (MARS)

MARS adopts the nonparametric regression model [1] as follows.

$$y_i = \hat{f}(x_i) + \varepsilon_i \quad (1)$$

where y_i is the objective function value at the i th experimental point. $\hat{f}(x_i)$ and ε_i stand for the approximate function value and the error at the point, respectively. And then, $\hat{f}(x)$ is expressed with plural basis functions B_m and truncation functions as shown in (2) and (3).

$$\hat{f}(x) = \alpha_0 + \sum_{m=1}^M \alpha_m B_m(x) \quad (2)$$

$$B_m(x) = \prod_{l=1}^{L_k} [s_{ml}(x_{v(m,l)} - t_{ml})]_+^q \quad (3)$$

where α is the unknown parameters to be calculated.

III. APPLICATION OF MARS TO MATHEMATICAL MODEL

First, we apply MARS to the mathematical model shown in (4) in order to examine its effectiveness by comparing its numerical results with that of the conventional high-order polynomial approximation in (5).

$$f = -2 \exp \left[15 \left\{ -(x_1 - 0.1)^2 - x_2^2 \right\} \right] - \exp \left[20 \left\{ -(x_1 - 0.6)^2 - (x_2 - 0.6)^2 \right\} \right] + \exp \left[20 \left\{ -(x_1 + 0.6)^2 - (x_2 - 0.6)^2 \right\} \right] + \exp \left[20 \left\{ -(x_1 - 0.6)^2 - (x_2 + 0.6)^2 \right\} \right] + \exp \left[20 \left\{ -(x_1 + 0.6)^2 - (x_2 + 0.6)^2 \right\} \right] \quad (4)$$

$$\hat{f}(l) = \beta_0 + \sum_{i=1}^m \beta_{i+m} l_i + \sum_{i=1}^m \beta_{i+2m} l_i^2 + \sum_{i=1}^m \beta_{i+3m} l_i^3 + \sum_{i=1}^m \beta_{i+4m} l_i^4 + \sum_{i=1}^m \beta_{i+5m} l_i^5 + \sum_{i=1, j < j}^m \beta_{ij} l_i l_j + \sum_{i=1, j < j}^m \beta_{ij} l_i^2 l_j \quad (5)$$

Figure 1 shows the approximation results. The figures clearly demonstrate the difference of the accuracies between MARS and the conventional polynomial approximation, which indicates the effectiveness of MARS.

IV. APPLICATION OF MARS TO BENCHMARK PROBLEM

Next, we apply MARS to the benchmark model, i.e., Die Press Model [2]. In this model, the function W_1 for the angle of the flux density and the function W_2 for the amplitude of the flux density are objective functions, respectively.

The proposed optimization procedure is shown in Fig. 3. In the procedure, to estimate the accuracy of the pareto optimal solutions obtained by the response surface with MARS, we recalculate their objective functions' values by the FE analysis, and compared them. By properly reducing the search domain around the space existing the obtained tentative pareto optimal solutions, it's expected that the conclusive pareto solutions are searched at short times diminishing the influence of the approximation error of the response surface.

6. Optimization

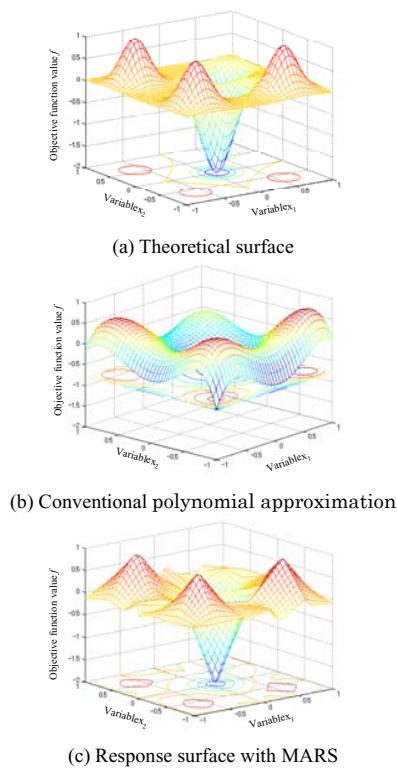

Fig. 1. Response surface configurations

Figure 4 shows the optimization results. The pareto optimal solutions obtained by the proposed method, i.e., RSM with MARS, are superior to ones without RSM. In addition, the total calculation time of the proposed approach is about 44% of the whole compared with that of the conventional method.

Incidentally, most of the calculation time with the proposed approach is spent on computing the response surface with MARS. So, the introduction of the parallelization with OpenMP is attempted with a view to enhancing the effectiveness of the proposed method. Furthermore, it's possible that the parallelization of the FE analysis at the experimental points leads to less calculation time. By actually calculating, the parallelization results in the reduction of the calculation time to almost 16% of the whole compared to that without parallelization and RSM.

Fig.2. Die Press Model

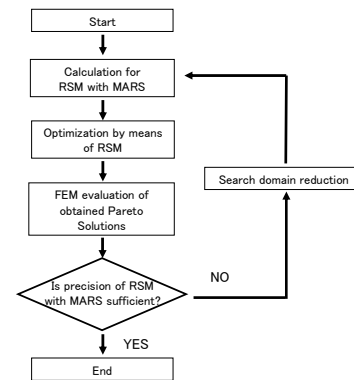

Fig. 3. Iterative optimization procedure

Fig. 4. Distributions of pareto solutions

V. OPTIMIZATION OF SHIELD CONFIGURATION

As the effectiveness of MARS is confirmed in the previous chapters, the application of MARS to the more complicated and practical model will be reported in the full paper.

The details of the optimization problem are as follows. As shown in Fig. 5, the signal receiver for the train operation control is placed under the train floor, where the noise from equipments such as the inverter has a negative influence on the signal reception from the rail currents. For the purpose of reducing the noise influence, we will efficiently carry out the design optimization of shield configuration without lowering the receiving level by using the proposed approach with MARS.

A Research on the Optimum Design of Magnet Structure for Improving Measurement Accuracy in the Dual Magnetic Float Type Level Gauge

Dong Sok Kim, Jae Min Kim, and Gwan Soo Park, *Member IEEE*
 Pusan National University, Busan 609-735, South Korea
kdongsok@pusan.ac.kr, jmin@pusan.ac.kr, gspark@pusan.ac.kr

Abstract — For the measurement of liquid level in ship's cargo tank, ballast tank, fuel oil tank and fresh water tank, several types of gauge meter are used such as tubular type, magnetic float type, reflex type, transparent type and welding pad type. Among them, magnetic float type gauge meter is environmental friendly device because it is free of power source and maintenance. The main obstacle of the device is relatively large error bound. In this paper, finite element method is used to design and analysis of the magnetic float type gauge meter. The operation of reed switch according to the magnetic field has been successfully described and agreed well with experimental measurement. The optimum geometry with combination of permanent magnet and reed switches are designed to achieve 95% and 98% accuracy of fluid level.

I. INTRODUCTION

Recently, the increase of a ship accident has a lot of economical and environmental problems. There are many causes but the explosion accident by inaccurate measure of the oil level has the biggest damage and is preventable. So, to detect the position of alert level is very important.^[1] For preventing the accident, the stability and exactitude is requested to a measuring instrument.^[2]

For the measurement of liquid level in ship's cargo tank, ballast tank, fuel oil tank and fresh water tank, several types of gauge meter are used such as tubular type, magnetic float type, reflex type transparent type and welding pad type.^[3] Among them, magnetic float type gauge meter is environmental friendly device because it is free of power source and maintenance. The main obstacle of the device is relatively large error bound. Mutual influence of magnets cause reed switch to malfunction in the dual magnetic float type gauge to detect a specific level.

In this paper, we designed the combination of permanent magnet and suitable distance of dual level gauge that reed switch operate exactly. The optimum geometry with combination of permanent magnet and reed switches are designed to achieve 98% reliability of fluid level.

II. STRUCTURE OF THE MAGNETIC FLOAT TYPE LEVEL GAUGE

The magnetic float type level gauge includes magnetic floats and reed switches. The reed switch is the magnetic field sensor. The magnetic float is comprised of permanent magnets and stainless steels (permeability: 1) like Fig.1. The magnets (Alnico 5) are round stick. And stainless steels set the magnets and move the fixed pipe. The reed switch module (two reed

switch) keep 'On' in a high magnetic density level and change to 'Off' at a low level.

It is distributed into four-magnet and six-magnet model by the number of magnets. The Material of magnets is Alnico 5. The ring type metal plates and metal pipe for fixing the permanent magnet are made stainless steel. The magnetic floats move by a buoyancy. The reed switch being the key element of the sensing part organizes two thin reed switches and a small glass pipe. If we put the magnet near the reed switch, magnetic field is concentrated at a magnetic material. The switch 'On/Off' are decided by the magnetic flux intensity and direction.

Fig. 1. Structure of Magnetic Float (4-magnet)

Fig. 2. Structure of Magnetic Float type level gauge

The two magnetic float type level gauge set at the upper position (98% of a whole tank) and the lower position (95% of a whole tank). The Magnetic Float is moved according to the quantity of fluid inside a tank and the sensor module is changed ‘On’ or ‘Off’ according to value of magnetic flux density in pipe. When it is ‘Off’ status, the system ring the alert sounds. However, if higher magnetic flux density than operation point (this system is 25[G]) of the switch, a range of switch operation is widen. Accordingly, a detection of correct position is impossible and we don’t measure the accurate position (95%, 98%). Also, if distance of two Magnetic Floats is close, the reed switch has error by mutual influence. In this paper, we researched on the optimal design for improving measurement accuracy using finite element method.

III. CHARACTERISTIC ACCORDING TO THE NUMBER OF MAGNETS

Fig. 3 is analyzed the magnetic flux density distribution of the magnetic float according to the number of magnets. And fig. 4 is values of magnetic flux density in Magnetic Float’ center. We can see magnetic flux density of type-II is higher than type-I. Accordingly, accuracy of type I is higher than type II.

Fig. 3. Magnetic flux density of Magnetic Float

Fig. 4. Magnetic flux density distribution of Magnetic Float’ center

IV. MUTUAL INFLUENCE OF DUAL MAGNETIC FLOAT

Two magnetic float type level gauges are on the position of 95% and 98% of inside the tank. When Dual Magnetic Float are situation 95% position and 98% position, magnetic field at the low position doesn’t have influence on sensor module of the high position. But, if distance is close, the magnetic floats

of a low position and high position have influence on each sensor module.

We analyzed a mutual influence of center’s magnetic flux density according to pole arrangement in dual magnetic float type level gauge. First structure is that magnetizing direction is NS(Magnetic Float of 95%’ position)-NS(Magnetic Float of 98%’ position). Second is structure of SN(Magnetic float of 95% position)- NS(Magnetic Float of 98%’ position).

Where, influence according to the number of magnets is analyzed together. Table I is to compare fore case. As a result, when use four magnets and are SNNS status, we get good result that distance of influencing each other is short and magnetic flux density value in middle point is 0[G].

TABLE I
INFLUENTIAL RANGE BY THE NUMBER OF PERMANENT MAGNET AND DISPOSITION OF POLE

	The number of Magnets	Pole Status of Manget (MF1-MF2)	Rang of non_interference (Reed Switch of 20[G] Range)	Magnetic Flux Density between two Magnetic Float
Type I	4	NS - NS	140[mm]	5[G]
	4	SN - NS	140[mm]	0[G]
Type II	6	NS - NS	86[mm]	6.8[G]
	6	SN - NS	87[mm]	0[G]

V. CONCLUSION

There are many kinds of the level gauge of measuring level of a kind of fluids. Among them, the magnetic float type level gauge needs not extra-power and is semi-permanent sensor system. This system includes reed switches and magnetic float. The reed switch become ‘On’ when it is near the high magnetic flux density. It is ‘Off’ during the low. If the range of ‘On’ is wide, the sensitivity of the level gauge is lower. And if distance between two magnetic float is short, mutual interference is caused and the reed switch is wrongly operated. So, this paper suggests the optimum structure and position of this level gauge by analyzing magnetic characteristic of the system and motion characteristic of reed switch. We analyzed a influence according to the number of permanent magnets and the arrangement of magnetized direction. In the result, when Magnet float has four magnets and arrangement of magnetized direction is SN-NS, it has the highest sensitivity and the lowest interference.

 norio@elec.okayama-u.ac.jp

Abstract — The topology optimization by distributing the magnetic material in the design domain, which is called as the ON/OFF method, is attractive for designers of magnetic devices, because an initial conceptual design, which we could not imagined beforehand, may be obtained. We examined how to apply the ON/OFF sensitivity method to the IPM motor in order to determine the optimal topology of the rotor. A technique to apply the ON/OFF method to the design of motor considering the nonlinearity and rotation of rotor is shown. The effect of various design requirements on the obtained topology of motor core is discussed.

I. INTRODUCTION

It is required to design an efficient and miniature motor with small cogging torque. If the ON/OFF method [1] is used, there is a possibility that a new magnetic circuit is discovered, because it is not necessary to set design variables in advance. There are few reports of the optimal design of motors [2] using the ON/OFF method.

In this paper, the ON/OFF method is expanded to the optimal design of permanent magnet motor, and techniques how to satisfy constraints, such as the limitation of terminal voltage, are examined. The effect of design requirements, such as the improvement of efficiency, on the optimal shape of motor core is also shown.

II. METHOD OF ANALYSIS

In the ON/OFF method, the sensitivity dW/dp (W : objective function, p : design variable) of an element is calculated by using the adjoint variable method. If the sensitivity is negative, the air is put in the element. If it is positive, the iron is put in the element. The sensitivity of the i -th element is obtained by differentiating the objective function W by the design variable ν .

$$\left(\frac{dW}{d\nu_i} \right)_k = \frac{\partial W}{\partial \nu} + \frac{\partial W}{\partial A} \frac{\partial A}{\partial \nu} \quad (1)$$

where ν_i is the reluctivity of the i -th element. The sensitivity $(dW/d\nu_i)_k$ is calculated at each rotor position k . The sensitivity $dW/d\nu_i$ which is used for judging ON(iron) or OFF(air) of material is the sum of $(dW/d\nu_i)_k$ during one pole pitch for example, 90deg, as follows:

$$\frac{dW}{d\nu_i} = \left(\frac{dW}{d\nu_i} \right)_1 + \dots + \left(\frac{dW}{d\nu_i} \right)_k + \dots + \left(\frac{dW}{d\nu_i} \right)_n \quad (2)$$

where, n is the number of steps during the rotation.

The objective function of the obtained shape by using the ON/OFF method is calculated using FEM and the torque is calculated using the nodal force method. The calculation is terminated when this process is repeated and the objective function does not decrease.

III. OPTIMIZATION OF THE ROTOR OF THE IPM MOTOR

The analyzed model of the rotor of the IPM motor is shown in Fig.1. The thickness in the z -direction is 100mm. The initial material of elements in the design region was set as a magnetic material.

Fig.1. Model of IPM motor.

The current of each phase is given by:

$$\begin{cases} I_U = I_m \sin(\omega t + \beta) \\ I_V = I_m \sin(\omega t - 120^\circ + \beta) \\ I_W = I_m \sin(\omega t + 120^\circ + \beta) \end{cases} \quad (3)$$

β is the current phase, which is set to 45° . The maximum ampere turns of the coil are set 1297AT (50Hz). The specification of analysis is shown in Table I.

TABLE I
SPECIFICATION OF ANALYSIS

Material	Stator core	35H230
	Rotor core (design domain)	35H230
	Magnet	HS-40FH
Direction of magnetization (T)		1.23
Magnetization		Parallel
Speed (min^{-1})		1500
Number of Nodes		14420
Number of Elements		6964

The objective function was defined as follows in order to minimize the torque ripple of the rotor and maximize the torque of the rotor:

$$W_1 = \sum_{i=1}^n [T_i - T_{ave}]^2 \quad (4)$$

$$W_2 = \sum_{i=1}^n \left(\frac{1}{T_i}\right)^2 \quad (5)$$

$$W = k_1 W_1 + k_2 W_2 \quad (6)$$

Both k_1 and k_2 are chosen as unity. T_i is the torque of a rotor at an angle i . T_{ave} is the average torque during a pole pitch angle. The optimal shape is shown in Fig.2 (a). The flux at the 1st step is shown in Fig.2 (b). Fig.3 shows the cogging torque.

(a)optimal shape (b)flux distribution
Fig.2. Result of analysis.

By removing a small part of rotor surface, the cogging torque of optimal shape is reduced. It is thought that the magnetic flux is transmitted to the teeth smoothly from the rotor. The torque ripple and average torque is shown in Table II. The torque ripple r_d is calculated by

$$r_d = \frac{T_{max} - T_{min}}{T_{ave}} \times 100 \quad (7)$$

where T_{max} is the maximum of the torque and T_{min} is the minimum of the torque. T_{ave} is the average of the torque. Compared with initial shape, the average torque of the optimal shape is a little reduced, because the air gap is increased at the removed part of the rotor. But the cogging torque is about 2% improved.

Fig.3 Cogging torque.

TABLE II
TORQUE RIPPLE AND AVERAGE TORQUE

	torque ripple (%)	average torque(N/m)
Initial Shape	13.96	7.79
Optimal Shape	11.56	7.56

Fig.4 shows the objective functions W_1 and W_2 in (3) and (4). It is understood that W depends on mainly W_1 .

Fig.4 Objective function.

IV. CONCLUSION

It is shown that the ON/OFF method can be applied to the design of rotor shape by using the sum of the sensitivity at each angle of rotor. A technique how to satisfy a constraint of limitation of terminal voltage, and the effect of design requirement of improving the efficiency will be shown in the full paper.

Abstract— This paper presents parameter optimization of inductor shapes using immune algorithm (IA) and micro genetic algorithm (GA). It is shown that the inductor volume can be almost halved satisfying constraints on values of inductance under different DC current conditions. The best results of the parameter optimization obtained from IA and micro-GA are similar to each other. During the optimization processes, values of inductance are repeatedly computed using finite element method taking the nonlinear BH characteristics into account. The dependence of inductance on the imposed current obtained by the present method is in good agreement with the experimentally measured results.

I. INTRODUCTION

Inductors are important electric parts widely used in electric and electronic devices such as mobile phones and computers. Size reduction, higher operation frequency and larger current tolerance have been strongly required from the industries. While development of new materials having better characteristics is important to meet these requirements, improvements in inductor shapes are also indispensable. For the latter purpose, shape optimization based on computational electromagnetism is thought to be effective.

The goal of this study is to develop reliable optimization methods for inductor shapes on the basis of computational electromagnetism. Evolutionary optimization methods are suitable for this kind of optimization because objective functions often present non-linearities due to the ferromagnetic material, and complicated constraint conditions must be considered. In this paper, we adopt immune algorithm (IA) and micro genetic algorithm (μ -GA) which has good computational efficiency compared with the conventional GA. The values of inductance under a high DC current bias are computed using the finite element method. The parameter and topology optimization are studied, with only the former results shown in this digest due to page limitation. We also test the reliability of the optimal solutions by comparing their performance with experimentally measured results.

II. OPTIMIZATION METHODS

A. Immune algorithm

The IA draws inspiration from the *Clonal Selection Principle*, and combines local and global search characteristics [1]. In the parameter optimization, each candidate solution is referred to as an *antibody* according to our immunological metaphor. The procedure of IA is described below [2].

1. Generate an initial population of N random candidate solutions.
2. Evaluate the objective function and the constraint condition for each *antibody*.
3. Test a stop criterion. If it is satisfied, stop the procedures.
4. Eliminate P (%) low-ranking *antibodies*.
5. Generate *clones* for each surviving *antibodies*. The highest-ranking *antibodies* receive a higher number of clones.
6. A small-amplitude Gaussian noise is applied to the *clones*, which are then evaluated over the objective and constraints. Only the best candidate solution from each subset of (parent *antibody* + *clones*) is allowed to survive to the next generation.
7. Add randomly generated *antibodies* to replace the ones eliminated in Step 4, in order to keep the population size constant.
8. Back to step 2.

Steps 5 and 6 have a role of regulating the local search of the algorithm, while step 7 promotes global search. We can control the balance of local and global search by adjusting the parameters N and P .

B. Micro genetic algorithm

The main difference between μ -GA and the conventional GA is that very small populations are used in the former [3]. To avoid the convergence to local optima, all individuals except the best-ranking one are replaced by randomly generated individuals if the population is converged to a local optimum. The procedures of μ -GA are shown below.

1. Generate a small number N of initial individuals randomly. In this work, N is set to 5.
2. Evaluate the objective function and the constraint condition for each individual, preserving the best one.
3. Test the stop criterion. If it is satisfied, stop the procedures.
4. Make pairs by randomly selecting two individuals, and the higher ranking individual for each pairs is called the parent.
5. Select two pairs randomly, and apply the crossover operation to the parents of selected pairs. This yields the children. Steps 4 and 5 are repeated until the number of children reaches $N-1$.
6. Check the convergence of population. If the population falls into a local optimum, $N-1$ individuals are replaced by randomly generated ones. These individuals and the reserved best individual remain for the next generation.
7. Back to step 2 until the end criterion is satisfied.

III. OPTIMIZATION SETTINGS

The inductor optimized in this study consists of a bobbin-shaped ferrite core and a coil surrounding it. The parameter optimizations with 5 variables (X_1 , X_3 , Y_1 , Y_2 , Y_3) shown in Fig. 1 are performed using IA and μ -GA. Note here that X_2 depends on X_1 and Y_1 because the coil area is fixed to that of the original mass product model whose inductance in specification is $100(\mu\text{H})$. Other settings such as material properties are also fitted to the original model.

The objective of the optimization is to reduce the volume of inductor keeping the inductance to the specification value for small AC currents. Moreover, it is important to reduce the variation in the inductance against DC bias current, because this type of inductors is used for AC signal with high DC bias current. Considering these requirements, we define the objective function to be minimized as,

$$f = |L_{AC1} \times 10^6 - 100| + 10^8 W^2 H + \text{penalty}, \quad (1a)$$

$$\text{penalty} = \begin{cases} 80 - 10^6 L_{AC2} & (L_{AC2} < 80 \times 10^{-6}) \\ 0 & \text{otherwise} \end{cases}, \quad (1b)$$

where L_{AC1} is the inductance at AC current of 0.2 [A] without DC bias, L_{AC2} is that inductance under DC bias current of 1 [A], W [mm] and H [mm] denote the radius and height. The finite element analysis taking the nonlinear BH relations into account is performed for computation of L_{AC1} and L_{AC2} . The constraint condition is $Y_1 \leq Y_2 \leq Y_3$, and the range of parameters is $0 < X_1 < 2$, $0.5 < X_3 < 4$, $1 < Y_1 < 4$, $1 < Y_2 < 5$, $1 < Y_3 < 5$ [mm].

Fig. 1. 1/4 Model for parameter optimization.

IV. OPTIMIZATION RESULTS

Table I and Figure 2 summarize the best solutions obtained by the IA and μ -GA. We can see that the inductor volumes in the optimal solutions are around 55% of the original model. Moreover, these optimal solutions have similar tendencies: low height (Y_3), wide width (X_2), and fat radius of core (X_1).

We manufacture a trial piece shown in Fig. 3(a) based on the solution obtained by IA to test reliability of numerical analysis. Figure 3(b) shows that the numerical results are in good agreement with the experimentally measured results.

We also performed topology optimizations which result in finding a novel shape. It will be discussed in the full version.

TABLE I OPTIMIZATION RESULTS

Method	Value of f	L_{AC1} (μH)	L_{AC2} (μH)	Volume ratio against the original model (%)
IA	2.71	100.03	80.11	55
μ -GA	2.74	99.99	82.54	56

Abstract— This work presents results of a multiobjective approach for optimization of design parameters of Mach-Zehnder lithium niobate modulators with additional floating electrodes. This process uses a genetic algorithm to search for geometrical parameters of the modulators and their characterization is performed by the finite-element method. The multiobjective approach is based on the weighted sum method in order to mapping the Pareto frontier, optimizing simultaneously three characteristics of a modulator.

I. INTRODUCTION

Mach-Zehnder modulators made of titanium diffused lithium niobate (Ti:LN) substrate with traveling-wave electrodes present low bias drift and large electrooptic coefficients [1], and technological advances in this kind of devices have produced high-quality LN modulator components for use in many sectors of the society.

A LN modulator can be characterized, in a quasi-static regime, by the analysis of the some electrical characteristics such as: the characteristic impedance (Z_c), the half-wave voltage ($V\pi$), the effective index of the microwave (N_m) and the driving power for the modulator (P_{in}), which depend on a large number of parameters. Stochastic methods are often employed in optimization techniques to analyze the effects of the geometric parameters, which affect the characteristic of these devices. These methods present good trade-off between the quality of the solution and the processing time.

However, to treat multiobjective problems, in which more than one characteristic have to be optimized at once, specific optimization techniques have been developed to reduce time development, analyzing different models and are able to choose the most convenient models.

II. THE MACH-ZEHNDER MODULATOR

The cross-section of a Mach-Zehnder modulator with CPW is presented in Fig. 1. Three extra floating electrodes are included under the main electrodes and deposited on the LN substrate without electrical contacts with any other part of the device. The purpose of these extra electrodes is to apply the available RF voltage directly across the indiffused optical waveguides, increasing the coupling between electric field and optical field. The expected result is to improve modulation, reducing the required RF input [2]. In this figure, T_b is the thickness of the buffer layer, T_e is the electrode thickness, G is the gap between the hot electrode and the ground electrode, W_H is the width of the hot electrode and g is the gap of the

floating electrodes.

Fig. 1. Cross sectional structure of a X-cut floating electrodes LN modulator.

III. CHARACTERIZATION OF A MODULATOR

The modulation of the LN modulators is produced by a voltage-induced change in the refractive index. To change this index, either large voltages or long electrode lengths are needed to obtain an adequate modulation. A useful figure of merit for modulation is the product of the half-wave voltage ($V\pi$) and the electrode length (L). By using traveling-wave electrodes, in which the electrical signal propagates along the same direction as the optical wave, much higher bandwidths can be obtained, but they are limited by the mismatch between the electrical and optical propagation constants.

Other electrical characteristics of the modulator, which are determined from the microwave propagation (electromagnetic wave) characteristics of its electrodes, are the effective index of the microwave N_m , the characteristic impedance Z_c and the driving power for the modulator (P_{in}). These characteristics can be calculated by using quasi-static analysis. Simple quasi-TEM analysis using scalar potential function can be performed using the Finite-Element Method which is capable of handling transmission lines with rather arbitrary configurations, such as thick metal electrodes, ridge type structures, besides the anisotropic permittivity of the LN [3].

Several parameters, as cited in section II, have to be analyzed in order to obtain a modulator model that satisfies the required performance, using a lossless quasi-static analysis.

IV. DESIGN OPTIMIZATION APPROACH

An optimization problem consists of finding one or more solutions (usually the best ones) from all solutions in a feasible region which correspond to extreme values, minimum or maximum, of one or more objectives. Some basic factors in this type of problem are an objective function, which it is intended to minimize or maximize; a set of variables, or parameters, which affect the value of the objective function and, a set of constraints that allow some values for the variables and exclude others.

A stochastic method, the genetic algorithm – GA, is used in this work for the design optimization process. GA's have been widely applied for optimization and for inverse problems in several areas. GA's mimic the survival of the fittest individual among competing organisms [4].

Multiobjective optimization aims the optimization of more than one characteristic of the problem. In this case, there is one objective function for each characteristic to be optimized. It is desirable to identify a set of solutions known as Pareto-optimal solutions in which each optimal solution corresponds to a particular trade-off of the different objectives [5]. The multiobjective optimization tries to find as many optimal solutions as possible. Many of the solutions obtained by the GA are going to be on the Pareto front, the line formed by the optimal solutions. An approach to find the Pareto-optimal solutions that compose the Pareto-optimal front is the weighted sum method. This method compose a multiobjective function $F(x)$ by performing the weighted sum of the objective functions $f_i(x)$ of each characteristic to be optimized. The multiobjective optimization is converted to a single objective optimization, as follows:

$$\text{Min } F(x) = \sum_{i=1}^n w_i f_i(x) \text{ and } \sum_{i=1}^n w_i = 1, w_i \in [0,1]. \quad (1)$$

where x is the parameters vector that defines the modulator geometry and w_i is the weight of the n -th objective function.

V. RESULTS

In a previous work [3], the weighted sum method was used to performed multiobjective experiments in order to optimize two characteristics at a time of a conventional and a floating electrodes LN modulators.

In this work, three design parameters, the gap (G) and the thickness (Te) of the electrodes and the gap (g) of the floating electrodes were encoded in the individual chromosome, to obtain preliminary results of the optimization for three characteristics at a time for the floating electrodes LN modulator, that are: the $V\pi L$, Z_c and N_m . The optimal value for the first characteristic is 0 Volts, while the optimal value for Z_c is the impedance of commercial microwave sources, namely 50Ω and the optimal value for N_m is N_o (2.142), the effective index of the optical wave. Also, a constraint was defined: a penalty term added to the objective function, if the calculated electric field between the electrodes and the air exceeds a threshold value. For all configurations analyzed in this work, the calculated electric fields were bellow the adopted threshold (1.0E6 V/m).

The minimization of the three respective objective functions yielded the Pareto-optimal solutions presented in Fig. 2. The points of the Pareto frontier, obtained from each set of weight w_i , were plotted on a surface graph. In order to illustrate the differences of the obtained configurations, two regions (A and B) are pointed. The region A includes the matching of the characteristic impedance, Z_c values near 50Ω , but with penalties in the $V\pi$ and N_m . Otherwise, in region B, it is obtained excellent values of $V\pi$ and N_m but mismatching Z_c . Notice that for this region small driving power are obtained,

despite the mismatch of the characteristic and source impedance. Despite possible losses caused by reflection of electromagnetic wave, resulting in a decrease in a bandwidth, this type of configuration of modulator may be of interest for operation in environments with limited energy source and to operate the device at small frequencies. Tables I and II present the values of characteristics and geometric parameters, respectively, for two configurations of modulators, obtained in the regions cited above.

Abstract — In this paper, a layering analysis scheme for reconstruction of deep Stress Corrosion Cracks (SCC) from ECT signals is proposed based on a strategy of multi-frequency and multiple liftoff in order to improve the sizing accuracy. The shape profiles and conductivity of the crack are reconstructed respectively using a hybrid inversion scheme. The profiles of several cracks are reconstructed from simulated signals of conductive notches and measured signals of artificial SCC. It is demonstrated that the new strategy is promising for improvement of the sizing precision.

I. INTRODUCTION

Sizing of Stress Corrosion Cracks (SCC) is an important task once such kind of defect is detected in key structural components of a nuclear power plant in order to evaluate its propagation behaviors. Ultrasonic Testing (UT) is a major NDE tool for this purpose currently. However, UT is not efficient especially for shallow SCC because of their complicated microstructures [1] and the anisotropic property of welding joint. As a supplement of UT, the Eddy Current Testing (ECT) technique has been applied to the reconstruction of several kinds of natural cracks including some SCC recently [2]-[4]. For a deeper SCC, however, the reconstruction accuracy is still not satisfactory even using the conductive crack model, because the crack conductivity and shape may significantly change at different crack depth.

In this paper, a scheme to improve the ECT inversion accuracy for a deep SCC is proposed, which reconstructs crack profile at different depth with signals of different excitation frequencies and liftoffs. Several cracks are reconstructed to demonstrate the efficiency of the new strategy for sizing of artificial SCC.

II. A LAYERING ANALYSIS SCHEME USING SIGNALS OF MULTIPLE FREQUENCY AND LIFTOFF

The eddy current density exponentially decays with the perpendicular distance from the conductor surface because of skin depth effect. Therefore, higher excitation frequency gives a better possibility to detect surface small defect. On the other hand, the ECT signals of high excitation frequency contain less crack information from deeper position. It is an issue that deserves to be weighed between improving the detection sensitivity and the penetration depth of ECT. Recently, the potential of using multi-frequency eddy current technique for nondestructive testing applications has been explored [5]-[7].

On this background, a layering analysis scheme for reconstruction of a deep SCC is proposed based on multi-frequency excitation and multiple liftoff strategy in order to improve the sizing accuracy of SCC in this paper.

A. Crack Reconstruction using Multi-Frequency Signals

Since the signal of high excitation frequency mainly depends on crack profile at the near surface layers, more information of crack at deeper position will appear in signals of smaller excitation frequency. Therefore, if crack profile at the surface layers has been reconstructed properly by using signals of high frequency, a signal of smaller frequency is more suitable for the reconstruction of the crack profile at deeper layers. In this way, the sizing accuracy is possibly to be improved by using signals of multiple frequencies based on this layering analysis scheme.

B. Reconstruction Using Multiple Liftoff Signals

There is certain error using above-mentioned layering analysis strategy as the crack conductivity reconstructed of upper layers is an equivalent result. In order to reduce the cumulative error further in the layering analysis, a multiple liftoff strategy is also introduced. The strategy is based on the phenomenon that the proportion of crack information from the deep layers is bigger for the signals of large liftoff than that of a small liftoff. Therefore, for the reconstruction of crack segments in the upper layers, signals of smaller liftoff should be applied, while the signals of larger liftoff is more suitable for reconstruction of crack segments at deeper layers. Together with the multi-frequency strategy, further improvement on the accuracy of SCC reconstruction can be expected.

C. Layering Analysis Strategy for SCC Reconstruction

In practice, the layering analysis strategy is realized as follows. The inspection target is divided into a group of layer segments (see Fig. 1), where the crack conductivity and length are supposed as different values in each layer. The depth of each layer is set as a constant value referring to the skin depth of the selected highest excitation frequency. As the crack width and the crack conductivity affect the crack signal together [8], the crack width is supposed as a constant for all crack segments, which will be estimated based on the signal of high frequency, i.e., the reconstructed crack conductivity will become an equivalent parameter. The crack profile of the top layer is predicted by adopting ECT signals of high frequency and small liftoff using the conventional ECT inversion scheme [9]-[10]. By utilizing crack information reconstructed at top layers, the crack profiles

6. Optimization

of deeper layers can be evaluated efficiently by using signals of lower frequency and bigger liftoff. The multiple frequencies and liftoffs inversion strategy is illustrated in Fig. 2. Based on the proposed inversion strategy, profiles of several conductive cracks are reconstructed from the simulated ECT signals. The numerical results show that the proposed strategy can improve the sizing precision of SCC.

Fig. 1. An example of selected frequency and crack layers

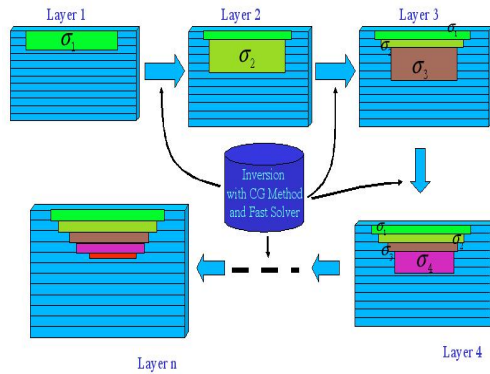

Fig. 2. Layering analysis and multiple frequencies and liftoffs strategy

III. A COMBINATORIAL INVERSION SCHEME FOR CRACK

Concerning the significantly different effects of crack conductivity and shape on the crack signal, it is not efficient to solve them by using the same inversion scheme. Hence a hybrid scheme of the Conjugate Gradient (CG) method and the advance-retreat algorithm [11] is applied.

IV. A NUMERICAL EXAMPLE

To validate the proposed scheme, cracks in a SUS 316 plate of 5 mm thickness (conductivity 1.4 MS/m) is taken as examples to be reconstructed. A small plus-point coil (inner diameter 4.5 mm, outer diameter 5.5 mm and thickness 2.0 mm) and a big plus-point coil (inner diameter 7.5 mm, outer diameter 12.5 mm and thickness 2.5 mm) are applied as the inspection probe, while excitation frequencies are chosen as those shown in Fig. 1 for each layer, i.e. the thickness of each layer is 0.5 mm.

To establish the database for the fast forward solver, the selected possible crack region (search region) is taken as 16 mm in length, 5 mm in depth and 0.2 mm in width, and subdivided into 120 (6×10×2) crack cells.

A rectangle conductive crack of 4.5 mm depth, 14 mm in length is reconstructed from the signals of multiple excitation frequency and multiple liftoff at first. The reconstructed crack depth is 4.48 mm by using the new strategy, while the result is 3.75 mm with the conventional method (see Fig. 3). This result shows that the proposed strategy gives a good possibility to improve the sizing precision for a deeper SCC. Results using experimental signals will be presented in the full paper.

Fig. 3. Comparison of results reconstructed by using multi-frequency and multiple liftoff scheme for a rectangle conductive crack model

Accelerating Evolution Algorithm Using Kriging Metamodel

Dong-Kyun Woo, Jang-Ho Seo, Chany Lee, and Hyun-Kyo Jung

School of Electrical Engineering, Seoul National University, Shillim-dong, Kwanak-gu, Seoul, 151-742, Korea
E-mail underdamp@snu.ac.kr

Abstract — This paper presents and analyzes in detail a evolution strategy (ES) assisted by Kriging metamodeling to pre-select the most promising solution. The role of Kriging metamodeling is to predict objective function value for new candidate solution by exploiting information recorded during previous generations. The use of promising solution for screening the candidate solutions makes it possible to significantly reduce the computational cost of ES. The efficiency and usefulness of proposed method are verified by means of mathematical test cases.

I. INTRODUCTION

Evolution Strategies are excellent optimization tools for solving complex parameter problems where classical deterministic methods are known to have failed [1]. However, like other population based algorithms they require a very high number of fitness function evaluations.

The cost of optimizing expensive problem is dominated by the number of fitness function evaluations in order to reach a global optimum with adequate precision. Therefore, standard ES is not practical for such application.

ES using computationally expensive evaluation may reduce the cost through metamodeling [2]. Metamodel should be understood as surrogate evaluation model that is built by exploiting information of evaluated individuals [3]. This information can be used to adapt the recombination and the mutation operator in order to sample promising offspring. Evaluated individuals are obtained during one or more generations of ES and the algorithm can get back once more to the true fitness function for updating the metamodel with newly evaluated points expected to be closer to the global optimum. Therefore, the prediction quality generally improves with a growing number of evaluated points in the optimization process.

From the various existing modelisation methods, Kriging is chosen since it is more suitable for the design and analysis of computer experiments (DACE).

In this paper, Kriging replaces the objective function during the optimization process and decreases the number of expensive fitness evaluations which results in a better convergence rate of the algorithm.

II. PROPOSED ALGORITHM

As stated briefly in the Introduction, the main feature of proposed algorithm is the reduction of fitness function evaluation by Kriging-metamodel assisted ES (KAES). The proposed method adopts the concept of elite which stores superior solution. The element of the elite is replaced with

much superior or improved solution during the optimization iteration.

Total process of the proposed algorithm is as follows :

A. Step 0 - Initialization

a) Initialize α_{min} , α_{max} , α_{init} for each design variable.

α_{min} The minimum variation of design variable.
This factor controls the convergence rate.

α_{max} The maximum variation of design variable.

α_{init} Initial value for α_i .

α_i Evolution range of the i th design variable.

If the i th individual is p_i , the child generation is generated within $[p_i - \alpha_i, p_i + \alpha_i]$ where $\alpha_{min} < \alpha_i < \alpha_{max}$. This factor is modified during the generation except at the starting time.

b) Create initial population by (1)-(2) and save in a database

$$n = \left(\prod_{i=1}^n (b_i - a_i) \right)^\delta, \quad 0.5 < \delta < 1.5, \quad (1)$$

$$a_i < x_i < b_i, \quad i = 1, \dots, n, \quad (2)$$

n The size of initial population.

x_i x_i means the i th design variable.

δ According to the problem characteristic and the design variable of range, δ can be adjustable.

In the KAES, since the convergence ratio is decisively dependent upon the fitness landscape by initial sample s, an adequate selection of δ is essential.

B. Step 1 - Generation of initial parent set

Among initial population with n individuals, μ solutions are selected as members of the initial parent set. Those are determined by following rules.

a) Put the currently best solution into the parent set and check the position of the best solution.

b) Find another best solution except the checked position and repeat a) until μ elite solutions are found.

C. Step 2 - Generating Children

Make new λ children within evolution range.

D. Step 3 - Annealing

If the current elite solution is improved compared to prior generation, the evolution range is increased by dividing 0.8. If the elite solution is not improved, the evolution range is decreased by multiplying 0.8.

E. Step 4 - Shaking

Random solution is generated in the whole search space. In standard ES, since a high shaking ratio drops the

convergence rate, the ratio is decreased generally according to convergence degree. However, in case of the KAES, since the random solutions improve overall quality of the fitness landscape, the shaking ratio is increase in proportion to optimization iteration.

F. Step 5 - Reshaping

a) Update check

The metamodel is continually updated using the new datas obtained during iteration that does not satisfy the convergence criterion [4]. One drawback of the Kriging Interpolation with a growing number of samples is a computational cost. Then, we adapt the reconstruction algorithm to probable behavior of the evolutionary algorithm. It is assumed that the set of data points obtained in the early stages are weakly correlated with the global optimum and that those obtained in later generations are better and better correlated. Therefore, a reasonable strategy is to use a high value of p reshape probability in the early stages of iteration and to reduce this value near to zero in the later generations. The proposed reconstruction method is hence :

$$p = r \left(1 - \frac{g}{g_{\max}}\right)^{\omega} < 1, \quad (3)$$

$$0 < r < 1, \quad (4)$$

$$0 < \omega < 1, \quad (5)$$

where r is the random number, g_{\max} is the maximum number of generation allowed and ω is the control parameter. Because the reconstruction algorithm depends on ω control parameter, an understand on the influence of this parameter would be necessary.

b) Mean square error check

If the prior model is updated by the reconstruction algorithm, we search the best promising solution in the new fitness landscape and examine local mean square error (MSE) at that position. If a candidate solution has more MSE than specified criterion, the algorithm scatters samples near the candidate solution and repeats until lower than basis.

G. Step 6 - Convergence check

Repeat A - G until the solution is not improved any more.

III. NUMERICAL TEST AND RESULT

The proposed algorithm was applied to the optimization of the mathematical function. Fig. 1 and Fig. 2 show two examples of the test functions and optimized results. From the figures, we can see that the results show very fast convergence speed and the proposed method is very efficient to find the global optimum.

IV. CONCLUSION

In this paper, an algorithm of the ES for the reduction of fitness function evaluation was proposed. The algorithm is based upon combination of the evolution strategy and the Kriging metamodeling. The usefulness of the proposed

method was verified by the application to various test functions.

Topology Optimization of Electrostatic Actuator Using Level Set Method and Shape Design Sensitivity

Young Sun Kim, and Il Han Park

School of Information and Communication Engineering, Sungkyunkwan University
300, Cheoncheon-dong, Jangan-gu, Suwon, 440-746, Korea
youngsun@skku.edu, ihpark@skku.ac.kr

Abstract— This paper treats a level set method for topology optimization of electrostatic actuator. The classical shape optimization has meshing problem for shape change. To overcome this difficulty, the level set method is employed because of its efficient representation of evolving geometry. The velocity field is required for solving the level set equation of Hamilton-Jacobi equation and it is obtained by the continuum shape sensitivity in a closed form by the material derivative concept. The optimization problem is modeled as coupled system of Poisson's equation and the level set equation and they are solved using a standard FEM in time domain. The design goal is to obtain a maximum torque for operating actuator. A result of optimal shape and topology of the salient pole actuator is presented.

I. INTRODUCTION

The classical shape optimization has been applied to many design problems for electromagnetic systems. One of its major difficulties is related the meshing problems coming from the shape modifications. In order to circumvent this kind of technical difficulties of the moving mesh problems, a couple of researches have tried to formulate shape optimization with fixed mesh analyses based on fixed grid finite elements. This approach was naturally associated with the Level Set description of the geometry to provide an efficient treatment of such problems involving geometry change and discontinuities. The level set method is a numerical technique first developed to track moving interface. It was first devised by Osher and Sethian [1] and has been recently introduced in the field of structure shape optimization [2],[3]. The level-set method has several advantages. Its main advantage is to enable an accurate description of the boundaries on a fixed mesh. Therefore it provides with fast and efficient numerical algorithms. It can also handle topological changes since it allows the boundary in a natural way to split apart or merge together with no extra technique by controlling the level-set function of a Hamilton–Jacobi equation. Such treatment of topological change can transform the difficult topology optimization problem into a relatively easier shape optimization problem. In this paper, we apply the level set method to a topology optimization of electrostatic actuator using continuum sensitivity [4],[5] for the velocity field that is inserted into the Hamilton–Jacobi equation for the level set function. The goal of actuator design is to generate maximum torque operation. The numerical algorithm is implemented

with a standard finite element procedure.

II. LEVEL SET METHOD

We employ the level set method to define evolving boundaries since it provides a convenient way to describe closed interfaces of curves and surfaces. The level set function is expressed in an implicit form of a high dimensional function, and then the boundary changes are traced by the deformation of this function. In shape optimization, the design boundaries are changed to minimize or maximize an objective function.

Generally, for a given region Ω with arbitrary boundary, we assume the implicit function $\phi(\mathbf{x})$ as

$$\begin{aligned} \phi(\mathbf{x}) > 0 & \quad \mathbf{x} \in \Omega^+ & : \text{free space} \\ \phi(\mathbf{x}) = 0 & \quad \mathbf{x} \in \partial\Omega & : \text{boundary} \\ \phi(\mathbf{x}) < 0 & \quad \mathbf{x} \in \Omega^- & : \text{dielectric} \end{aligned} \quad (1)$$

To compute an evolving domain, one can define the function and determine the evolution of domain Ω^- via

$$\Omega^-(t) = \{ \phi(\mathbf{x}, t) < 0 \}. \quad (2)$$

The boundary $\Gamma(t)$ of $\Omega^-(t)$ is given by the zero level set,

$$\Gamma(t) = \{ \phi(\mathbf{x}, t) = 0 \} \quad (3)$$

The evolution of the shape is determined by a velocity \mathbf{V} .

$$\frac{d\mathbf{x}(t)}{dt} = \mathbf{V}(\mathbf{x}(t), t), \quad (4)$$

Since the zero level set holds at any time t , its total derivative is expressed by using an Eulerian formulation and chain rule as

$$\frac{\partial \phi}{\partial t} + V_n |\nabla \phi| = 0 \quad (5)$$

This is called Hamilton-Jacobi equation and the level set function is determined by solving it. The velocity \mathbf{V} has to be given depending on each objective of design problem.

III. OPERATION OF ELECTROSTATIC ACTUATOR

Fig. 1 shows the initial shape of electrostatic actuator with 16 electrodes around the dielectric materials. The actuator is driven by switching the voltages clockwise. The initial shape of actuator is given 19 dielectric regions that will be topologically modified to generate maximum torque.

Fig. 1. Initial shape of electrostatic actuator containing 19 dielectric regions. Voltage switching position of (a) maximizing and (b) minimizing an electrostatic energy.

IV. FORMULATION OF OPTIMIZATION PROBLEM

To generate maximum torque, the electrostatic energy of switching A position must be maximized and be minimized at switching B position. In other words, the energy difference between two positions is maximized. Therefore an optimization problem in this case can be defined as

$$\begin{aligned} & \text{Maximize : } F = (W_A - W_B) \\ & \text{Subject to :} \end{aligned} \quad (6)$$

$$\begin{aligned} & \nabla^2 V = -\rho / \varepsilon(\phi) \quad : \text{ electric field equation} \\ & \int_{\Omega} H(\phi) d\Omega = S^* \quad : \text{ constraint of constant area} \end{aligned}$$

where the design domain is represented by Ω . The Poisson equation for electrostatics is used to calculate the electric scalar potential V and the electric permittivity ε is determined by using $\varepsilon(\phi) = \varepsilon_1 H(\phi) + (1 - H(\phi))\varepsilon_0$ where ε_1 is the material permittivity and ε_0 is the permittivity of free space.

Design variables are the movable boundary between dielectric and free space. The design boundary $\partial\Omega$ is represented using the level set function such that

$$\phi(\mathbf{x}, t) = 0 \quad : \text{ zero level set} \quad (7)$$

The velocity field determines shape variation and it results in variation of the objective function through the Poisson's equation. In order to impose a constraint condition of constant volume, the velocity field is modified from V_n to \hat{V}_n using Lagrange multiplier technique as

$$\hat{V}_n = V_n - V_0 \quad \text{where } V_0 = \int_{\gamma} V_n d\Gamma / \int_{\gamma} d\Gamma \quad (8)$$

V. CONTINUUM SENSITIVITY ANALYSIS FOR SHAPE DERIVATIVE

The total derivative of any objective function in electromagnetic systems can be derived in a closed form using the material derivative concept of continuum mechanics and an adjoint variable technique.

Firstly, the continuum sensitivity formula of switching position A is represented as

$$\frac{dF}{dt} = \int_{\gamma} G_A(V, \lambda) V_{nA} d\Gamma \quad (9)$$

where

$$G_A(V, \lambda) = \left(\frac{\varepsilon_1}{\varepsilon_2} - 1 \right) \left[\varepsilon_1 E_n(V^*) E_n(\lambda^*) + \varepsilon_2 E_t(V^*) E_t(\lambda^*) \right] \quad (10)$$

V_{nA} the normal component of the velocity field vector, λ an adjoint variable, γ design boundary.

The sensitivity of switching A position represents the relation between the objective function and the velocity field. If the velocity field is taken as

$$V_{nA} = G_A(V, \lambda) \quad : \text{ switching A position,} \quad (11)$$

the system energy will increase since it is in a gradient direction. Also, if the sensitivity of switching B position is chosen as

$$V_{nB} = -G_B(V, \lambda) \quad : \text{ switching B position,} \quad (12)$$

the system energy will decrease. The velocity field is inserted into the level set equation (5) in order to obtain a maximum torque of electrostatic actuator.

$$\frac{\partial \phi}{\partial t} + [G_A(V, \lambda) - G_B(V, \lambda)] |\nabla \phi| = 0 \quad (13)$$

Here we can see that the iterative optimization procedure is transformed to a first-order PDE in time domain.

VI. NUMERICAL RESULTS

In order to generate a maximum torque, the difference of the electrostatic system energy between two voltage switching positions has to be maximized. Numerical results showed that the proposed algorithm produced the optimal shape and topology of the salient pole actuator without previous information of dielectric layout as in Fig. 2.

Fig. 2. (a) Final shape of dielectric area and (b) electrostatic energy variation with time.

Abstract— The objective of this research is the electromagnetic characterization of biological tissues in radiofrequency domain. In this aim, a measurement bench including a vector network analyzer and an open-end coaxial probe was introduced. The complex permittivity identification of the middle under testing is performed by solving an inverse problem. A quadratic fitness function that represents the difference between reflection coefficient measurement and reflection coefficient acquired with the normalized aperture admittance is minimized. The optimization is based on a heuristic algorithm: particle swarm. The approach is validated on well known dielectric middle and then tested on biological tissues.

I. INTRODUCTION

Numerical simulations of electric field distribution in the human body exposed to radiofrequencies waves require the knowledge of dielectric tissues properties [1]. In the radiofrequency domain, several experimental techniques can be used for measuring permittivity ($\epsilon^* = \epsilon_r - i\epsilon_i = \epsilon_r + i\sigma/\epsilon_0\omega$): free space, resonant technique, transmission/reflection line and open-ended coaxial [2]. In our study, the open-ended coaxial probe has been selected for its suitability for liquid or soft materials such as biological materials without specific preparation. Temperature can be easily controlled and after the bench calibration several samples can be rapidly treated. This point is crucial since biological samples can be easily altered or desiccated. The bench measurement provides an electric Scattering (S) parameter or reflection. The permittivity is identified on the base of an inverse method that using Particle Swarm Optimization (PSO) procedure for minimizing the quadratic difference between the measured and the calculated reflection from a direct model. In the first part, the global procedure measurement is described and the method to identify the permittivity of the Middle Under Testing (MUT) is exposed. In the second section, the proposed approach is validated on MUT known and then tested on biological tissues.

II. PROCEDURE

The characterization contents two parts, the reflection coefficient measurement from probe aperture/MUT interface and the identification of permittivity from the reflection coefficient measured. A sensitivity analysis has been performing so as to optimize the experiments. Calibration, sensitivity and identification procedure are in C-language.

A. Measurement bench and calibration

The experimental radiofrequency bench is composed of a Vector Network Analyzer (VNA), an open-ended coaxial

probe and an optical fiber thermometer. The probe is a semi-rigid coaxial line (UT85) mounted on a N connector. The probe is 200 mm long, inner and outer radius are respectively $a=0.255\text{mm}$ and $b=0.84\text{mm}$. The reflection coefficient (S_{11} parameter) of the MUT is obtained with VNA in the frequency range fixed (0.5 to 4 GHz) and for each frequency imposed by the linear step.

To determine the correct reflection coefficient of MUT, it is necessary to apply to the measured parameter $S_{11,m}^*$ some correction coefficients [3]. These coefficients are obtained from three additional measurements, on well known middles, respectively j =short circuit ($S_{11,m}^* = -1$), air ($\epsilon_r=1$, $\epsilon_i=0$) and de-ionized water ($\epsilon_s=25$, $\epsilon_o=4.3$, $\tau=170\text{ps}$) (1). The corrected $S_{11,c,MUT}$ is then calculated for each frequency (1).

$$S_{11,m,j}^* = E_D + \frac{E_R S_{11,c,j}^*}{1 - E_S S_{11,c,j}^*} \quad (1)$$

B. Inverse problem

The identification of the MUT permittivity is based on the normalized aperture admittance [4]:

$$Y^* \approx \frac{-i2\omega\epsilon_0\epsilon^*}{\ln b/a} \quad (2)$$

$$\int_a^b \int_a^b \int_0^\pi \frac{\cos \varphi}{r} + ik \cos \varphi - \frac{k^2 r}{2} \cos \varphi - i \frac{k^3 r^2}{6} \cos \varphi \cdot d\varphi \cdot d\rho \cdot d\rho'$$

with $k = \omega \sqrt{\mu_0 \epsilon_0 \epsilon^*}$, the propagation constant for the MUT, $r = \sqrt{\rho^2 + \rho'^2 - 2\rho\rho' \cos \varphi}$, the distance between the source point and the field point, ρ' and ρ are respectively the radial coordinates of these points at the aperture of coaxial probe. The reflection coefficient is related to the normalized probe admittance (3) with $Y_0=1/50$.

$$S_{11,adm}^* = \frac{Y_0 - Y^*}{Y_0 + Y^*} \quad (3)$$

The Fitness Function (FF) to minimize is given by (4).

$$FF = \left(\frac{\text{Re} \{ S_{11,adm}^* - S_{11,c,MUT}^* \}}{\text{Re} \{ S_{11,c,MUT}^* \}} \right)^2 + \left(\frac{\text{Im} \{ S_{11,adm}^* - S_{11,c,MUT}^* \}}{\text{Im} \{ S_{11,c,MUT}^* \}} \right)^2 \quad (4)$$

This minimization problem is solving with PSO technique. PSO involves simulating social behavior among individuals (particles) “flying” through a multidimensional search space, each particle representing a single intersection of all search dimensions [5]. Particles in a swarm move in discrete steps based on their current velocity, memory of where they found

their best fitness value, and a desire to move toward where the best fitness value was found so far by all of particle during a previous iteration (Fig. 1). Each particle has a position and a velocity: their values are randomized initially. The position with highest fitness score in each iteration is set to be the entire swarm's global best (gbest) position, towards which other particles move. In addition, each particle keeps its best position that it has visited, known as the particle's personal best (pbest). Each particle n of the swarm is defined as a potential solution to the problem.

Fig.1. The Particle Swarm Optimization algorithm.

The particle dynamics are governed by the following rules which update particle positions x_n and velocities:

$$v_n = wv_n + c_1 \text{rand} 1 \frac{pbest_n - x_n}{\Delta t} + c_2 \text{rand} 2 \frac{gbest - x_n}{\Delta t} \quad (5)$$

After a new velocity for each particle, the position is calculated according to $x_{n+1} = x_n + v_n \Delta t$. Where x_n is the current position of particle n , Δt the time step equal to 1, x_{pbest} is the best position attained by particle n , x_{gbest} is the swarm's global best position, v_n is the velocity of particle n , w is a random inertia weight, c_1 and c_2 are two positive constants, called the social and cognitive parameter, $\text{rand}1$ and $\text{rand}2$ are random numbers between 0 and 1.

III. VALIDATION AND RESULTS

All the measurements presented in the following are realized on MUTs at 23°C for 1 000 frequencies linearly spaced. The swarm size is fixed to 10 particles. In a purpose of comparison an ethanol MUT has been tested and our proposed approach has been compared to Debye model (6) with these parameters $\epsilon_\infty=4.3$, $\epsilon_s=25$ and $\tau=170\text{ps}$ (Fig. 2).

$$\epsilon(\omega)^* = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + i\omega\tau} \quad (6)$$

Validation results are presented, a good agreement is found between the Debye model and our model approach results, the impact of calibration is also studied (Fig. 2). Then our approach is used on pork skin tissues (Fig. 3), since a sensibility analysis with reduced sensitivity functions has shown the ability to easily identify both imaginary and real of

the permittivity in the range of frequencies by using the imaginary part or the phase of the reflection coefficient.

Fig.2. Validation on ethanol sample with and without calibration.

Fig.3. Complex permittivity of pork skin tissues.

IV. CONCLUSIONS AND PERSPECTIVES

Several perspectives of this work are considering. Firstly, a comparison in term of efficiency between the Levenberg Marquardt and the genetic algorithm will be done with application of the sensitivity conclusions. Secondly, the mono-layer approach presented in this paper will be enhanced for applications on bi-layered or multi-layered MUT and thirdly a micro coaxial probe will be developed.

V. ACKNOWLEDGMENT

Abstract—his paper studies the relevance of features in time- and frequency-domain given a scattered Ground Penetrating Radar (GPR) wave. This wave is used to identify inclusions, such as reinforcement bars and fissures, in concrete structures. The right choice of features is fundamental to the design of intelligent machines to support the detection, qualification and quantification of fissures. This work analyses the problem of classifying the material inside a concrete structure, which may be conductor, water or air. Both noiseless and features selected given a white Gaussian noise are considered. Many features were extracted and those selected are presented, indicating that the features in the frequency-domain are the most relevant.

Index Terms—Ground Penetrating Radar, Inverse Problems, Noise, Neural Networks, Multiobjective Training Algorithms.

I. INTRODUCTION

As existing concrete structures age, effective inspection has become a greater issue due to environmental, economical and socio-political aspects. Virtually all concrete structures exposed to natural environments experience deterioration over time. Consequently, passive concrete facilities will have to demonstrate that they are capable of continuing to fulfil their intended function with an adequate level of safety when seeking to extend their operating life. Better ways of doing this evaluation can avoid tragedies and decrease maintenance cost. This paper is based on the use of Ground Penetrating Radar (GPR) techniques together with machine learning techniques to support the detection of faults in a non-destructive way. This is known as one of the best options to detect fissures in concrete structures [1]. Even though the reflected wave amplitude is a good feature to detect the presence of inclusions, it is not sufficient to determine properties such as its geometry.

In [2] it was empirically proposed the use of three features to train a Neural Network (NN) classifier. Even though they proved useful in a homogenous problem, they were not successful when non-homogenous host media were considered [3]. The non-homogenous medium is a better representation of a real concrete structure but it brings more variables to the problem. The most important problem when working with many variables and NN is the difficulty to process the vast data set in high-dimensional space. The Parallel Layer Perceptron (PLP) network [4] was applied as the main classifier in [3].

The approach presented here is to use the feature selection algorithms, Simba and Relief [5], to select parameters from a scattered GPR wave. These are based on the concept of margin

to define the relevant features of the data. Both algorithms have selected similar parameters as the most important, and these are presented. The inclusions were considered to be conductor, water or air given both noiseless and noisy situations. The results show that features in the frequency-domain are the most relevant and that they are also more robust in the presence of noise than those in the time-domain. The purpose of this work is to increase the level of information extracted in the non-destructive evaluation of concrete structures by using intelligent systems and electromagnetic field computation.

II. FEATURE SELECTION

Feature selection (also known as subset selection) is a process commonly used in machine learning, wherein a subset of the features available from the data are selected for application of the learning algorithm. The best subset contains the least number of dimensions that most contribute to accuracy; we discard the remaining, unimportant dimensions. This is an important stage of pre-processing and is one of two ways of avoiding the well known curse of dimensionality (the other is feature extraction). Feature selection is, therefore, the task of choosing a small subset of features which is sufficient to predict the target labels. This step is fundamental to build reliable classifiers.

Feature selection aims at choosing for a given data set a sub-set which can capture the relevant information. The choice of features is important to avoid the curse of dimensionality and, therefore, guarantee good convergence of the learning machines. It can also provide some understanding concerning the nature of the problem, as it indicates the main physical properties needed to classify an underground target. This paper will consider feature selection algorithms based on the filter model to feature selection, Relief and Simba [5]. In this case the feature selection is a type of pre-processing, using some pre-defined cost function, suchh as the separation margin of classes.

III. THE GPR PROBLEM

For radar assessment of concrete, the objective is to determine the features needed to characterize inclusions in a dielectric slab by identifying electrical (permittivity and conductivity) and geometrical (depth and radii) properties. The computation of the electric field is done by the FDTD method

as forward solver. A data set obtained with a FDTD model with 1071 samples of the reflected wave from cylindrical inclusions buried in a non-homogeneous concrete model was considered [3]. The depth was defined in the range [0.05:0.010:0.25]m and the radius [0.02:0.005:0.1]m. Water, air and conductor inclusions were considered. From the reflected wave, 14 features were selected. The following were selected in the time-domain:

- delay of the first reflection (Delay) [2],
- maximum amplitude (max(W)) [2],
- reflected wave mean (mean(W)),
- reflected wave standard deviation (std(W)),
- mean of the wave derivative (mean(dW)),
- standard deviation of the wave derivative (std(dW)).

Using the Fourier Transform of the reflected wave the following features were extracted in the frequency-domain:

- maximum amplitude of the Fourier transform (mFFT),
- frequency of maximum amplitude of the Fourier transform (fmFFT),
- energy in six different bands (B_1, B_2, \dots, B_6) of the Fourier transform.

Some features are shown in Fig. 1.

Fig. 1. Parameters considered for Simba and Relief algorithms in both time- and frequency-domain.

IV. RESULTS

The experiments produced the reflected waves from cylindrical inclusions with and without a white Gaussian noise of 6 dB signal-to-noise ratio. Water/Air/Conductor discrimination was evaluated, taken in pairs. The results are outlined in Tables I and II where F_1 indicates the most relevant feature and F_4 the fourth one. The remarkable point is that both algorithms, which are based on different concepts of feature selection, have selected the same set of features but with different ordering. This can help separate the clutter from the target reflections

since each feature is related with a different aspect of the problem. It is also interesting that most of the features are related to the frequency-domain. In the noisy situation they are more robust than, for instance, the amplitude and the first delay, which are hard to calculate given some noise.

TABLE I
SUMMARY OF THE RESULTS WITHOUT NOISE.

Inclusions	Method	F_1	F_2	F_3	F_4

V. CONCLUSION

This paper introduced the use of feature selection algorithms in the study of the GPR reflected waves. The feature subset selection problem in supervised learning for a non-homogeneous GPR problem was described, which involves identifying the relevant or useful features in a dataset obtained by electromagnetic field computation and providing only that subsets to the learning algorithm. In addition, the relevance and irrelevance of features was investigated, and two degrees of relevance: weak and strong were defined.

Water, air and conductor inclusions were considered as non homogeneous media. The conditions were considered in the presence of Gaussian noise as well as in the absence of noise. Many features were considered in the study. Some features were extracted in the time-domain, others in the frequency-domain. Two different algorithms were applied and showing consistent results. The results indicate that the features in the frequency-domain are more relevant and more robust in the presence of noise. These results support our claim that subset selection can improve accuracy, and that this approach can help separate clutter from buried targets information.

Abstract—We report on recent results concerning the development of a discontinuous Galerkin time domain (DGTD) method for the solution of the system of Maxwell equations in general domains and heterogeneous propagation media. This DGTD method is formulated on simplicial meshes (triangles in 2D and tetrahedra in 3D). Within each mesh element, the electromagnetic field components are approximated by an arbitrarily high order nodal polynomial interpolation while time integration is achieved either by an explicit or an hybrid explicit-implicit scheme.

I. INTRODUCTION

Nowadays, a variety of methods exist for the numerical treatment of the time domain Maxwell equations ranging from the well established finite difference time domain (FDTD) methods [1] to finite element time domain (FETD) methods [2] and discontinuous Galerkin time domain (DGTD) methods. In the recent years, there has been an increasing interest in the latter methods due their ability to easily deal with unstructured meshes. Besides, when combined with explicit time stepping schemes, DGTD methods lead to block diagonal mass matrices, a feature which is often recognized as one of the main advantages with regards to classical FETD methods. Such DGTD methods have been developed on quadrangular/hexahedral [3] and triangular/tetrahedral [4] meshes. In this paper, we report on some recent achievements concerning the development of a high order DGTD- \mathbb{P}_p method on simplicial meshes that was originally introduced in [5]. We first present results regarding the design of a hp -like DGTD method that allows for both a non-conforming local refinement of the mesh and a local definition of the approximation order. Then, we discuss issues related to the definition of a time stepping strategy for overcoming grid-induced stiffness in a DGTD method. The works discussed here are continuations of preliminary studies respectively presented in [6] and [7].

II. NON-CONFORMING DGTD METHOD

One of the distinguishing features of a DGTD method is that it can easily accommodate a non-conforming locally refined mesh (*i.e.* h -refinement) as well as a local definition of the approximation order (*i.e.* p -enrichment), or of both of them in the context of hp -adaptive solution strategy. In [6] we have reported on the lessons from a preliminary investigation of a h -refinement non-conforming DGTD method, by mainly

concentrating on stability issues. The non-conforming DGTD method discussed in [6] combines a centered scheme for the evaluation of the integral term defined on the interface between neighboring elements of the mesh, with a second order leap-frog scheme for time integration. The resulting DGTD method is non-dissipative and stable under a CFL-like condition. Thereafter, this initial study has progressed towards the development of a hp -like DGTD method combining h -refinement and p -enrichment, in the context of the solution of the 2D Maxwell equations.

Fig. 1. Scattering of a plane wave by a multi-layered dielectric cylinder. Problem setting and computational domain.

We illustrate the capabilities of the resulting hp -like DGTD method by considering the simulation of the scattering of a plane wave ($F=300$ MHz) by a multi-layered dielectric cylinder (see Fig. 1). Each layer consists of a dielectric non-magnetic material, with $\epsilon_i > 1$ for $2 \leq i \leq 5$ and $\epsilon_1 = \epsilon_6 = 1$ (relative values). We first construct a conforming mesh consisting of 14401 nodes and 28560 triangles and we use different DGTD- \mathbb{P}_p methods, where the interpolation order p is uniform in space. Then, a non-conforming mesh is obtained by locally refining a coarse conforming mesh where the level of refinement depends on the local wavelength in each region. The resulting non-conforming mesh consists of 27640 triangles and 14441 nodes in which 920 are hanging nodes. In that case, the interpolation order is allowed to vary across the layers. Results are shown on Fig. 2 in terms of the x -wise 1D distribution along $y = 0.0$ m of the E_z component. One can observe that the proposed non-conforming DGTD method treats very well the steep variations of the field at the material interfaces.

Fig. 2. Scattering of a plane wave by a multi-layered dielectric cylinder. 1D distribution of E_z along $y = 0$. Conforming (top) and non-conforming (bottom) DGTD- \mathbb{P}_i methods.

III. HYBRID EXPLICIT-IMPLICIT DGTD METHOD

Existing DGTD methods generally rely on explicit time integration schemes and are thus constrained by a stability condition that can be very restrictive on highly refined meshes, and when the local approximation relies on high order polynomial interpolation. An implicit time integration scheme is a natural way to obtain a time domain method which is unconditionally stable, but at the expense of the inversion of a global linear system at each time step. A more viable approach consists in applying an implicit time integration scheme locally in the refined regions of the mesh, while preserving an explicit time scheme in the complementary part. Such a hybrid explicit-implicit DGTD method has been proposed by Piperno in [8]. In this method, the elements of the mesh are assumed to be partitioned into two subsets, \mathcal{S}_i and \mathcal{S}_e , on the basis of an appropriate geometrical criterion. Then, the elements of \mathcal{S}_i are handled using a Crank-Nicolson scheme while those of \mathcal{S}_e are time advanced using a variant of the classical leap-frog scheme known as the Verlet method (see [8] for more details). We have recently completed a stability analysis of this method and subsequently implemented it for the solution of the 2D and 3D time domain Maxwell equations discretized in space by a high order conforming DGTD- \mathbb{P}_p method on simplicial meshes.

The effectiveness of the resulting hybrid explicit-implicit DGTD- \mathbb{P}_p method is demonstrated here by considering the simulation of the propagation of an electromagnetic wave emitted by a localized dipole type source in a heterogeneous geometrical model of head tissues (see Fig. 3). The underlying tetrahedral mesh consists of 61358 vertices and 366208 elements. The non-uniformity of this mesh can be assessed by evaluating the ratio between the maximum and minimum values of the local time step which is approximately equal to 135 in the present case. In particular, the smallest elements

of the mesh are in the vicinity of the source (localized near the right ear) and in the skin thickness. For the particular choice of geometric criterion adopted for this simulation, the distribution of mesh tetrahedra is such that $|\mathcal{S}_e| = 5142$ and $|\mathcal{S}_i| = 361066$ and the implicit elements are time advanced with a global time step which is approximately 4.7 times larger than the smallest time step of the mesh. The linear system of equations associated to the implicit elements is solved using an optimized sparse direct solver. The factorization of the implicit matrix is performed once for all before entering the time stepping loop and the resulting L and U factors are used for triangular solves at each time step. The simulations have been carried out on a workstation equipped with an Intel Xeon 2.3 GHz and 16 GB of RAM. The simulation time for the fully explicit DGTD- \mathbb{P}_1 method is 14 h 22 mn for a total of 42940 time steps, while the corresponding time for the hybrid explicit-implicit DGTD- \mathbb{P}_1 method is 1 h 49 mn for a total of 2780 time steps. The memory overhead induced by the use a sparse direct solver is 774 MB and the time for the factorization of the implicit matrix is 98 sec.

Abstract — A new technique is proposed to reconstruct faulty wiring networks from the time domain reflectometry response. The developed method is also for characterization of defects in the branches of the network. The direct problem (propagation along the cables) is modelled by RLCG circuit parameters computed by finite elements (FEM) and the Finite Difference Time Domain (FDTD) method. Genetic Algorithms (GAs) are used to solve the inverse problem. The proposed method allows to accurately locating wire faults. Some examples are presented to validate and illustrate the ability of this reconstruction method.

I. INTRODUCTION

Aging wiring in cars, aircraft, trains, and other transportation mean is identified as a critical security area. Fault location in wiring is a major cause for concern in automotive health maintenance. As automotive wires age increases they become brittle and are subject to several electrical, chemical and mechanical stresses. This leads to the occurrence of defects in the wiring. Wiring networks can be affected with two types of faults: “soft ones” are created by the change of the impedance along the line due to simple deformation in the wire, “hard faults” such as open and short circuits. For the first type of faults, the reflectometry response of the faulty network presents a simple deviation or variation versus the impedance of the fault, in the defects location. In the case of hard faults the structure of network as well as the response changes. According to the application domain, the defects of cables may have catastrophic consequence [1].

There are several emerging technologies that may help to locate and characterize the fault on the wires [1]-[3]. The most widely used technique for testing wires is reflectometry. It is based on the same principle that radar. A high frequency electrical signal is sent down the wire, where it reflects from any impedance discontinuity such as open or short circuits. The difference (time delay or phase shift) between the incident and reflected signal is used to locate the fault on the wire. However the reflectometry response itself is not self-sufficient to identify and locate the defects in the wire. There is the need to solve efficiently the inverse problem which is to deduce knowledge about the defects from the response at the input of the line. For such analysis an adequate wave propagation model is required in order to simulate the response of the line.

The novelty of this paper is to propose an efficient method for the detection, characterization and localization of defects in faulty wiring networks using the time domain reflectometry response and genetic algorithms. As a first step a suitable model describes the propagation of the electromagnetic wave along multiconductors transmission lines (MTL) in the time domain: the model is based on the telegrapher’s equations where the per-unit-length electrical parameters matrices of R, L, C and G are computed by a finite element technique. Then the wave propagation equations are solved with the Finite Difference Time Domain (FDTD) method. In order to deal with the inverse problem a genetic algorithm is used to minimize the error between the reflectometry response and the response given by the direct model. Several examples illustrate the ability of the proposed approach.

II. WAVE PROPAGATION MODEL

The propagation in a multiconductor transmission line (including n conductors) can be modelled by a RLCG circuit model [4] and is governed by the telegrapher’s equations (MTL equations):

$$\frac{\partial}{\partial z} V(z, t) = -R \cdot I(z, t) - L \cdot \frac{\partial}{\partial t} I(z, t) \quad (1)$$

$$\frac{\partial}{\partial z} I(z, t) = -G \cdot V(z, t) - C \cdot \frac{\partial}{\partial t} V(z, t) \quad (2)$$

where V and I are $n \times 1$ vectors of the line voltages and line currents, respectively. The position along the line is denoted as z and time is denoted as t . The $n \times n$ matrices R (resistance), L (inductance), C (capacitance) and G (conductance) contain the per-unit-length parameters. The coefficients of these matrices are computed either with a 2D finite element approach for the case of uniform transmission lines or with a full wave approach for more complex configurations [5]. The case of twisted wire cables is treated with the approach developed in [6]. The time-domain analysis of the MTL is determined by the Finite Difference Time Domain (FDTD) method which converts the differential equations into recursive finite difference equations.

III. RESULTS

In the problem, both the reflectometry response (measured or simulated) and the direct model are used to characterize the defects or reconstruct the wiring network.

3. Wave Propagation

From the reflectometry data of the wiring network under test, the methodology leads to solve an inverse problem: GA's are used to minimize the objective function F given by:

$$F(v) = \left\{ \int_0^T \frac{|v^{\text{TDR}}(t) - v^{\text{Mod}}(t)|^2}{|v^{\text{TDR}}(t)|^2} dt \right\}^{1/2} \quad (3)$$

where $v^{\text{TDR}}(t)$ is the given initial impulse response and $v^{\text{Mod}}(t)$ the response given by the direct model.

A. Identification of modified local impedance

The faulty network shown in figure 1 is first considered. The terminations of the branches are open circuits. It is assumed to be affected by a single defect. The reflectometry response used as the input of GA corresponds to a defect located at 2 m from the input. The change of impedance (due to the defect) is respectively of the order 10%, 20% and 60% of the characteristic impedance of the healthy wire. Figure 2 illustrates the time variation of the signals corresponding to the characteristics of the defects deduced from GA.

Fig. 1. Studied network

Fig. 2. Time Domain Reflectometry response

B. Reconstruction of a wiring network

This second example illustrates the performances of the approach for the reconstruction of a network (location of hard faults). The healthy wiring network of figure 1 is considered. The reflectometry response used as the input is obtained from measurements provided by a vector network analyzer in frequency domain. The parameters of GA are the lengths of the different branches $L = [L_1, L_2, \dots, L_i]$ with i is the total number of branch. Figure 3 shows the reconstructed network and Figure 4 compares the reflectometry response of the healthy network (measurements data) and the reconstructed one.

Fig. 3. Reconstructed network.

Fig. 4. Comparison between the reflectometry responses of the network reconstructed with GA with the healthy version.

IV. CONCLUSION

This paper describes a numerical model and an inverse procedure dedicated to time domain reflectometry for the location and characterization of defects in wiring networks. The work addresses both the modification of local impedance and the reconstruction of faulty wiring networks affected by hard faults.

Abstract—In this paper, we present a multiharmonic model able to take into account general nonlinear optical media [1]. As a particular example, two- and three-photon processes are considered here. The numerical model is based on the finite element method that allows to take into account the inhomogeneities of the refraction index due to the nonlinearities. It consists of several harmonic equations at various frequencies coupled via some nonlinear terms.

I. MULTIHARMONIC NONLINEAR MODEL

In this paper, we propose a numerical model for nonlinear optics based on a systematic approach of the nonlinearity in the frequency domain together with a very general setting via the finite element method. This model aims at applications in nanophotonics since the size of the scattering objects are of the same order of magnitude as the wavelength of the incident waves that are infrared or visible light. Considering a given incident monochromatic electric field of pulsation ω_I , we would like to solve the nonlinear vector wave equation:

$$\nabla \times (\mu^{-1} \nabla \times \mathbf{E}) + \partial_t^2 \mathbf{D} = 0.$$

for a given geometry and where the material properties are $\mathbf{D} = \varepsilon_0 \mathbf{E} + \mathbf{P}$ and $\mathbf{B} = \mu_0 \mathbf{H}$. We assume here that the polarization \mathbf{P} is of the form:

$$\begin{aligned} \mathbf{P}(\mathbf{s}, t) = & \mathbf{P}^{(0)}(\mathbf{s}) + \\ & \sum_{n \in \mathbb{N}} \varepsilon_0 \int_{-\infty}^{\infty} d\omega_1 \cdots \int_{-\infty}^{\infty} d\omega_n \chi^{(n)}(\mathbf{s}, \omega_1, \dots, \omega_n) \\ & \hat{\mathbf{E}}(\mathbf{s}, \omega_1) \cdots \hat{\mathbf{E}}(\mathbf{s}, \omega_n) e^{-i(\omega_1 + \dots + \omega_n)t}, \end{aligned}$$

where $\hat{\mathbf{E}}(\mathbf{s}, \omega)$ is the Fourier transform of $\hat{\mathbf{E}}$ with respect to time. We set $\mathbf{E}_p := \hat{\mathbf{E}}(\mathbf{s}, p\omega_I)$ and we note that $\mathbf{E}_{-p} = \bar{\mathbf{E}}_p$. The $\chi^{(n)}$ tensors describe the physical behaviour of the media. We now make the simplifying assumption that $\chi^{(n)}(\omega_1, \dots, \omega_n) = 0$ if $\omega_i \neq p\omega_I$, $p \in \mathbb{Z}$ so that the electric field is $\mathbf{E}(\mathbf{s}, t) = \sum_{p \in \mathbb{Z}} \mathbf{E}_p(\mathbf{s}) e^{-ip\omega_I t}$. To further simplify and to obtain tractable problems, we set $\chi^{(n)} = 0$ if $n > 3$. We introduce the following notations for the nonlinear terms involving the $\chi^{(n)}$:

$$[\mathbf{E}_{p_1}, \dots, \mathbf{E}_{p_n}]_{\omega_I} := \chi^{(n)}(p_1\omega_I, \dots, p_n\omega_I) \mathbf{E}_{p_1} \cdots \mathbf{E}_{p_n}$$

and for the linear part \mathcal{M}_p^{lin} of the wave operators:

$$\mathcal{M}_p^{lin}(\mathbf{E}_p) := -c^2 \nabla \times (\nabla \times \mathbf{E}_p) + (p\omega_I)^2 \varepsilon_r^{(1)}(p\omega_I) \mathbf{E}_p$$

where $\varepsilon_r^{(1)} = 1 + \chi^{(1)}$. With the previous assumptions, the time domain problem becomes an infinite set of coupled harmonic equations:

$$\begin{aligned} \mathcal{M}_p^{lin}(\mathbf{E}_p) + (p\omega_I)^2 \left(\sum_{q \in \mathbb{Z}} [\mathbf{E}_q, \mathbf{E}_{p-q}] + \right. \\ \left. \sum_{(q,r) \in \mathbb{Z}^2} [\mathbf{E}_q, \mathbf{E}_r, \mathbf{E}_{p-q-r}] \right) = 0, \quad \text{for } p \in \mathbb{Z}. \end{aligned}$$

Moreover, we limit our nonlinear phenomena to two- and three-photon processes. The corresponding problems are encountered in numerous nonlinear optics experiments involving second and third harmonic generation. Therefore we have $p \in \{-3, -2, -1, 1, 2, 3\}$, and a system of three coupled nonlinear equations is obtained:

$$\begin{aligned} \mathcal{M}_1^{lin}(\mathbf{E}_1) \\ + \omega_I^2 \left(2[\mathbf{E}_3, \mathbf{E}_{-2}] + 2[\mathbf{E}_2, \mathbf{E}_{-1}] \right. \\ + 6[\mathbf{E}_3, \mathbf{E}_1, \mathbf{E}_{-3}] + 3[\mathbf{E}_3, \mathbf{E}_{-1}, \mathbf{E}_{-1}] + 3[\mathbf{E}_2, \mathbf{E}_2, \mathbf{E}_{-3}] \\ \left. + 6[\mathbf{E}_2, \mathbf{E}_1, \mathbf{E}_{-2}] + 3[\mathbf{E}_1, \mathbf{E}_1, \mathbf{E}_{-1}] \right) = 0, \end{aligned}$$

$$\begin{aligned} \mathcal{M}_2^{lin}(\mathbf{E}_2) \\ + (2\omega_I)^2 \left(2[\mathbf{E}_3, \mathbf{E}_{-1}] + [\mathbf{E}_1, \mathbf{E}_1] \right. \\ + 6[\mathbf{E}_3, \mathbf{E}_2, \mathbf{E}_{-3}] + 6[\mathbf{E}_3, \mathbf{E}_1, \mathbf{E}_{-2}] + 3[\mathbf{E}_2, \mathbf{E}_2, \mathbf{E}_{-2}] \\ \left. + 6[\mathbf{E}_2, \mathbf{E}_1, \mathbf{E}_{-1}] \right) = 0, \end{aligned}$$

$$\begin{aligned} \mathcal{M}_3^{lin}(\mathbf{E}_3) \\ + (3\omega_I)^2 \left(2[\mathbf{E}_2, \mathbf{E}_1] \right. \\ + 3[\mathbf{E}_3, \mathbf{E}_3, \mathbf{E}_{-3}] + 6[\mathbf{E}_3, \mathbf{E}_2, \mathbf{E}_{-2}] + 6[\mathbf{E}_3, \mathbf{E}_1, \mathbf{E}_{-1}] \\ \left. + 3[\mathbf{E}_2, \mathbf{E}_2, \mathbf{E}_{-1}] + [\mathbf{E}_1, \mathbf{E}_1, \mathbf{E}_1] \right) = 0. \end{aligned}$$

A geometry invariant along the z -axis and an appropriate principal axis for the $\chi^{(n)}$ tensors are considered here together with a polarization of the electric field along this axis in order to reduce the problem to a scalar two-dimensional one. The numerical implementation is performed in COMSOL Multiphysics with triangular finite elements. The incident field is a plane wave imposed via a virtual antenna [2], a special

Abstract—We present a multiple-scattering solver for non-convex geometries obtained as the union of a finite number of convex surfaces. The algorithm is a finite element reformulation of the high-frequency integral equation technique proposed in [1]. It is based on an iterative solution of the scattering problem, where each iteration leads to the resolution of a single scattering problem in terms of a slowly oscillatory amplitude.

I. INTRODUCTION

Solving multiple-scattering problems at high frequencies is a challenging problem, especially when the wavelength is significantly smaller than the size of the scattering obstacles.

For non-convex geometries obtained as the union of a finite number of convex surfaces, an efficient algorithm was proposed in [1] based on three main elements: 1) an iteratively computable Neumann series for the currents induced on the scattering surfaces, which accounts rigorously for multiple scattering; 2) a generalized ansatz that allows for *a priori* determination of the highly oscillatory phase of the currents in each term of the series; and 3) use of the single-scattering boundary-integral solver from [2] for the efficient evaluation of each one of the terms in this series.

In this paper we present a reformulation of this algorithm using a finite element approach, which requires a fundamental rethinking of steps 2) and 3) since the fields are to be computed in the volume instead of only on the boundary of the scatterers. This new finite element approach exhibits many interesting features, amongst which possible extensions to non-homogeneous media and more complex geometries. Also, the proposed finite element formulation uses standard basis functions and can thus be easily implemented in existing finite element codes.

II. MULTIPLE-SCATTERING ITERATIONS

We investigate the numerical solution of the time-harmonic acoustic scattering problem of a plane wave $u^{\text{inc}}(\mathbf{x}) = e^{ik\boldsymbol{\alpha}\cdot\mathbf{x}}$, $|\boldsymbol{\alpha}| = 1$, by a collection of impenetrable obstacles $\Omega_p^- \subset \mathbb{R}^2$, $p = 1, \dots, N$, with closed boundaries Γ_p (this is equivalent to solving a TE- or TM-electromagnetic problem in 2D). Setting $\Omega^- = \cup_{p=1}^N \Omega_p^-$, $\Gamma = \cup_{p=1}^N \Gamma_p$ and $\Omega^+ = \mathbb{R}^2 \setminus \overline{\Omega^-}$, the boundary value problem reads:

$$\begin{aligned} \Delta u + k^2 u &= 0 \quad \text{in } \Omega^+, \\ u &= -u^{\text{inc}} \text{ or } \partial_n u = -\partial_n u^{\text{inc}} \quad \text{on } \Gamma, \\ \lim_{|\mathbf{x}| \rightarrow +\infty} |\mathbf{x}|(\nabla u \cdot \frac{\mathbf{x}}{|\mathbf{x}|} - ik u) &= 0. \end{aligned} \quad (1)$$

This work was supported by the Belgian Science Policy under grant IAP P6/21 and by NSF under grant DMS-0609824.

Instead of trying to solve (1) directly, we look for the solution in terms of the series $u = \sum_{m=1}^{\infty} \sum_{p=1}^N u_p^{(m)}$, where $u_p^{(m)}$ is the solution of the problem:

$$\begin{aligned} \Delta u_p^{(m)} + k^2 u_p^{(m)} &= 0 \quad \text{in } \mathbb{R}^2 \setminus \overline{\Omega_p^-}, \\ u_p^{(m)} &= s_p^{(m)} \text{ or } \partial_n u_p^{(m)} = \partial_n s_p^{(m)} \quad \text{on } \Gamma_p, \\ \lim_{|\mathbf{x}| \rightarrow +\infty} |\mathbf{x}|(\nabla u_p^{(m)} \cdot \frac{\mathbf{x}}{|\mathbf{x}|} - ik u_p^{(m)}) &= 0, \end{aligned} \quad (2)$$

with

$$s_p^{(m)} = \begin{cases} -u^{\text{inc}} - \sum_{q=1}^{p-1} u_q^{(m)} & \text{for } m = 1, \\ -\sum_{q=1}^{p-1} u_q^{(m)} - \sum_{q=p+1}^N u_q^{(m-1)} & \text{for } m > 1, \end{cases} \quad (3)$$

In other words, we perform a Gauss-Seidel-type iteration where at each step we solve a scattering problem around the single obstacle Ω_p^- , using the fields scattered from the other obstacles as boundary condition [3]. As each correction $u_p^{(m)}$ can be interpreted as the correction introduced by the m -th wave reflection [1], [3], the iteration can be stopped when the norm of all corrections at step m is smaller than a prescribed tolerance.

Note that instead of performing this Gauss-Seidel iteration, other iterative schemes can be used as well. Indeed, the Dirichlet or Neumann boundary condition in (2) can equivalently be written in vector form as:

$$U^{(m+1)} - AU^{(m)} := F = \begin{cases} -U^{\text{inc}} & m = 1 \\ 0 & m > 1 \end{cases}, \quad (4)$$

where A is the iteration operator acting on the traces of the field, mapping the traces at iteration (m) onto those at iteration $(m+1)$. The desired solution of this problem satisfies

$$(I - A)U^* = F, \quad (5)$$

which can be solved iteratively e.g. with a Krylov subspace method like a preconditioned GMRES. An explicit expression of the iteration operator A in the context of integral equations was given in [1].

III. FINITE ELEMENT SOLUTION

A standard finite element code could be used to solve (2), but the cost of each iteration would be similar to the cost of solving the original problem (1) and this would thus present little practical interest. However, if the obstacles Ω_p^- are convex each step in the iterative process can be accelerated with the phase reduction (PR) procedure proposed in [4],

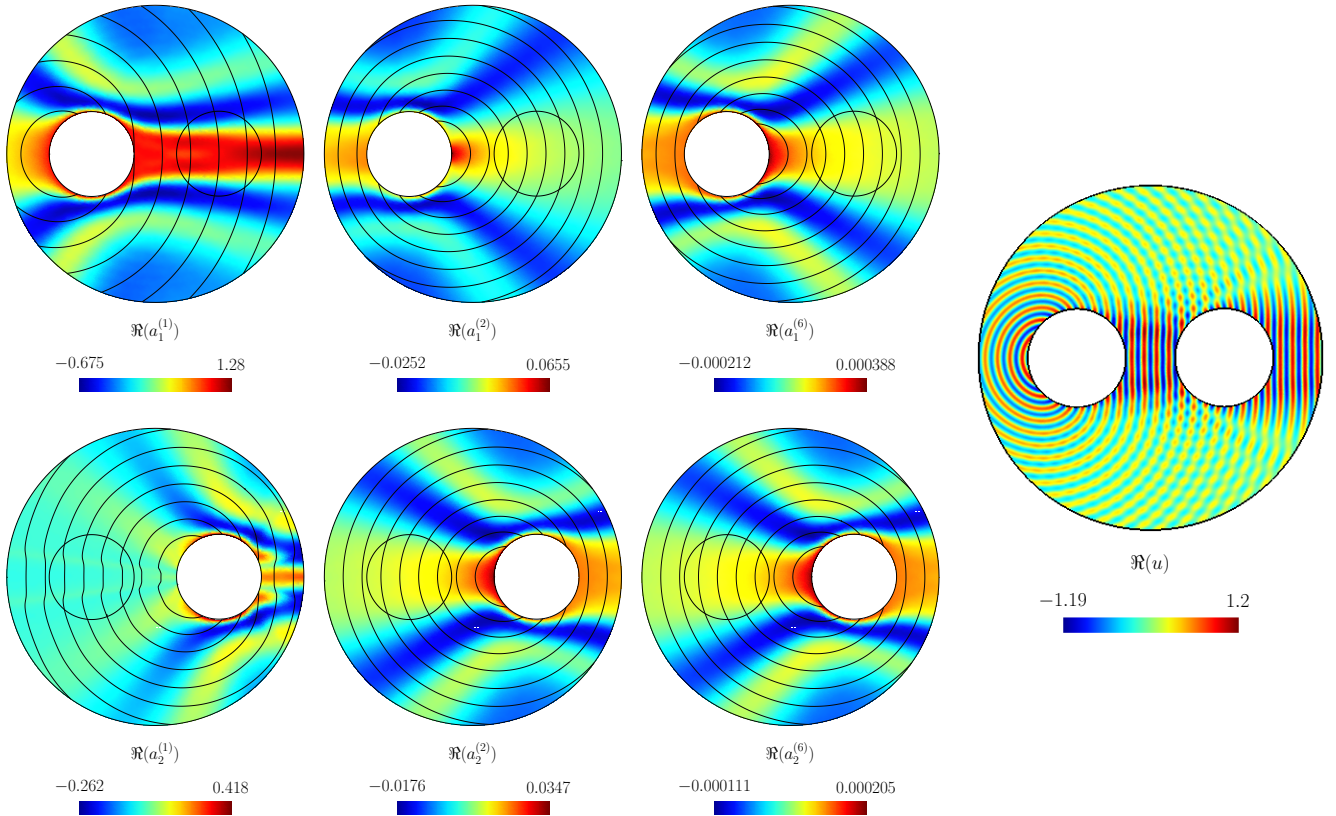

Fig. 1. Iterative solution around two circular cylinders of unit radius R for an incident plane wave arriving from the left, with $kR = 25$. Left: Real part of the amplitudes $a_p^{(m)}$ for $p = 1$ and $p = 2$ (top to bottom) and $m = 1, 2, 6$ (left to right). On each graph iso-curves of the approximate phase $\phi_p^{(m)}$ are superimposed. Right: Real part of the final solution $u = \sum_{m=1}^6 \sum_{p=1}^2 a_p^{(m)} e^{i25\phi_p^{(m)}}$.

[5]. Indeed, if Ω_p^- is convex then (2) amounts to solving a *single scattering* problem in $\mathbb{R}^2 \setminus \Omega_p^-$. The PR procedure approximates the phase $\phi_p^{(m)}$ of the solution of the p -th single scattering problem at iteration m and replaces the original unknown $u_p^{(m)}$ of the single scattering problem with a slowly oscillatory amplitude $a_p^{(m)} = u_p^{(m)} e^{-ik\phi_p^{(m)}}$, which can be represented on a coarse grid.

IV. NUMERICAL TEST

As an example, we consider the scattering of a plane wave e^{ikx} by two circular cylinders of unit radius R , separated by a distance $d = R$. We use a Bayliss-Gunzburger-Turkel-like radiation condition to truncate the infinite domain. Using a prescribed tolerance of 10^{-3} the iterative process converges after 6 iterations. Figure 1 shows, for $kR = 25$, the amplitude $a_p^{(m)}$ and the phase $\phi_p^{(m)}$ for $m = 1, 2, 6$ and $p = 1, 2$, as well as the final solution u .

Of particular notice is how each term in the series is not highly oscillatory and can thus be computed on a coarser grid than the final solution. In this example we used about 2 points per wavelength to compute the approximate phase and the slowly oscillating amplitude, leading to a mesh containing 4300 nodes. The original problem would have required a mesh density of at least 10 points per wavelength, leading to about 25 times more unknowns.

The full paper will provide details on the variational formulation and analyze the results on different geometrical configurations.

Abstract—Solving scattering problems using the finite element method (FEM) introduces two sources of error: from the discretization and from the truncation boundary. Here both errors are addressed in an iterative, balanced way. For the discretization error, p -adaption is used. An *a posteriori* error indicator automatically determines which elements should be increased in order to reduce and equi-distribute the discretization error. For the boundary error, an iterative absorbing boundary condition is applied. The overall scheme starts with low order polynomials and a first order absorbing boundary condition and progressively improves the quality of the solution by a combination of p -adaption and updating the boundary condition, so that both the discretization and the boundary errors are similar at each stage. Results are presented to show the reduction of computation time when p -adaption is used as opposed to an earlier approach of uniformly increasing the element orders.

I. INTRODUCTION

When the finite element method (FEM) is applied to the scattering of electromagnetic waves, the infinite domain has to be reduced to a finite volume by the introduction of a truncation boundary, S_1 . Maxwell's equations are solved in the finite volume, subject to a condition on S_1 that absorbs the scattered field. Of the many ways of doing this, one of the most appealing is the iterative absorbing boundary condition (IABC) [1], [2], because at each iteration it is computationally inexpensive and yet it can converge to a highly accurate absorber. Initially, a first-order ABC is applied to S_1 ; then the fields inside are computed, and the boundary condition on S_1 is updated by making use of the computed fields on an inner surface, S_2 (which may be on the surface of the scatterer itself). The fields inside are computed again, and so on.

At every iteration there is a solution error introduced by the IABC, called the boundary error. This is in addition to the error arising from the finite elements themselves, called the discretization error. The latter can be controlled by adaption, which can be carried out at each iteration of the IABC. In the present work, p -adaption is chosen, making use of the hierarchical properties of the vector tetrahedral elements described in [3]. A control scheme is used to balance the two sources of error, so that the overall error reduces as rapidly as possible with increasing computational cost.

The present contribution builds on earlier work [4] in which the element orders, while varying from one iteration to the next, were kept uniform throughout the mesh, i.e., no p -adaption was involved. The incorporation of p -adaption requires changes to the control scheme, and the development of a suitable error indicator, described next.

II. ERROR INDICATOR

The implicit indicator presented here is related to the goal oriented error indicator described in [5]. In this paper, a similar approach is used to yield a general indicator of the field error. A formulation employing the magnetic field \mathbf{H} is used for the solution of the 3-D electromagnetic scattering problem. The weighted residual formulation is of the form [6]:

$$a(\mathbf{H}, \mathbf{w}) = b(\mathbf{w}) \quad \forall \mathbf{w} \quad (1)$$

where \mathbf{w} is a weight function; a and b are bilinear and linear forms, respectively [2]. Suppose that $\bar{\mathbf{H}}$ is a computed solution of (1). We aim to estimate the error arising from element k by the following expression:

$$\mathbf{e}_k = \mathbf{H}_k - \bar{\mathbf{H}} \quad (2)$$

where \mathbf{H}_k is the computed field when the order of element k is incremented by 1. The error indicator η_k for element k is based on the 'energy norm' of \mathbf{e}_k and is defined by [7]:

$$\eta_k = \|\mathbf{e}_k\|_a = \sqrt{|a(\mathbf{e}_k, \mathbf{e}_k)|} \quad (3)$$

which can also be evaluated as:

$$\eta_k = \sqrt{|b(\mathbf{e}_k) - a(\bar{\mathbf{H}}, \mathbf{e}_k)|} \quad (4)$$

When \mathbf{e}_k is exactly as given by (2), expressions (3) and (4) are identical. However, (4) is less sensitive than (3) to errors in \mathbf{e}_k when \mathbf{e}_k is approximated.

III. APPROXIMATING THE ERROR INDICATOR

Equation (1) can be discretized using the Galerkin method with a set of functions \mathbf{N}_i used as both weight and trial functions. The result will have the form [6], [7]:

$$[K] \{\bar{H}\} = \{b\} \quad (5)$$

where $[K]$ is a symmetric matrix, $\{b\}$ is the source term arising from the incident plane wave, and $\{\bar{H}\}$ is the vector of coefficients to be determined. After evaluating $\{\bar{H}\}$, the field $\bar{\mathbf{H}}$ can be found:

$$\bar{\mathbf{H}} = \{\mathbf{N}\}^T \{\bar{H}\} \quad (6)$$

where superscript \mathbb{T} denotes the transpose. After incrementing the element order of the k^{th} element, (5) becomes:

$$\begin{bmatrix} [K_k^{oo}] & [K_k^{no}] \\ [K_k^{on}] & [K_k^{nn}] \end{bmatrix} \begin{Bmatrix} \{H_k^o\} \\ \{H_k^n\} \end{Bmatrix} = \begin{Bmatrix} \{b_k^o\} \\ \{b_k^n\} \end{Bmatrix} \quad (7)$$

where $\{H_k^o\}$ is the vector of coefficients corresponding to the original (old) DOFs. $\{H_k^n\}$ is the vector of coefficients corresponding to the new DOFs added to element k to raise its order by 1. b_k^o and b_k^n are the corresponding old and new source terms. A reasonable approximation can be made by putting $\{H_k^o\} = \{\bar{H}\}$. Equation (7) then gives the following small matrix equation, which can be solved for each element k , in turn:

$$[K_k^{nn}] \{H_k^n\} \approx \{b_k^n\} - [K_k^{on}] \{\bar{H}\} \quad (8)$$

After substituting $\{H_k^n\}$ in (2), the error of element k is:

$$\mathbf{e}_k \approx \{\mathbf{N}^n\}^T \{H_k^n\} \quad (9)$$

where $\{\mathbf{N}^n\}$ is a column vector of the trial functions associated with the new DOFs. Then $b(\mathbf{e}_k)$ and $a(\bar{\mathbf{H}}, \mathbf{e}_k)$ can be evaluated as:

$$b(\mathbf{e}_k) \approx \{H_k^n\}^T \{b_k^n\} \quad (10)$$

$$a(\bar{\mathbf{H}}, \mathbf{e}_k) \approx \{\bar{H}\}^T [K_k^{on}] \{H_k^n\} \quad (11)$$

Then the error indicator (4) can be calculated.

IV. CONTROL SCHEME

The control scheme used here is similar to the one used in [4]. In this paper, instead of increasing the order of all elements uniformly, only a certain percentage of the elements are adapted. Also in [4], after increasing the element order, a boundary update was always performed as it was found that this was needed following an increment of the order of all elements by one. But, with the p -adaptive scheme, it is not needed. A modified flow chart will be presented in the extended paper.

V. RESULTS

The example consists of two dielectric spheres, as shown in Fig. 1. The incident plane wave propagates in the $-x$ -direction, with y -polarized electric field. The truncation boundary is a rectangular box placed $l = 0.1\lambda$ away from the spheres (Fig. 1). 6,685 elements are used. The problem is first solved at order 3 and the radar cross section (RCS) obtained after 10 iterations is used as the reference solution. Then the same FE problem is solved twice using the p -adaptive control scheme. First, at each p -adaptive step, 75% of elements with the highest error (4) are increased in order; this is the curve "75% adaption". In the second solution, all of the elements are increased in order ("100% adaption"). Fig. 2 also shows

Fig. 1. Two dielectric spheres along with the truncation boundary S_1 . All the dimensions are in wavelengths. The dielectric constant of each sphere is $\epsilon_r = 2$. $l = 0.1$ is the separation between the spheres and truncation boundary.

the error when the order is fixed at 3 throughout. Total time is the summation of the field solution time and the boundary update time for all the solutions up that point. Average error (dB) is the average error in the value of $10 \log_{10}(\text{RCS}/\lambda^2)$ over the range $(\phi = \pi/2, 0 \leq \theta \leq \pi)$. From the graph it is clear that the new p -adaptive scheme is more effective at reducing the error than either the use of an element order that is fixed order throughout the iteration (i.e., just boundary iteration) or the use of an order that changes but is uniform throughout the mesh.

Fig. 2. Average error in the bistatic RCS in the plane $\phi = \pi/2$ (the yz plane) as a function of total time. Triangles represent results using 75% adaption; circles represent the results using uniform order; crosses represent the results obtained using 3rd order elements at every iteration.

Abstract—By using the method of time domain integral equation (TDIE) and equivalent principle, the shading effect of reinforced concrete construction to lightning radiation field is analyzed. The reinforced concrete surface is assumed to be metallized and modeled based on the equivalent principle. The electromagnetic field inside and out of the reinforced concrete are both calculated by using the time domain electric field integral equation. The proposed technique, which is efficient to analyze the far field, is more applicable to evaluate the shading effect of reinforced concrete construction to lightning radiation magnetic field in time domain.

I. INTRODUCTION

Due to the widespread existence of tall reinforced concrete constructions in city, the lightning radiation electromagnetic field detected by nearby lightning location sensor may be influenced. Accordingly the peak value and derivative of the corresponding lightning current derived from the measured lightning radiation magnetic field may deviate from their real values. In order to obtain lightning current reliable enough, it is necessary to investigate the shading effect of the reinforced concrete construction to the lightning radiation magnetic field and determine the minimum distance from the lightning detection system to nearby tall building further.

Generally the shielding effect of reinforce concrete construction on the radiation electromagnetic field in space is concerned in literature, typically as discussed in [1, 2]. There are two approaches widely used to identify the shielding effect of the reinforced concrete buildings exactly. The first is based on FDTD or TLM method [1], which is complicated for reinforce concrete despite the relatively simple separation of space. Additionally, it is not convenient to determine the electromagnetic field of any point in space. The Second one, using volume cell MoM to investigate the scattering field of concrete block or analogical lump medium [2], is also not applicable for reinforce concrete. In the analysis of the shading performance of reinforced concrete construction to electromagnetic field in space, both the influence of steel grid and that of concrete should be taken into account, thus more efficient calculation is of requirement.

In this paper, a method in time domain to investigate the shading effect of reinforced concrete construction to lightning radiation magnetic field is developed based on the time domain integral equation (TDIE) and equivalent principle. The electromagnetic response caused by the interaction between the inner surface and the outer surface of the concrete, which is usually not easy to be identified, is modeled by

introducing electric currents on the surface. With the concrete surface taken to be metallized, an equivalent surface electric current is introduced on the surface. The field in the concrete is resulted from the equivalent surface electric current on the concrete surface and the line current flowing on the steel grid buried in the concrete. While the field out of the concrete is generated by the equivalent surface electric current and the incidence lightning radiation electromagnetic wave. On the concrete surface, the fields inside and outside the concrete satisfy the continuity of tangential electric field.

Thus the spatial electromagnetic field intensity can be determined to evaluate the shading effect of reinforced concrete construction. Since the inversion of lightning current is mainly dependent on the lightning radiation magnetic field intensity, only the waveform of the radiation magnetic field is displayed. At last, the proposed method is used to analyze the effect of a simplified reinforced concrete building to the lightning radiation magnetic field.

II. DESCRIPTION OF THE APPROACH

A. Basic Model of Reinforce Concrete Block

In order to reasonably simplify the calculation model of reinforced concrete construction, the following two assumptions are necessary. 1) The medium of the concrete is uniform and isotropic; 2) Compared with the thickness of the concrete, the steel conductors buried in the concrete is of radius small enough that can be modeled as thin wire.

Fig.1 The model of a section of concrete

The geometry of the simple reinforce concrete block model is shown in Fig.1. The steel grid is buried in concrete. The concrete surface separates the whole space into two sections, namely the space in and outside the concrete, with the interior surface O and exterior surface O^+ .

Based on the two assumptions, an equivalent electric current pair \mathcal{J}^c is introduced on the exterior surface O^+ and interior surface O of the reinforced concrete block. The outside field, therefore, is the sum of the field produced by the equivalent current source \mathcal{J}^c and that from outer excitation source \mathcal{J}^{inc} , while the field in the concrete is yielded by \mathcal{J}^c plus the scattering field of current I^v flowing on the steel grid.

According to the equivalent theorem, the scattering field from the metal conductor buried in the concrete can be analyzed as that in the uniform medium.

Since electric field intensity is continuous on the concrete surface and the tangential electric field component on the surface of steel grid is equal to the voltage drop in the conductor, the continuity discussed above on the surface of reinforced concrete yields the following equations.

$$\mathbf{E}_t^o(\mathbf{J}^{inc}) + \mathbf{E}_t^o(\mathbf{J}^c) = \mathbf{E}_t^i(\mathbf{J}^c) + \mathbf{E}_t^i(\mathbf{J}^w) \quad (1)$$

$$\mathbf{E}_t^w(\mathbf{J}^c) + \mathbf{E}_t^w(\mathbf{I}^w) = Z\mathbf{I}^w \quad (2)$$

Equation (1) and (2) are for the concrete surface and the steel surface respectively. Where $\mathbf{E}_t^o(\mathbf{J}^{inc})$ and $\mathbf{E}_t^o(\mathbf{J}^c)$ are the tangential electric field at O^+ due to \mathbf{J}^{inc} and \mathbf{J}^c respectively. $\mathbf{E}_t^i(\mathbf{J}^c)$ and $\mathbf{E}_t^i(\mathbf{I}^w)$ are the tangential electric field given by \mathbf{J}^c and \mathbf{I}^w respectively at O^- . The tangential component $\mathbf{E}_t^w(\mathbf{J}^c)$ and $\mathbf{E}_t^w(\mathbf{I}^w)$ on steel surface is resulted from \mathbf{J}^c and \mathbf{I}^w respectively. And Z is the impedance per unit length of the steel grid.

By using the method of moment equation (1) and (2) can be solved. Since the reinforced concrete construction is supposed to be rectangular volume, the surfaces are discretized into a lot of rectangular patches. The roof-top basic functions are adopted to expand the unknown electric currents on these patches and wire segments.

B. Electromagnetic Field out of the Concrete Block

In order to simplify the calculation, the ground out of the concrete is supposed to be perfect electric conductor.

As illustrated by the engineer model of lightning return stroke, the lightning current flows in the lightning channel as does in transmission line. The following is the most simple relation expression

$$i(z', t) = i(t - z'/v) \quad (3)$$

where z' is the height of return stroke front along the lightning channel, v is velocity of return stroke. The double exponential function is adopted to represent the channel base current in our calculation. Since the lightning channel concerned here is relatively very far from the involved building, the effect of the scattering from the building on lightning current is neglected, namely the original lightning radiation field is considered to be incidence field. The calculation equation for the field out of the concrete can be established based on following formula.

$$\left(\frac{\partial^2}{\partial t^2} - c^2 \nabla \nabla \cdot \right) \mathbf{A} \Big|_{\tan} = \frac{\partial}{\partial t} \mathbf{E}^i \Big|_{\tan} \quad (4)$$

where c is the lightning speed in free space, \mathbf{E}^i is the lightning radiation electric field, and $\mathbf{A}(\mathbf{r}, t)$ is the vector potential generated from the surface electric current in free space.

C. Electromagnetic Field in the Concrete Block

The surface current \mathbf{J} on the inside surface of the concrete and the current \mathbf{I}^w flowing on the steel grid of the concrete produce the electric field in the concrete block. The concrete is modeled as lossy medium with permittivity ϵ , conductivity σ , and permeability μ . There is no inject field existing in the reinforce concrete block, thus the integral equation of time domain electric field is given by

$$\left(\frac{\partial^2}{\partial t^2} + a^2 c^2 \frac{\partial^2}{\partial t^2} - c^2 \nabla \nabla \cdot \right) \mathbf{A} \Big|_{\tan} = 0 \quad (5)$$

where $a = \sqrt{\mu\sigma}$, $c = 1/\sqrt{\mu\epsilon}$. The vector potential $\mathbf{A}(\mathbf{r}, t)$ is expressed as

$$\mathbf{A}(\mathbf{r}, t) = \mu \int_s \mathbf{J}(\mathbf{r}', t) g(|\mathbf{r} - \mathbf{r}'|, t) d\mathbf{r}' \quad (6)$$

where $g(|\mathbf{r} - \mathbf{r}'|, t)$ is the three dimensional scalar Green function for the lossy medium wave equation [3].

III. ANALYSIS OF THE INFLUENCE

In view of the irregular outline and various dimension of constructions, some usually used hypotheses are necessary, they are:

- 1) The construction is rectangular volume;
- 2) The steel grid is in the center of the construction;
- 3) The lightning channel is also vertical to the ground.

Based on these assumptions, the profile of calculation model can be expressed in Fig.2 as

Fig. 2 Calculation model profile

Suppose that lightning channel is 150km far from the building, Fig.3 shows the lightning radiation magnetic field waveform calculated on ground level at 50m from the building for the cases that the width of building is 50m, 100m, 150m, 200m, and 500m, as well as that without the existence of the building. The resistivity and relative permittivity of the building, which is 50m high, are $50\Omega\cdot\text{m}$ and 8 respectively. The steel grid in the concrete is $1 \times 1\text{m}^2$.

Abstract – In this work, we apply a meshless-based method to a set of integral equations arising in electromagnetic wave propagation and scattering. The objective is not only to solve these equations through a meshless-based method, but also to find a way to build shape functions that could work for any cross-sectional geometry. We have found that the Moving Least Squares (MLS) approximation is not able to provide useful shape functions in every situation. This technique relies on matrix inversions and, according to the geometry, singular matrices can occur. In order to avoid this problem, we have taken the Improved Moving Least Squares (IMLS) approximation, that doesn't depend upon matrix inversions and works well in a number of cross-sectional geometries.

I. INTRODUCTION

Meshless methods have successfully been applied in Mechanics as an alternative to the traditional finite element method (FEM). Now they are being brought to the study of electrodynamics and presented as an additional aid in the solution of high-frequency [1] problems. In this work we take a different approach by applying a meshless discretization directly into the classical integral field equations instead of applying it to the weak form. We have already solved the problem for a circular cylinder using the MLS approximation [2], but the solution is not as general as to be applied to every cross-section form. For other geometries (e.g. rectangular) the MLS approximation fails in providing accurate results, because singular local matrices are obtained, leading to an inconsistent outcome. The IMLS approximation thus seemed to be the right one; despite having to build an orthogonal basis first, the associated matrices are diagonal, there is no need for inversions and the shape functions could then be built consistently for any cross-sectional geometry.

II. PROBLEM DESCRIPTION

In the investigated problems, a monochromatic incident plane wave is scattered by perfect electric conductor (PEC) cylinder infinite in the z -direction. For a TM^z polarized incident wave, the electric surface current density \vec{J}_s is directed along the z -direction. One of the equations governing the phenomenon is the electric field integral equation (EFIE):

$$E_z^i(\vec{\rho}) = \frac{\omega\mu}{4} \oint J_s(\vec{\rho}') H_0^{(2)}(kR) dl' \quad (1)$$

$E_z^i(\vec{\rho})$ is the incident electric field at $\vec{\rho}$, $R = \|\vec{R}\| = \|\vec{\rho} - \vec{\rho}'\|$, $\vec{\rho}$ and $\vec{\rho}'$ locate the observation and source points at the perimeter, respectively, $\omega = 2\pi f$, where f is the

wave frequency, and $H_0^{(2)}$ is the zero-order Hankel function of the second type. The other is the magnetic field integral equation (MFIE):

$$[\hat{n} \times \vec{H}_i(\vec{\rho})] \cdot \hat{z} = \frac{1}{2} J_s(\vec{\rho}') + \frac{jk}{4} \oint J_s(\vec{\rho}') H_1^{(2)}(kR) [\hat{n} \cdot \hat{R}] dl' \quad (2)$$

where $\vec{H}_i(\vec{\rho})$ is the incident magnetic field at $\vec{\rho}$, $H_1^{(2)}$ is the first-order Hankel function of the second type and \hat{n} is the unit surface normal. The EFIE and MFIE formulation can be seen in [3]. To avoid spurious resonant solutions one can form the combined field integral equation (CFIE) through a linear combination from the EFIE and MFIE:

$$CFIE = \alpha EFIE + (1 - \alpha) \eta MFIE \quad (3)$$

where α is a parameter ranging from zero to one and η is the intrinsic impedance of the exterior medium [3].

III. THE MESHLESS APPROACH

The meshless approach begins by spreading nodes over the domain of the problem to be solved. In the present study, the domain of interest is the perimeter of the cylinder cross section. To each node a shape function with compact support is associated. The vicinal region in which the shape function is different from zero is called the *influence domain* of the corresponding node [4]. The main difference between meshless methods and mesh-based methods (like the FEM) is that the *element* concept is not present. The influence domains are arbitrary (the only restriction is that the set of influence domains must cover the entire domain) and can overlap. So, the nodes can be distributed arbitrarily without generating an element mesh.

Once the shape functions have been determined, the approximated value of a function u in a point \vec{x} is given by u^h and is expressed as

$$u^h(\vec{x}) = \sum_{I=1}^N \phi_I(\vec{x}) \hat{u}_I \quad (4)$$

where $I = 1 \dots N$ are the nodes whose influence domains include the point \vec{x} and the numbers \hat{u}_I associated to each node are called the *nodal parameters*.

There are several ways to build the shape functions [4]; among them we chose the moving least squares approximation (MLS). The MLS approximation begins by expressing u^h as

$$u^h(\vec{x}) = \sum_{i=1}^m p_i(\vec{x}) a_i(\vec{x}) = p^T(\vec{x}) a(\vec{x}) \quad (5)$$

where $p_i, i = 1 \dots m$ are monomial functions, m is the number of terms in the basis p and a_i are coefficients (e.g., in two dimensions, one could have $p^T = [1, x, y]$). The next step is to force the difference between the approximation u^h and the exact value at the nodal points to reach a minimum through the minimization of a weighted functional; this takes several matrix manipulations whose detailed descriptions can be found in [4]. The results are:

$$[\phi_1(\vec{x}), \phi_2(\vec{x}), \dots, \phi_N(x)] = p^T(\vec{x}) A^{-1}(\vec{x}) B(\vec{x}), \quad (6)$$

$$A(\vec{x}) = P^T W(\vec{x}) P \text{ and } B(\vec{x}) = P^T W(\vec{x}) \quad (7)$$

$$P = \begin{pmatrix} p_1(\vec{x}_1) & \dots & p_m(\vec{x}_1) \\ \vdots & \ddots & \vdots \\ p_1(\vec{x}_N) & \dots & p_m(\vec{x}_N) \end{pmatrix} \quad (8)$$

and W is a diagonal matrix whose elements are

$$[W(\vec{x})]_{ii} = w(\vec{x} - \vec{x}_i) \quad (9)$$

$w(\vec{x} - \vec{x}_i)$ is a weight function with compact support (i.e. a cubic spline [4]).

The MLS approximation doesn't always provide useful shape functions, because sometimes the A -matrices become singular, preventing inversion. This phenomenon occurs for some geometries, like the rectangular one. The reason is that for points lying in regions along the sides, *away from the corners*, the parameter that describes the contour line experiments variation only in one variable (x only or y only). For a given point \vec{x} in the rectangle upper side, for example, the y -variable is a constant $y = c$. So the basis becomes $p^T = [1, x, c]$. One sees that all N nodes whose influence domains act upon \vec{x} have the y -coordinate equal to c . Consequently, P has two constant columns. So, the product $A = P^T W P$ will have two linearly dependent columns. Hence, A is singular.

One way to solve that is to make the nodal influence domains bigger than the side of the rectangle, in order to assure that inside this domain there will be points distributed along two adjacent sides. By doing this, both x and y will vary, P will no longer have two linearly dependent columns and A shall not be singular. But it revealed to be a bad approach: one sees that as the influence domains become larger, the local perspective of the method is destroyed. Besides that, the results are not so much accurate.

To remedy this problem, a different approximation was developed: the improved moving least squares (IMLS) [5]. In the IMLS, it is required that the terms of the basis p be orthogonal to each other. In order to do so, they are viewed as belonging to a Hilbert space in which the following inner product between functions f and g is defined:

$$\langle f, g \rangle = \sum_{l=1}^N w(\vec{x} - \vec{x}_l) f(\vec{x}_l) g(\vec{x}_l) \quad (10)$$

The orthogonality condition is assured through the property ($k, j = 1, 2, \dots, m$):

$$\langle p_k, p_j \rangle = \sum_{l=1}^N w(\vec{x} - \vec{x}_l) p_k(\vec{x}_l) p_j(\vec{x}_l) = \begin{cases} A_k, & k = j \\ 0, & k \neq j \end{cases} \quad (11)$$

After some matrix manipulations [5], one concludes that inversions are no longer necessary. The shape functions are

$$[\phi_1(\vec{x}), \phi_2(\vec{x}), \dots, \phi_N(x)] = p^T(\vec{x}) \bar{A}(\vec{x}) B(\vec{x}) \quad (12)$$

where \bar{A} is a diagonal matrix whose elements are given by

$$[\bar{A}(\vec{x})]_{ii} = \frac{1}{\langle p_i, p_i \rangle} \quad (13)$$

IV. PRELIMINARY RESULTS

For a rectangular cross-section cylinder, we have begun by spreading nodes over the contour and applying the IMLS approximation to build the shape functions. We can express the unknown surface current density at a nodal point $\vec{\rho}_i$ along the contour as in (4), with u^h replaced by J and \vec{x} by $\vec{\rho}_i$. The next step is to insert that expression for J in (3) and get a linear system that can be solved in order to find the nodal parameters. The following results were obtained (scattering by a square cylinder with sides $2a$, where $a = 1/k$ and $k = 2\pi/\lambda$ is the wave number, λ being the wavelength):

Fig. 1. Normalized current density along cylinder contour

The figure above shows the absolute value of the normalized current density (with respect to the incident magnetic field H_i) along the path ABCD. One sees that the result is accurate when compared to the method of moments (MoM). The peaks in the current density at the vertices B and C are theoretically predicted for a TM incident wave.

Further studies on the precision and the convergence of the method will be presented in the final paper. We have found out that the MLS approximation is not general enough to deal with any cross-sectional geometry. It should be noted that the IMLS approximation runs faster than the MLS, as there is no need for matrix inversion.

Numerical Techniques for Multi-Objective Synthesis of an Inverted-S Antenna

Lei Liu¹, Junwei Lu², Shiyu Yang¹, and Guangzheng Ni¹

¹College of Electrical Engineering, Zhejiang University, Hangzhou, 310027, China

²Faculty of Engineering and Information Technology, Griffith University, Australia

Abstract—The synthesis of a dual-frequency band Inverted-S Antenna (ISA) using low profile PCB configuration is studied. To manipulate the multi-objectives and the huge amount of turning work involved in the synthesis of a dual-frequency band Inverted-S Antenna, special numerical techniques such as approaches to integrating different objectives, an improved vector genetic algorithm and a modified radial basis function based response surface model are proposed. Numerical results as reported serve to demonstrate the pros and cons of the proposed techniques.

I. NUMERICAL TECHNIQUES FOR ISA SYNTHESIS

Nowadays, a large amount of commercial PC cards are operating at 2.4 GHz and 5 GHz. Consequently, the compact dual-frequency antenna becomes a topical research subject in both academic researches and engineering applications. In this point of view, the Inverted-S Antenna (ISA) is a promising candidate since it can achieve an adjustable dual frequency with omnidirectional radiation patterns. In contrast to the inverted-F antenna (IFA), which is now widely used in handsets, ISA is a kind of micro-strip antennas with a centrally located parasitic element between a folded and feed element, originally developed in the early 1990's and patented in Australia [1] and USA [2]. In this smart configuration, the folded element connected to the ground line and the feed element connected to the feed produce an adjustable dual frequency and provide omnidirectional radiation patterns at two different frequency bands. Moreover, the element connected to ground determines the lower operating frequency, and the feed element the higher one. In addition, the two operating-frequencies of the antenna are found to have the same polarization plane and broadside radiation patterns. However, as a large number of objectives, decision parameters and considerable parameter tuning work are involved, as well as the field coupling between different elements is required to take into consideration in the synthesis of an ISA, the promising performances of an ISA can only be pursued when some specified robust synthesis methodologies are applied.

A. Mathematical Model

To design an ISA with desirable performances, apart from the minimization of the volume of the antenna, the goals of the optimization are proposed further to include: maximize the bandwidth of S_{11} and minimize the return loss at the two resonant frequencies. Such synthesis problem is a many-objective synthesis, which might result in dramatic deteriorations of the selective pressure when a vector genetic algorithm is employed. Therefore, it would be desirable if the objectives could be reduced without sacrificing the solution quality. In this point of view, the bandwidth and return loss

requirements for each resonant frequency are integrated into a new fitness function of the bandwidth of S_{11} . Mathematically, the proposed fitness functions are formulated as:

$$f_j = \sum_i^N [1 + \delta(f_i - f_{c_j})][S_{11}(f_i) - 10] (j=1,2) \quad (1)$$

where, f_{c_j} is a resonant frequency, i.e. 2.4GHz or 5GHz, $\delta(f - f_{c_j})$ is the Dirac function, N is the number of sweeping frequency points within 5% bandwidth of the resonant frequency.

By using this new defined fitness function, the fitness assignment mechanism will favour trying on different intermediate solutions when these solutions, other things being equal, have the same bandwidths, which will sustain the necessary diversity of the population in the optimization process.

After introducing the two new fitness functions f_j ($j=1,2$), the optimal goals of the synthesis of an ISA read as: minimize f_j ($j=1,2$) and the volume of the antenna.

B. An Improved Vector Optimizer

The Non-dominated Sorting Genetic Algorithm-II (NSGA-II) [3] is extended as the vector optimizer for solving the ISA synthesis in this paper. Since the penalty-parameterless constraint-handling approach of NSGA-II often gives unfeasible geometric parameters for finite element modeling, one introduced and incorporated some geometrical constraints into the optimal model. Moreover, these constraints are transformed into two linear constraints with preconditioned variable bounds, resulting in a simple randomly iterative sampling procedure in the numerical implementation. Finally, thanks to the success in the development of some specific intermediate recombination manipulator as the crossover operator, all the individuals generated are automatically met these linear constraints.

C. Field Computation and the Application of a Response Surface model

To consider the coupling effect of different elements, the finite element method is used to determine the performance parameters of an ISA. However, the heavy computational burdens of a considerable large number of total finite element analysis required by NSGA-II are unaffordable for some engineering applications. In this regard, the multiquadric radial basis function [4] based response surface model is extended and used. It should be pointed out when the number of sampling points employed is within certain limits, a small shape parameter is better in view of constructing the profile of the response surface. However, this will lead to inaccurate numerical results. Moreover, with the increase of sampling points, an ill-conditioned matrix will appear. To alleviate

these deficiencies, some regularization technique, or the introduction of smoothness parameter together with a stabilizing function, are proposed. In this regard, Engl's criterion to optimize the smoothness parameter is introduced, resulting in not only a more smoothed response surface, but also an improvement of the condition number for the interpolation matrix.

II. NUMERICAL EXAMPLE AND CONCLUSION

The proposed numerical techniques are employed to optimize a dual-frequency band inverted-S antenna operating at 2.4 GHz and 5 GHz. In the numerical experiments, the finite element method is used to determine the performance parameter of the antenna.

To start with, 800 sampling points are firstly generated and the performance parameters of these sampling points are determined by means of finite element analysis; and the improved multiquadric radial basis function is then used to reconstruct the optimal problem; finally, the NSGA-II is run on the reconstructed problem to efficiently find the Pareto optimal of the optimal problem. If no proper solutions are searched in the current iterative cycle, some sampling points are added and the aforementioned procedures are repeated until some good solutions are attainable. In the numerical implementation of NSGA-II, the size of population is set to 100, and the number of maximum generations is set to 1000.

The final Pareto solution searched by using the proposed methodology is shown in Fig. 1. To compare performances of the optimized configuration and the original design which is obtained by using a rule of thumb, of the ISA, a solution in the Pareto front as marked in red circle is selected and the details are tabulated in Table I. The corresponding curves for Parameter S_{11} are depicted in Figs.2~3. From these numerical results, it is obvious that the proposed methodology can find a set of best compromising solutions of a many-objective design problem in a single run. Moreover, the performance parameters for the selected specific solution are much better than those of the original design. Therefore, the paper provides not only robust synthesis technique for an ISA design, but also provide more freedoms for a decision maker to select a specific solution from these Pareto solutions according to his/her preferences.

Abstract—This work presents an alternative method of electromagnetic (EM) optimization applied to design frequency selective surfaces (FSSs) with Koch island patch elements and desired stop band filter specifications. The problem is addressed by means of the natural optimization algorithm based on particle swarm optimization (PSO). Multilayer perceptrons (MLP) artificial neural network (ANN) was trained for FSS modeling with the efficient resilient backpropagation (RPROP) algorithm. The resultant MLP model for FSS design was used for fast and accurate evaluation of cost function in PSO iterations. The results for one FSS design example are presented and the advantages of the PSO-ANN algorithm are discussed.

I. INTRODUCTION

The design of frequency selective surfaces using fractals was originally proposed in [1] through the use of space-filling properties of certain fractals, such as the Minkowski loop and the Hilbert curve, in order to reduce the overall size of the FSS elements. The self-similarity property of these fractals enables the design of multiband fractal elements or fractal screens [2]-[4].

This work investigates the use of periodic arrays of Koch island patch elements to design FSS stop band filters. In order to control the FSS resonant frequency and bandwidth we modify the metallic shape of Koch elements adjusting the fractal iteration-factor and iteration-number. A parametric analysis is accomplished through the use of the Ansoft Designer™ commercial software. To verify the simulations some FSS prototypes were fabricated and measured through a network analyzer (model N5230A, Agilent Technologies).

The obtained EM-dataset from full-wave parametric analysis of FSS filters was used for the training of the MLP model. The training dataset comprises 48 examples that correspond to the input parameter values: the substrate dielectric constant ($\epsilon_r = 2.2, 3.0, 4.0, 4.8, 6.15, 7.0$), iteration-factor ($a = 3, 4, 6, 9$) and iteration-number ($k = 1, 2$). The FSS filter resonant frequency (f_r) and bandwidth (BW) were defined as design output parameters.

The Koch FSSs were constructed from a conventional array of rectangular patch elements on a single substrate layer. The Koch island patch elements are illustrated in Fig. 1, where W , W_1 and W_2 are the width and L , L_1 and L_2 are the length of the patch at levels 0, 1 and 2, respectively. For the Koch island fractal initiator, we consider a rectangular patch printed on a FR-4 fiberglass substrate ($\epsilon_r = 4.4$, thickness = 1.5 mm), with

dimensions: $W = 4.93$ mm, $L = 8.22$ mm, $t_x = 8.22$ mm and $t_y = 12.32$ mm, resulting a resonance of 16.57 GHz.

Fig. 1. Periodic array of rectangular patch elements.

II. PARTICLE SWARM OPTIMIZATION

PSO is a natural algorithm inspired by the social behavior of animals, such as bird flocking or fish schooling. Each PSO swarm individual (or particle) moves about the cost surface with an individual velocity. The velocities and positions of the particles are updated based on the local and global best solutions [5]. A flow chart of the proposed PSO algorithm is shown in Fig. 2(a). The innovation is the introduction of the MLP model for PSO cost function evaluation. The used MLP network configuration is shown in Fig. 2(b). Only five hidden neurons were enough to solve the modeling learning-task with the RPROP training algorithm [6]. The outputs of the MLP model are computed by means of (1):

$$\mathbf{y} = \mathbf{V} \cdot \left[-1 \cdot \frac{1}{1 + \exp(-\mathbf{W} \cdot \mathbf{x})} \right] \quad (1)$$

where $\mathbf{x} = [-1, k, a, \epsilon_r]^T$ is the input vector, \mathbf{W} and \mathbf{V} are the MLP weight matrix, and $\mathbf{y} = [f_r, BW]^T$ is the output vector.

Given a Koch FSS filter desired specification ($f_{r,desired}$, $BW_{desired}$), the goal is the minimization of the quadratic cost function as defined in (2) in terms of absolute percent errors:

$$\text{cost}(n, m) = \left(\frac{f_{r,desired} - f_r(\epsilon_{rm}^n, a_m^n)}{f_{r,desired}} + \frac{|BW_{desired} - BW(\epsilon_{rm}^n, a_m^n)|}{BW_{desired}} \right)^2 \quad (2)$$

The integers n and m take into account the n -th particle at the m -th PSO iteration. The PSO algorithm updates the velocities and positions of the particles based on the local and global best solutions according to (3) and (4), respectively.

$$\mathbf{v}_n^{m+1} = C \left[r_0 \mathbf{v}_n^m + \Gamma_1 r_1 (\mathbf{p}_n^{localbest(m)} - \mathbf{p}_n^m) + \Gamma_2 r_2 (\mathbf{p}_n^{globalbest(m)} - \mathbf{p}_n^m) \right] \quad (3)$$

$$\mathbf{p}_n^{m+1} = \mathbf{p}_n^m + \mathbf{v}_n^{m+1} \quad (4)$$

Here, \mathbf{v}_n is the particle velocity, \mathbf{p}_n is the particle position, r_0 , r_1 and r_2 are independent uniform random numbers; Γ_1 is the cognitive parameter and Γ_2 is the social parameter, $\mathbf{p}_n^{localbest(m)}$ and $\mathbf{p}_n^{globalbest(m)}$ is the best local and global solution, respectively and C is the constriction parameter.

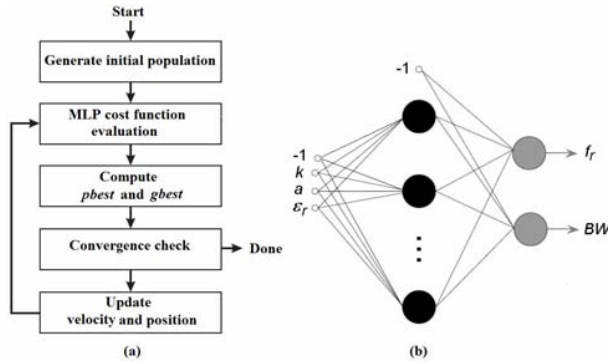

Fig. 2. (a) Flow chart of PSO-ANN algorithm; (b) MLP configuration.

III. RESULTS AND DISCUSSION

In the design example presented in this section we tested PSO-ANN algorithm implementation with the input/output parameters: $\epsilon_r = 4.4$, $k = 2$, $a = 5$, $f_r = 10$ GHz and $BW = 2.1$ GHz. Fig. 3 shows the cost surface contours, the initial, intermediate and final swarms, as well as the best path obtained from the PSO-ANN simulations, which converges for the optimal solution: $\epsilon_r = 4.4$ and $a = 5$. Fig. 4 shows the evolution of the average cost and best global cost for the PSO swarm. It is observed that the best-fit individual of the PSO final swarm converges to the global minimum of the cost function given in (1) and the algorithm is limited in precision to the round off error of the computer. Fig. 5 presents a comparison between the simulated and measured results for the transmission coefficient (in dB) of the Koch fractal FSS used as design example. A good agreement can be verified between simulated and measured data.

IV. CONCLUSION

The PSO-ANN algorithm showed to be faster and easier to implement as a global design tool in synthesizing FSS structures. These technique main advantages are related to its great flexibility of application in structures that do not have an explicit analytical cost function. It also presents a very low time processing, which is a very desired characteristic.

Abstract—The accuracy of the NS-FDTD method is dependent on the coefficients of the finite difference (FD) operators, however, they have not been derived analytically for rectangular cells. It is therefore necessary to obtain the coefficients numerically such that the phase velocity error is minimized, as we have previously reported. However, the calculation cost is very expensive. In this paper, we propose a new method to obtain the coefficients with a far lower computational cost. It is shown that the method reduces the computational time to 1/360 or less compared to the previous one.

I. INTRODUCTION

The NS-FDTD method is a time-domain analysis technique for electromagnetic waves with a fixed frequency [1]-[3]. A superior feature of the NS-FDTD method is the high accuracy based on the excellent isotropy. The quality of the isotropy is dependent on the coefficients α_v , where the special FD operators [1] with opposite anisotropic phase velocity errors are combined. Therefore, obtaining proper α_v for the best error cancellation is very important to guarantee the high accuracy of the NS-FDTD method. Analytical expressions for α_v for cubic cells have been given [1], but the α_v for rectangular cells have not yet been presented. Previously, we reported a method to obtain α_v numerically in a rectangular cell [3]. However, the method employs a stable, but an inefficient direct search technique, so the calculation cost may be more expensive than the NS-FDTD calculation itself in three-dimensions.

In this paper, we propose a semi-analytical method to obtain α_v with a low computational cost in three dimensions. Our proposed method can reduce the computation time to 1/360 or less compared with the previous method [3].

II. PRESENT METHOD

We consider the normalized FD Laplacian in the NS-FDTD, $[\sum_{\zeta} d_{\zeta}^{(1)} d_{\zeta}^{(0)} \psi / s_k^2(\Delta_{\zeta})] / (k^2 \psi)$, where $d_{\zeta}^{(0)} = \sum_{v=1,2,3} \alpha_v d_{\zeta}^{(v)}$ is the special FD operators [1], Δ_{ζ} the spatial increments, $s_k(\Delta_{\zeta}) = 2 \sin(k \Delta_{\zeta} / 2) / k$, and $\psi = e^{\pm i k \cdot r}$ with k the physical wavenumber and r the position. If we assume that the 3D normalized FD Laplacians correspond to the 2D normalized FD Laplacians on (Δ_x, Δ_y) , (Δ_x, Δ_z) and (Δ_y, Δ_z) for $\theta = \pi/2$, $\phi = 0$ and $\phi = \pi/2$, respectively, it yields the relations

$$\left(\frac{\sin(k_{\xi} \Delta_{\xi} / 2)}{\sin(k \Delta_{\xi} / 2)} \right)^2 \left[\alpha_1 + \alpha_2 \cos k_{\zeta} \Delta_{\zeta} + \frac{\alpha_3}{2} (\cos k_{\zeta} \Delta_{\zeta} + 1) \right] \Bigg|_{3D} = \left(\frac{\sin(k_{\xi} \Delta_{\xi} / 2)}{\sin(k \Delta_{\xi} / 2)} \right)^2 \left[\alpha_0 + (1 - \alpha_0) \cos k_{\zeta} \Delta_{\zeta} \right] \Bigg|_{2D}, \quad (1)$$

where $\xi, \zeta = x, y, z$ and $\xi \neq \zeta$. From (1), we can obtain the following relations by the definition $\alpha_1 + \alpha_2 + \alpha_3 = 1$ [1]:

$$\alpha_2 = 1 - 2\alpha_0 + \alpha_1, \quad \alpha_3 = 2(\alpha_0 - \alpha_1). \quad (2)$$

Using the relations (2), it is only necessary to determine α_1 in three dimensions, although the two-dimensional coefficient α_0 should be obtained according to [3] prior to the calculation. Next, using (2), we define the error in the normalized FD Laplacian as

$$\varepsilon(\theta, \phi) = 1 - \sum_{\eta, \xi, \zeta} \left(\frac{\sin(k_{\eta} \Delta_{\eta} / 2)}{\sin(k \Delta_{\eta} / 2)} \right)^2 \left[\alpha_1 + (1 - 2\alpha_0 + \alpha_1) \cos k_{\xi} \Delta_{\xi} \cos k_{\zeta} \Delta_{\zeta} + (\alpha_0 - \alpha_1) (\cos k_{\xi} \Delta_{\xi} + \cos k_{\zeta} \Delta_{\zeta}) \right], \quad (3)$$

where $\eta, \xi, \zeta = x, y, z$ and $\eta \neq \xi \neq \zeta$. Using (3), the $\alpha_1(\theta, \phi)$ in the semi-analytical solution that satisfies $\varepsilon(\theta, \phi) = 0$ is given by

$$\alpha_1(\theta, \phi) = \left[1 - \sum_{\eta, \xi, \zeta} \left(\frac{\sin(k_{\eta} \Delta_{\eta} / 2)}{\sin(k \Delta_{\eta} / 2)} \right)^2 \left[(1 - 2\alpha_0) \cos k_{\xi} \Delta_{\xi} \cos k_{\zeta} \Delta_{\zeta} + \alpha_0 (\cos k_{\xi} \Delta_{\xi} + \cos k_{\zeta} \Delta_{\zeta}) \right] / \left[\sum_{\eta, \xi, \zeta} \left(\frac{\sin(k_{\eta} \Delta_{\eta} / 2)}{\sin(k \Delta_{\eta} / 2)} \right)^2 (1 + \cos k_{\xi} \Delta_{\xi} \cos k_{\zeta} \Delta_{\zeta} - \cos k_{\xi} \Delta_{\xi} - \cos k_{\zeta} \Delta_{\zeta}) \right] \right]. \quad (4)$$

Here, we define the average error for $\alpha_1(\theta, \phi)$ by

$$\varepsilon^{Average}(\alpha_1(\theta, \phi)) = \left(\frac{2}{\pi} \right)^2 \int_{\theta'=0}^{\pi/2} \int_{\phi'=0}^{\pi/2} |\varepsilon(\theta', \phi', \alpha_1(\theta, \phi))| d\theta' d\phi', \quad (5)$$

where $\varepsilon(\theta', \phi', \alpha_1(\theta, \phi))$ is given by equation (3) but with $\alpha_1(\theta, \phi)$ instead of α_1 . In our proposed method, we select the $\alpha_1(\theta, \phi)$ which minimizes the average error (5) as the coefficient α_1 . Our proposed algorithm is shown in Fig. 1.

III. NUMERICAL VERIFICATION

Using the algorithm shown in Fig. 1, α_1 coefficients were obtained for various rectangular cells, as shown in Table I.

Here, λ is the wavelength. In the calculations, the angular steps, $\Delta\theta$ and $\Delta\phi$, were set to 1° , so the number of calculation loops was $3 \times 91 \times 91$. The calculation time was 7 seconds on an Intel Core 2 Duo processor (2.4 GHz) and is independent of N , the number of significant digits of α_v . In the previous method, the computational cost is proportional to $10^{2N} \times 91 \times 91$ for $\alpha_{v=1,2}$ and it took 42 minutes to obtain α_v .

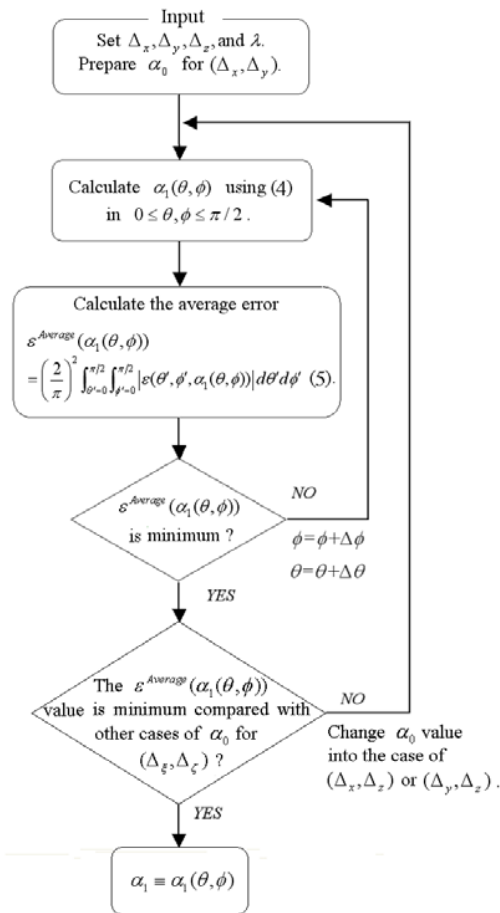

Fig. 1. Search algorithm for α_1 in three dimensions. To obtain the best α_1 , 2D coefficient α_0 that gives minimum value of $\epsilon^{Average}(\alpha_1(\theta, \phi))$ from three cases of (Δ_x, Δ_y) , (Δ_x, Δ_z) , and (Δ_y, Δ_z) is selected at the 2nd decision part.

for $N=4$, i.e. the cost was 360 times. We found that $N=6$ was necessary to maintain the high accuracy of the NS-FDTD, so the computational time becomes 42×10^4 minutes for the previous method. Note that the computing time to derive α_0 is negligible in Fig. 1. Thus our new method can reduce the calculation time dramatically.

Fig. 2 shows the minimum and maximum values of the normalized numerical phase velocity c_n/c_0 obtained from the numerical dispersion equation [3] for propagation angle θ , where the cell size is $(\Delta_x = \lambda/10, \Delta_y = \lambda/20, \Delta_z = \lambda/40)$ as an example. For comparison the results are shown when the coefficients $\alpha_{1,2,3}$ are obtained using the previous method [3]

and $\alpha_{1,2,3}$ for cubic cells [1], [2] are used. It is clear that the NS-FDTD has high accuracy and isotropy when our coefficient α_1 is used, as was also the case with the previous method. Consequently, the validity of our proposed method for α_v has been verified.

TABLE I
 α_1 IN THREE DIMENSIONS

Δ_x	Δ_y	Δ_z	α_1
$\lambda/10$	$\lambda/10$	$\lambda/10$	0.707742 ($\alpha_0 = 0.831119$)
$\lambda/10$	$\lambda/10$	$\lambda/20$	0.686118 ($\alpha_0 = 0.831119$)
$\lambda/10$	$\lambda/20$	$\lambda/30$	0.756030 ($\alpha_0 = 0.830203$)
$\lambda/10$	$\lambda/20$	$\lambda/40$	0.733334 ($\alpha_0 = 0.830203$)

Fig. 2 Minimum and maximum values of the normalized numerical phase velocity c_n/c_0 versus propagation angle θ in $0 \leq \phi \leq 90^\circ$ range. The subscript “cubic” means $\alpha_{1,2,3}$ of cubic cell was used [1], [2], “previous” means $\alpha_{1,2,3}$ of the previous method [3] was used. c_0 is the physical phase velocity.

IV. CONCLUSION

We have proposed an efficient method to obtain the coefficients α_v of the finite difference operators for the rectangular cell NS-FDTD method. As a result, our method reduces the computing time dramatically for obtaining the three-dimensional α_v while maintaining the accuracy of the NS-FDTD.

Abstract — In Radio Frequency Identification (RFID), the design and investigation of UHF circular loop antennas used as reader antennas as well as tag antennas is of growing importance. Since these antennas are electrically short, a 2D FEM analysis using a single-component magnetic vector potential together with PML's at the boundary is proposed in this paper in order to perform very fast and accurate axisymmetric simulations compared with very time consuming 3D calculations. In addition, the capacitances of the tag loops have been calculated using a 3D quasi-static electric approach taking the gap of the loops into account.

I. INTRODUCTION

UHF-RFID systems [1] consisting of a reader and one or more tag antennas are working at frequencies of about 1 GHz. In case of axisymmetric reader loops, tag loops and objects to be identified, a 2D axisymmetric FEM analysis using a one component magnetic vector potential and Perfectly Matched Layers (PML's) at the boundary can be used with advantage (high accuracy combined with minimal computational effort compared with 3D solutions [2]). However, the axisymmetric assumption is only valid, if the loops are small enough compared with the wavelength (electrically short).

In Fig. 1, the half model of a tag loop is shown. It consists of a loop with a gap where the IC is placed. The loop is on the surface of a substrate. Typical parameters of such a tag loop made of copper are a mean radius of 9mm, a cross section of 500 x 35µm and a substrate permittivity of 4. The thickness of the substrate is assumed to be 0.6mm. The gap width is taken to be 400µm and is neglected in case of solving the wave equations but not for calculating the capacitances.

Fig. 1. Half model of a circular tag loop. Gap in the axisymmetric solution neglected

Reader loops are built similarly. Due to their larger radius

(radius = 40 mm in the example), they have several gaps equally spaced along the circumference, whereby appropriate lumped capacitances are connected to the gaps in order to provide a constant current along the loop.

II. FORMULATIONS

Wave propagation phenomena can be described by Maxwell's equations using a magnetic vector potential \mathbf{A} and an electric scalar potential v (\mathbf{A}, v formulation). The field quantities \mathbf{E} and \mathbf{B} and the governing differential equations using a complex conductivity σ_c are then given by:

$$\mathbf{B} = \text{curl} \mathbf{A} \quad \text{and} \quad \mathbf{E} = -j\omega(\mathbf{A} + \text{grad} v) \quad (1)$$

$$\text{curl}(v \text{curl} \mathbf{A}) + j\omega\sigma_c \mathbf{A} + j\omega\sigma_c \text{grad} v = \mathbf{0} \quad (2)$$

$$-\text{div}(j\omega\sigma_c \mathbf{A} + j\omega\sigma_c \text{grad} v) = 0 \quad (3)$$

together with the appropriate boundary conditions.

In the axisymmetric case, (2) and (3) reduce to

$$\frac{\partial}{\partial r} \left(v \frac{\partial r A}{\partial r} \right) + \frac{\partial}{\partial z} \left(v \frac{\partial A}{\partial z} \right) - j\omega\sigma_c A = -\sigma_c \frac{U_e}{2\pi r}, \quad (4)$$

where U_e is the impressed voltage per loop.

Applying the superposition principle yields the admittance matrix \mathbf{Y} of the loop system. To get the matrix, as many calculations as there are loops in the system must be performed. Using a direct solver, only multiple right hand sides have to be taken into account. The loops can be voltage or current driven a fact that can be taken into account with the aid of the expression

$$\mathbf{I} = \mathbf{Y} \mathbf{U}, \quad (5)$$

where \mathbf{I} and \mathbf{U} are the vectors of the loop currents and voltages, respectively.

The capacitances of the tag loops are neglected in the axisymmetric model. They can be taken into account by additional 3D quasi-static electric field calculations. The differential equation for these analyses is

$$\text{div } \sigma_c \text{ grad} V = 0 \quad (6)$$

together with the appropriate boundary conditions. The loops are excited in the gap by a given voltage. The capacitance of the loops can be obtained from the electric energy. The capacitances thus computed can be used to update the admittance matrix \mathbf{Y} . This quasi-static approach is possible, since the dimension of the tag loops (radius = 10mm) is small compared with the wavelength of 300mm at 1GHz.

III. EXAMPLES

To verify the method, a circular loop antenna with a mean radius of 9.625mm with rectangular cross section of 0.25 x 0.25mm (conductivity = $5.7 \cdot 10^7$ S/m) has been analyzed at a frequency of 1GHz. By integration of the Poynting vector over a closed surface, a radiation resistance of 0.3273 Ω results. The analytical result for a circular filament loop with a radius of 9.625mm given by

$$R_r = \frac{2}{3} \pi \eta \left(\frac{2\pi^3 r^2}{\lambda^2} \right)^2 \quad (7)$$

is 0.3257 Ω showing an excellent agreement. In addition, the eddy current losses in the loop result in an AC resistance of 0.6267 Ω which is almost two times higher than the radiation resistance.

In the example shown in Fig. 2, the loop system consists of a reader and a stack of two close coupled tag loops (10mm distance) at a distance of 70mm from the reader. The reader is driven by 1V. The tag loops are terminated by $Z_1 = 50\Omega$ and $Z_2 = 50\Omega$. From the admittance matrix and with $U_1 = Z_1 I_1$ and $U_2 = Z_2 I_2$, the currents in the tag loops and in the reader can be obtained from (5).

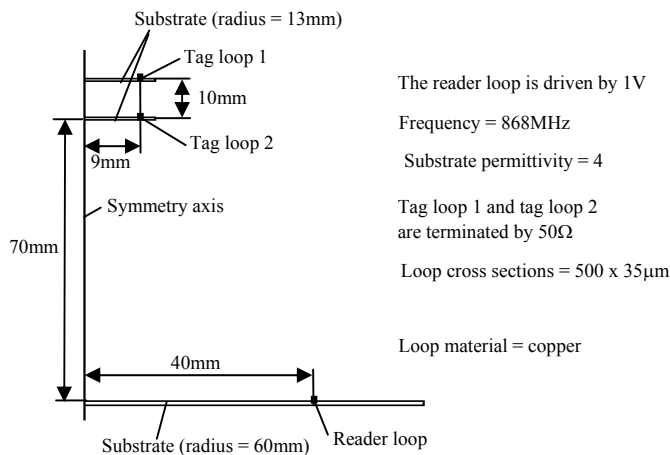

Fig. 2. System of a reader loop and two close coupled tag loops. Up to 100 tag loops can be stacked in special arrangements.

The results are shown in Table 1. The currents and the phases in the tag loops are quite the same. In this example, the

capacitances of the tag loops are not taken into account. They can be considered by updating Z_1 and Z_2 .

TABLE I
CURRENTS IN THE READER AND TAG LOOPS

	Current (μ A)	Phase (deg)
Tag-loop 1	8.316	46.37
Tag-loop 2	10.94	53.41
Reader	692.1	-88.06

The capacitances of the tag loops can be calculated using the quasi-static electric approach solving equation (6). In Fig. 3, the potential distribution is shown at the surface of a single loop and at the surface of the substrate.

Fig.3. Single tag loop: $C = 0.138$ pF (without substrate: $C = 0.0661$ pF).

The capacitance obtained from the 3D quasi static electric field calculation is 0.138pF and the inductance from the axisymmetric approximation is 47nH.

For comparison, the 3D full wave solution for the single loop at $f = 868$ MHz results in $C = 0.135$ pF and $L = 47.3$ nH.

In the second case (Fig. 4), a close coupled tag loop system (distance = 1.54mm) is shown. In this case the lower loop is driven and the upper loop is at floating potential. The capacitance is more than twice as high as that of the single loop without substrate.

Fig. 4. Stack of two close coupled tag loops. The distance of the loops is 1.54mm. The lower loop is driven. $C = 0.159$ pF

Abstract— This paper describes large-scale full wave analyses of electromagnetic fields by the finite element method with an iterative domain decomposition method. A stationary Helmholtz equation for the high-frequency electromagnetic field analyses is solved taking an electric field as unknown functions. Then, to solve subdomains by the direct method, the direct method based on the LDL^T decomposition method is introduced in subdomains. If the direct method is applied for solving subdomain problems, the computation time seems to be reduced by the improved accuracy of subdomain problems, and storing matrices that are results of the decomposition on main memory.

I. INTRODUCTION

The finite element method has been used to solve the Helmholtz equations in high-frequency electromagnetic problems, resulting in solving large-scale systems of simultaneous linear equations. Dealing with such large-scale problems is a crucial issue in solving system of equations derived from finite element discretization of the Helmholtz equations in high-frequency electromagnetic problems[1]. Currently, we are conducting research on large-scale finite element analyses for electromagnetic fields in the range of several MHz to several GHz by using parallelization techniques based on the iterative domain decomposition method (IDDM). The IDDM based on the conjugate orthogonal conjugate gradient (COCG) method is applied to solve the interface problem. Previously, an iterative method was applied to the subdomain problem. However, the convergence property of the interface problem was not good in solving large-scale problems of over 10 million complex DOFs. In this study, the direct method based on the LDL^T decomposition method is applied to the subdomain problem. In this paper, we provide the numerical examples of about 50 million complex DOFs based on the formulation of the E Method[2].

II. FINITE ELEMENT FORMULATION

Let Ω be a domain with the boundary $\partial\Omega$. The Helmholtz equations which describe an electromagnetic field with single angular frequency ω [rad/s] are drawn from Maxwell's equations containing the displacement current. The Helmholtz equations describing an electric field \mathbf{E} [V/m] are given by (1a) and (1b) below, using the current density \mathbf{J} [A/m²] and the electric field \mathbf{E} , and assigning j as an imaginary unit:

$$\text{rot}(\frac{1}{\mu} \text{rot} \mathbf{E}) - \omega^2 \varepsilon \mathbf{E} = j\omega \mathbf{J} \quad \text{in } \Omega \quad (1a)$$

$$\mathbf{E} \times \mathbf{n} = \mathbf{0} \quad \text{on } \partial\Omega \quad (1b)$$

$$\mathbf{J} = \sigma \hat{\mathbf{E}} \quad (1c)$$

Permittivity and permeability are given by ε [F/m] and μ [H/m], respectively. In this formulation, permittivity becomes complex permittivity $\varepsilon = \varepsilon' + \sigma/j$. The electric field \mathbf{E} on known points is substituted into (1a) by equation (1c), where the electrical conductivity is denoted as σ . By solving equation (1a), with imposing the boundary condition of (1b), we calculate the electric field \mathbf{E} . The magnetic field \mathbf{H} is then calculated from the electric field \mathbf{E} by post-processing using equation (2) below, which is one of Maxwell's equations[2].

$$\text{rot} \mathbf{E} - j\omega \mu_0 \mu_r \mathbf{H} = \mathbf{0} \quad (2)$$

Finally, we assume that

$$\text{div} \mathbf{J} = 0 \quad \text{in } \Omega \quad (3)$$

Next, we describe the finite element discretization. The electric field \mathbf{E} is approximated with Nedelec elements (edge elements)[3]. The finite element approximation is performed as follows.

Find \mathbf{E}_h such that

$$(\frac{1}{\mu} \text{rot} \mathbf{E}_h, \text{rot} \mathbf{E}_h^*) - \omega^2 (\varepsilon \mathbf{E}_h, \mathbf{E}_h^*) = j\omega (\mathbf{J}_h, \mathbf{E}_h^*) \quad (4)$$

where (\cdot, \cdot) denotes the complex valued L^2 -inner product. Here, \mathbf{J}_h is a corrected electric current density with consideration of the continuity[4].

III. ITERATIVE DOMAIN DECOMPOSITION METHOD

We introduce the IDDM to high-frequency problems using the E method. Let us put the finite element equations of (4) in matrix form, as follows:

$$Ku = f \quad (5)$$

where K denotes the coefficient matrix, u the unknown vector, and f the known right-hand side vector. The domain Ω is partitioned into non-overlapping subdomains. Then the linear system (5) is rewritten as follows:

$$\begin{bmatrix} K_I^{(1)} & \cdots & 0 & K_{IB}^{(1)} R_B^{(1)T} \\ 0 & \ddots & \vdots & \vdots \\ 0 & \cdots & K_I^{(N)} & K_{IB}^{(N)} R_B^{(N)T} \\ R_B^{(1)} K_{IB}^{(1)T} & \cdots & R_B^{(N)} K_{IB}^{(N)T} & \sum_{i=1}^N R_B^{(i)} K_{BB}^{(i)} R_B^{(i)T} \end{bmatrix} \begin{bmatrix} u_I^{(1)} \\ \vdots \\ u_I^{(N)} \\ u_B \end{bmatrix} = \begin{bmatrix} f_I^{(1)} \\ \vdots \\ f_I^{(N)} \\ f_B \end{bmatrix} \quad (6)$$

where subscripts I, B correspond to nodal points in the interior of the subdomains and on the interface boundary, respectively. Here, $R_B^{(i)T}$ represents the internal DOFs $u_B^{(i)}$ of subdomain $\Omega^{(i)}$ about u_B . It is a 0-1 procession to restrict.

At first, the unknown vector u_B is obtained from the application of the COCG method. After solving u_B , the vector $u_I^{(i)}$ is solved by the direct method with the LDL^T decomposition method, and can also be solved independently in each subdomain. Hence, we can get the unknown in the

whole domain[2][4]. The IDDM is implemented in a parallel computing environment using the hierarchical domain decomposition method (HDDM). In this paper, we use P-mode that is one of the parallel data handling types of HDDM, see [2] and [4].

IV. NUMERICAL EXAMPLES

A reentrant resonator model is used to verify the accuracy and performance of the parallel computation, of our proposed method. It is one of the benchmark problems defined as TEAM (Testing Electromagnetic Analysis Method) Workshop Problem 29[5]. The verification is performed on three kinds of meshes, as described in Table I. Mesh(1)-(4) are divided into first-order tetrahedral Nedelec elements.

TABLE I
MESHES FOR VERIFICATIONS

Mesh	Element	DOF	Num. of Subdomain
(1)	108,787	134,889	60 x 11
(2)	5,043,711	6,792,202	60 x 494
(3)	17,367,244	23,213,252	60 x 1,703
(4)	40,349,688	54,236,667	60 x 3,956

A. Accuracy Verification

Accuracy verification is performed using Mesh (1). To detect the resonant frequency and to compare solutions with actual measurements, the resonance state is investigated. The frequency band of 60 [MHz]-140 [MHz] is calculated for 2 [MHz] steps, and the response for every frequency step is investigated. All calculations are performed on a 15-node (60-core) PC cluster with Core2Quad Q6600 (2.40 GHz / L2 8 MB) and 8 GB RAM. A comparison between the measured resonant frequencies and the solutions obtained by the FDTD method in each mode is shown in Table II. The obtained solutions are in very good agreement. The maximum error rate between the obtained solution and the measurement is 4.96% in the 1st mode. As the mode becomes higher, the error rate decreases. The same tendency is shown in the comparison of the error rate with solution of the FDTD method. Therefore, it is proved that the solution obtained by the proposed method has sufficiently high accuracy.

TABLE II
RESONANT FREQUENCIES IN MHz ((): ERROR RATE BETWEEN MEASURED DATA AND NUMERICAL SOLUTIONS [%])

Mode	Measured ^(s)	FDTD ^(s) 25mm mesh	Result
1 st	68.6	67 (2.33)	65.2 (4.96)
2 nd	110	110	109 (0.91)
3 rd	134	134	134

B. Performance Verification

Performance verification by large-scale computation using Mesh (2)-(4) is described next. In the analyses, the 1st mode (65.2 [MHz]) frequency is analyzed. Other calculation conditions are the same as those for Mesh (1). Average CPU time and average memory requirements are shown in Table III. For Mesh (2) solving with the direct method based on the LDL^T decomposition method to the subdomain problem, the CPU time is reduced by 56% as compared to that of the incomplete Cholesky conjugate orthogonal conjugate gradient (ICCOCG) method to the subdomain problem. For Mesh (3)

and (4), solving with the ICCOCG method to the subdomain problem does not converge, but the direct method successfully converges to compute a result. Although the direct method uses approximately 40% more memory, the total amount used exceeds 65% of the available RAM, even for Mesh (4). Therefore, we do not consider memory usage to be a problem. The residual norm convergence history of COCG iterations in the interface problem is shown in Fig. 1. In the calculations with Mesh (4), we can see the convergence behavior of the ICCOCG method to the subdomain problem. Here the interface problem does not converge even after 40,000 iterations. In contrast, by the direct method, convergence is achieved after 29,235 iterations with a calculation time of 20.7 [h]. Those results confirm the superiority of the direct method to the subdomain problem in large-scale computations. It is also demonstrated that the proposed method using a direct method for subdomain problems is able to solved high-frequency electromagnetic field problems of more than 50 million complex DOFs.

TABLE III
CPU TIME AND MEMORY REQUIREMENTS FOR EACH MESH

	Solver for Subdomains	Iteration counts	CPU time[h]	Memory size [M Byte]
Mesh(2)	LDL^T	5,625	0.8	83
	ICCOCG	6,532	1.8	59
Mesh(3)	LDL^T	8,513	3.0	294
	ICCOCG	—	—	—
Mesh(4)	LDL^T	29,235	20.7	683
	ICCOCG	—	—	—

A New Waveguide Design Based in Thin Films of Niobium and Tantalum

Marcílio Nunes Freire and José Patrocínio da Silva
Environmental Science Department, UFERSA, Mossoró/RN, 59624-900, Brazil
patroc@ufersa.edu.br, nunesfreire@ufersa.edu.br

Abstract — Results of a simplified experimental apparatus used to obtain *in situ* optoelectrochemical measurements of the anodizing voltage versus time versus especular reflectance are used to design a new type of waveguide. The application of experiment was used to determine the thickness and refractive index (for wave-length of 0.6329 μm) of the waveguide. The proposed structure exhibits a simple geometry, and has been analyzed through a vectorial finite element BBP, FE-VBPM.

Keywords — Numerical Techniques, Waveguide, Thin Films.

I. INTRODUCTION

It's well known that thin films of niobium and tantalum pentoxides and its mixed oxides $(Nb,Ta)_2O_5$ can be grown anodically on the surface of metals, Nb, Ta and its alloys Nb-Ta, by placing samples in an electrochemical cell containing aqueous solution and three electrodes under a suitable anodic voltage. The anodizing process occurs under direct current until the applied voltage is no more sufficient to produce it. These films exhibit several colors depending upon the thickness [1, 2]. The anodic oxide films grown on the substrate surface of niobium and tantalum and its alloys may be applied as electronic devices just as: store condenser of random access memory [3], gate in transistors [4], electronic holes [5], electroluminescent panels [6], pH and humidity sensors [7], and optical waveguide [8]. The anodic oxide films have accepted attention in last decades due its good dielectric properties. These films constitute the proposed structure that is formed by one fine layer of $(Nb20\%wTa)_2O_5$ on a niobium pentoxide substrate as showed in Fig. 1. The new waveguide proposed has been analyzed by efficient vectorial finite element method [9].

Fig. 1. Rib waveguide

II. FINITE ELEMENT FORMULATION

We start from the second order vectorial Helmholtz equation in two dimensions, including the perfectly matching layers in order to avoid reflections,

$$\nabla \times \left(\bar{\bar{k}} \nabla \times \bar{H} \right) - k_0^2 \bar{H} = 0 \quad (1)$$

where, $\bar{\bar{k}} = 1/\bar{\bar{\epsilon}}$, with $\bar{\bar{\epsilon}}$ being the relative permmissivity tensor. Considering the dielectric media with transverse anisotropy, and defining the \hat{u}_x , \hat{u}_y and \hat{u}_z associated with x, y, and z

directions, respectively, $\bar{\bar{\epsilon}}$ can be written as $\bar{\bar{\epsilon}} = \epsilon_{xx}\hat{u}_x\hat{u}_x + \epsilon_{xy}\hat{u}_x\hat{u}_y + \epsilon_{yx}\hat{u}_y\hat{u}_x + \epsilon_{yy}\hat{u}_y\hat{u}_y + \epsilon_{zz}\hat{u}_z\hat{u}_z$. After some algebraic manipulations and assuming that the media and fields vary very slowly along the propagation coordinate [10]-[11], the equation (1) can be written as:

$$\begin{aligned} \bar{k}_a \frac{\partial^2 \bar{h}_T}{\partial z^2} - 2\gamma \bar{k}_a - \bar{k}_b \nabla_T (\nabla_T \cdot \bar{h}_T) - \nabla_T \times \bar{k}_{zz} \nabla_T \times \bar{h}_T \\ + (\bar{k}_c + \gamma^2 \bar{k}_a) \bar{h}_T = 0 \end{aligned} \quad (2)$$

Consequently the transverse tensors in (1) are defined as,

$$\bar{k}_a = \begin{bmatrix} k_{yy} & -k_{yx} \\ -k_{xy} & k_{xx} \end{bmatrix} \quad (2a)$$

$$\bar{k}_b = \gamma^{-1} \frac{\partial \bar{k}_a}{\partial z} - \bar{k}_a \quad (2b)$$

$$\bar{k}_c = k_0 - \gamma^{-1} \frac{\partial \bar{k}_a}{\partial z} \quad (2c)$$

$$\nabla_T = \hat{u}_x \alpha_x \frac{\partial}{\partial x} + \hat{u}_y \alpha_y \frac{\partial}{\partial y} \quad (2d)$$

where α_x , and α_y are parameters linked to the PML or virtual loss media. Since the waves are assumed to propagate along the z direction, the parameters α_x , and α_y have to be determined in such a way that the wave impedance is continuous across the interfaces formed between the inner computational domain and the PML. This ensures perfect wave matching over such interfaces, allowing the undesired radiation to leave the effective computational domain freely without any reflection. The PML parameters are specified from the parameter S given by $S = 1 - j(3c/2\omega_0 nd)(\rho/d)^2 \ln(1/R)$ [9], where ω_0 is the angular frequency, d is the thickness of the PML, n is the refraction index of the adjacent medium, ρ is the distance from inner PML's interface, R is the reflection coefficient, and c is the free-space speed of light.

Applying the conventional finite element method to the transverse variation of (2), the following differential equation is obtained:

$$[M] \frac{\partial^2 \{\bar{h}_r\}}{\partial z^2} - 2\gamma[M] \frac{\partial \{\bar{h}_r\}}{\partial z} + ([K] + \gamma^2[M]) \{\bar{h}_r\} = \{0\} \quad (3)$$

where $\{\bar{h}_r\}$ represents a column vector containing the unknowns hxj and hyj , $\{0\}$ is the null column vector, and $[M]$ and $[K]$ are the so-called global matrices, defined in [9]. Applying the Padé (1,1) approximation [9], to (4) the matrix equation given below is obtained,

$$[\tilde{M}] \frac{d\{\bar{h}_r\}}{dz} + [K]\{\bar{h}_r\} = \{0\} \quad (4)$$

with, $[\tilde{M}] = [M] - \frac{1}{4\gamma^2}([K] + \gamma^2[M])$.

III. NUMERICAL RESULTS

The results of a simplified experimental apparatus used to obtain in situ optoelectrochemical measurements of the anodizing voltage versus time versus specular reflectance, while the oxide films were growing by galvanostatic anodizing, has been used to design a new waveguide type. The results of the experiment were used to determine the thickness and refractive index (for wave-length of 0.6329 μm) of the films. The Table I shows that characterization of experiment to obtain the refractive indexes.

TABLE I
REFRACTIVE INDEX AND THICKNESS OF ANODIC OXIDE FILMS
GROWN IN *Nb* AND *Nb-Ta* SUBSTRATE

Material	Thickness (\AA)	Wavelength (μm)	Refractive index
<i>Nb₂O₅</i>	2.025 ± 64	0.6329	2.02 ± 0.06
<i>Nb20%wTa</i>	1.652 ± 32	0.6329	2.64 ± 0.05

In order to confirm the application of the FE-VBPM for analysis of the waveguide shown in Fig. 1, we consider $n_s = 2.02$, $n_g = 2.64$, $L = 500 \mu\text{m}$, $t = 0.1 \mu\text{m}$, $w = 1.4 \mu\text{m}$ and $h = 0.85 \mu\text{m}$. The substrate thickness was 3.5 μm and the computational domain considered was 9 μm (x direction) x 9 μm (y direction) surrounded by PML's with thickness $d = 1 \mu\text{m}$ covered by 12,000 linear elements with a propagation step size $\Delta z = 0.1 \mu\text{m}$. The structure was excited with one gaussian beam, given by $h_y = A \exp(-x^2 + y^2)/2\sigma$, where A is the amplitude of the beam and σ is the spot beam. The wavelength considered was $\lambda = 0.6329 \mu\text{m}$. Fig. 2 shows magnetic-field distributions of the y -polarized guide, Fig.2a shows the y -component of magnetic field launched in the structure, Fig. 2b shows the y -component of magnetic field after 500 μm propagated.

Fig. 2. Magnetic-field distributions of the y -polarized mode rib waveguide for (a) $z = 0 \mu\text{m}$, (b) $500 \mu\text{m}$.

Fig. 2. Reference refractive index variation along the propagation distance

Fig. 3 shows the convergence of the reference refractive index along the propagation direction in comparison with the results obtained using the modal analysis [10]. The loss in the waveguide after 1.0 km of the propagation is around 2.56×10^{-16} dB. This value has been obtained through of the subtraction between the maximum value of the magnetic field after 1.0 km of propagation and the maximum value of the magnetic field obtained through the modal analysis.

IV. CONCLUSIONS

A vectorial finite-element BPM for transverse anisotropic media was applied successfully to the analysis of a rib waveguide constituted by *Nb* and alloy of *Nb-Ta*. The refractive indexes used for constitute the waveguide was obtained thought experiments using anodic oxide films grown on *Nb* and alloy of *Nb-Ta* substrates by *in situ* monitoring. The resulting structure has a simple geometry and its optimization by using genetic algorithms is under consideration for applications in Passive Polarization Converter.

Abstract — Numerical and experimental investigations are presented for a dual-band frequency selective surface (FSS) with perfectly conducting rectangular patch elements. The work was developed in two steps. In the first step two single-band FSS screens were designed to obtain resonant frequencies at 9.5 GHz and 10.5 GHz, each one with about 1.5 GHz bandwidth. In the second step these single FSS screens were cascaded and separated by an air gap layer to achieve a dual-band response. The Moment Method is used to analyze the structures single band. After this, a numerical cascading technique is used to analyze the effect of the air gap between the cascading structures.

I. INTRODUCTION

Recently, we can observe an increasing demand on the multifunctional antennas for communication that requires the development of FSS with multi-band characteristics [1]. The use of frequency selective surfaces (FSS) has been successfully proven as a mean to increase the communication capabilities of satellite platforms. In space missions such as Voyager, Galileo, and Cassini, the use of dual-reflector antennas with FSS sub-reflectors has made it possible to share the main reflector among different frequency bands.

Therefore frequency selective surfaces with dual-band and multi-band responses have been studied by several researchers. Hill and Munk in [2] used a perturbation technique in a single-band FSS to obtain a single-layer dual-band FSS, but attenuation lower than -10 dB was obtained.

Wu in [3] designed and measured a four-band FSS with double square loop patch elements. The designed structure was complex with two layers separated by a honey comb. The structure was designed to reflect the Ka-band signal and transmit the S-, X-, and Ku-band signals. In [4], Wu and Lee designed a FSS with with circular concentric non symmetric rings. A very complex structure was developed, with three layers and with cells out of phase.

This paper shows that a dual-band or multi-band FSS response can be obtained by cascading two or more single-band FSS screens with simple elements, such as rectangular conducting patches. Two prototypes were analyzed, fabricated and measured. These prototypes were cascading to obtain a dual band response. A numerical cascading technique was used to analyze the effect of the air gap between the FSSs with single response. A good agreement between numerical and experimental results was obtained.

II. SINGLE BAND STRUCTURE ANALYSIS

The single band analyzed structure is shown in Fig. 1. It is composed by an array of rectangular patch elements on a dielectric isotropic layer. A low cost fenolite dielectric substrate with height (h) equal to 1.5 mm and relative permittivity equal to 3.9 was used. The unit cell can be seen in Fig. 1(b). The cell has periodicity T_x and T_y in x and y directions, respectively. The rectangular conducting patch has width W and length L .

Fig. 1. FSS geometry: (a) Single band structure and (b) Unit cell.

The analysis of scattering from a bi-dimensional FSS involves the solution of the induced surface current on the conducting element of FSS by an incident plane wave. The response of the FSS on the frequency domain is obtained as a sum of the incident field and the scattered field radiated by the induced surface current density. It can be seen in (1) [5]:

$$\vec{E}_t^s + \vec{E}_t^{inc} = 0 \quad (1)$$

We assume that the FSS is infinitesimally thin and the entire domain basis functions are employed to represent the unknown induced surface current density in the patch elements. The scattered field is related to the surface current density using the components of the Green's function as we can see in (2) [5]:

$$\begin{bmatrix} \tilde{E}_x^s \\ \tilde{E}_y^s \end{bmatrix} = \sum_{m,n} \begin{bmatrix} \tilde{Z}_{xxmn} & \tilde{Z}_{xymn} \\ \tilde{Z}_{yxmn} & \tilde{Z}_{yy mn} \end{bmatrix} \begin{bmatrix} \tilde{J}_{xmn} \\ \tilde{J}_{ymn} \end{bmatrix} e^{j(x\alpha_m + y\beta_n)} \quad (2)$$

where \tilde{J}_x and \tilde{J}_y are the x and y components of the Fourier transforms of the current density; and \tilde{Z}_{xx} , \tilde{Z}_{xy} , \tilde{Z}_{yx} , and \tilde{Z}_{yy} are the components of the Green's function. The parameters α_m and β_n in (2) may be expressed as [5]:

$$\alpha_m = (2\pi m / T_x) + k_x^{inc} \quad (3)$$

$$\beta_n = (2\pi n / T_y) + k_y^{inc} \quad (4)$$

where k_x^{inc} and k_y^{inc} are the projections of the incident plane wave vector along the x and y directions, respectively.

III. DUAL BAND STRUCTURE ANALYSIS

The interaction among the N structure can be accounted for by using the scattering matrices. To be exact, the matrices are of infinite order. Here, we use the so-called "one-mode interaction." It means that only the main beam is used in calculating the interaction. Using the one-mode interaction, the final results of reflection and transmission coefficient for the cascading structure in Fig. 2 are [6]

$$T = A - (BC/D) \quad (5)$$

$$R = -(C/D) \quad (6)$$

Fig. 2. Cascading FSS Structures.

The coefficients (A , B , C , D) are calculated in the following steps. First, for each sheet, we determine a 2×2 scattering matrix S , here

$$\bar{\bar{S}}_n = \begin{bmatrix} T_n(1 - R_n^2/T_n^2) & (R_n/T_n)e^{j2kl_n} \\ -(R_n/T_n)e^{-j2kl_n} & 1/T_n \end{bmatrix} \quad (7)$$

$$l_n = d_1 + d_2 + \dots + d_{n-1} \quad (8)$$

then

$$\begin{bmatrix} A & B \\ C & D \end{bmatrix} = \bar{\bar{S}}_n \bar{\bar{S}}_{n-1} \dots \bar{\bar{S}}_3 \bar{\bar{S}}_2 \bar{\bar{S}}_1 \quad (9)$$

IV. RESULTS

Fig. 3 shows a comparison between numerical and experimental results and a good agreement is observed. The structure 1 has a resonance that occurs at 9.3 GHz, with -26.96 dB for the results obtained with MoM, and it occurs at 9.55 GHz, with -54.08 dB for the measured results. The structure 1 has a resonance that occurs at 10.40 GHz, with -20.6 dB for the results obtained with MoM, and it occurs at 10.27 GHz, with -26.42 dB for the measured results.

Fig. 4 shows a comparison between numerical and experimental results for a cascading structure. We can observe a little difference between the results. The air gap was 1.5mm.

Fig. 3. Single band structure responses.

Fig. 4. Dual band structure response.

V. CONCLUSIONS

In this paper, a simple dual-band frequency selective surface was analyzed, fabricated and measured. We can see that the use of simple elements such as rectangular conducting patches can be used to obtain dual-band response. Numerical and experimental results were presented for single and dual-band FSSs. The agreement observed between experimental and numerical results validates the various analysis approaches described in this paper. The air gap can be used to control the separation between the cascaded FSS bands.

Abstract—In this paper we consider the interaction of an electromagnetic wave with an homogeneous dielectric material. The numerical model of the interaction is described by a surface integral equation obtained by using the Calderón projector. This approach allows to improve significantly the condition number of the resulting linear system of equations as well as allows to develop an efficient preconditioner.

I. INTRODUCTION

In the last few decades we have experienced an unprecedented growth in the numerical methods for computing the electromagnetic field. Despite the intense effort made by researchers all around the World, the demands for faster and reliable numerical models is continuously increasing with the complexity of the devices such as electronic circuits, IC etc. Currently, computer aided design is entered in the common practice of electronic and electrical design and, moreover, the computational power of modern computers provides the resources to face problems of unpaired complexity. A current trend is in the development of numerical methods for the simulation of multiscale problems in a broad frequency range.

In this context, surface integral equations are very attracting for solving problems involving impenetrable bodies (usually PEC) or piecewise homogeneous penetrable materials [1]-[3]. Surface integral equations require the discretization of only the surfaces of PEC and/or the interfaces between different penetrable materials and incorporate the radiation condition. Moreover, fast numerical methods such as fast-multipole methods and SVD compression (see [4]-[7] and references therein) can be successfully used to reduce the computational cost when using iterative solvers to solve the related linear algebraic systems characterized by fully populated stiffness matrices.

The present contribution deals with frequency domain surface integral equations (EFIE type) for evaluating the full-wave 3D interaction of an electromagnetic wave with a homogeneous (eventually lossy) dielectric body. Classical EFIE operator present singular values accumulating at zero and

infinity [8]. Therefore, the condition number of the stiffness matrix arising from the discretization grows rapidly with the discretization thereby compromising the accuracy when applied to structures with subwavelength geometric features. In this framework, the role of the preconditioner is crucial. Recently, it has been show that the EFIE equation written by exploiting the Calderón projector operator bring to very effective preconditioners [9], [10]. These techniques exploit that the square of the EFIE operator does not have eigenvalues accumulating at zero or infinity [11]-[14]. In this contribution we want to lay the basis for: (i) a broadband numerical model for treating homogeneous dielectric bodies by using the Calderón projector operator and (ii) the related preconditioner. The integral equation is those proposed in [16] and will be coupled with a proper choice of shape functions to overcome the arise of the low-frequency breakdown problem [15]. Homogeneous dielectric materials have also been treated by means of Calderón projector operator in [17]. Here we are considering the integral model of [16], that is of minimum order, and we are developing the related efficient preconditioner.

II. NUMERICAL MODEL

The reference problem, sketched in figure 1, consists of the evaluation of the interaction of an electromagnetic field with a penetrable scatterer. The scatterer is homogenous, characterized by the material properties ε_1 and μ_1 and hosted in a homogenous infinite space (having material properties characterized by ε_2 and μ_2). The incident field is $(\mathbf{E}_2^{inc}, \mathbf{H}_2^{inc})$, the scattered field is $(\mathbf{E}_2, \mathbf{H}_2)$ and the transmitted field is $(\mathbf{E}_1, \mathbf{H}_1)$.

The integral equation follows from the concept of Calderón projector applied to full wave Maxwell equations as proposed in [16]:

$$\begin{bmatrix} M_1 + M_2 & \alpha_1 C_1 + \alpha_2 C_2 \\ \alpha_1^{-1} C_1 + \alpha_2^{-1} C_2 & M_1 + M_2 \end{bmatrix} \begin{bmatrix} \mathbf{m}_2 \\ \mathbf{j}_2 \end{bmatrix} = \begin{bmatrix} I/2 - M_1 & I/2 - \alpha_1 C_1 \\ I/2 - \alpha_1^{-1} C_1 & I/2 - M_1 \end{bmatrix} \begin{bmatrix} \mathbf{m}_0 \\ \mathbf{j}_0 \end{bmatrix} \quad (1)$$

where $\mathbf{m}_2 = \hat{\mathbf{n}} \times \mathbf{E}_2|_{\Sigma_+}$, $\mathbf{j}_2 = j\omega \hat{\mathbf{n}} \times \mathbf{H}_2|_{\Sigma_+}$, $\mathbf{m}_0 = \hat{\mathbf{n}} \times \mathbf{E}^{inc}|_{\Sigma_+}$, $\mathbf{j}_0 = j\omega \hat{\mathbf{n}} \times \mathbf{H}^{inc}|_{\Sigma_+}$, $\alpha_j \triangleq k_j^{-1} \mu_j$, M_k and

Antonello Tamburrino is also with the department of Electrical and Computer Engineering, Michigan State University, USA.

Fig. 1. The reference configuration: an incident electromagnetic field $(\mathbf{E}_2^{inc}, \mathbf{H}_2^{inc})$ produced in the homogeneous region Ω^c impinges on an homogeneous obstacle Ω . $(\mathbf{E}_1, \mathbf{H}_1)$ is the total (transmitted) field in Ω whereas $(\mathbf{E}_2, \mathbf{H}_2)$ is the scattered field in Ω^c . The material properties are (ε_1, μ_1) in Ω and (ε_2, μ_2) in Ω^c . The problem is full-wave and 3D.

C_k are properly defined operators and Σ_+ is the external page of Σ . It is worth noting that the unknowns of (1) are the tangential components of the electric and magnetic field onto Σ . Moreover, all the tangential traces are element of the functional space \mathbf{X} defined as $\mathbf{X} \triangleq \left\{ \boldsymbol{\lambda} \in V'_\pi | \nabla_S \cdot \boldsymbol{\lambda} \in H^{-1/2}(\Sigma) \right\}$, V'_π being the dual space of $V_\pi \triangleq \left(\hat{\mathbf{n}} \times H^{1/2}(\Sigma) \right)^3 \times \hat{\mathbf{n}}$.

The discrete model is obtained by means of the following non-standard Galerkin projection onto the test functions $\tilde{\mathbf{m}}$ and $\tilde{\mathbf{j}} \in \mathbf{X}$:

$$B \left(\begin{bmatrix} (M_1 + M_2) \mathbf{m}_2 + (\alpha_1 C_1 + \alpha_2 C_2) \mathbf{j}_2 \\ (\alpha_1^{-1} C_1 + \alpha_2^{-1} C_2) \mathbf{m}_2 + (M_1 + M_2) \mathbf{j}_2 \end{bmatrix}, \begin{bmatrix} \tilde{\mathbf{m}} \\ \tilde{\mathbf{j}} \end{bmatrix} \right) = B \left(\begin{bmatrix} (I/2 - M_1) \mathbf{m}_0 - \alpha_1 C_1 \mathbf{j}_0 \\ -\alpha_1^{-1} C_1 \mathbf{m}_0 + (I/2 - M_1) \mathbf{j}_0 \end{bmatrix}, \begin{bmatrix} \tilde{\mathbf{m}} \\ \tilde{\mathbf{j}} \end{bmatrix} \right) \quad (2)$$

where

$$B \left(\begin{bmatrix} \mathbf{m} \\ \mathbf{j} \end{bmatrix}, \begin{bmatrix} \tilde{\mathbf{m}} \\ \tilde{\mathbf{j}} \end{bmatrix} \right) = \int_\Sigma \tilde{\mathbf{m}} \cdot (\mathbf{j} \times \hat{\mathbf{n}}) dS - \int_\Sigma \tilde{\mathbf{j}} \cdot (\mathbf{m} \times \hat{\mathbf{n}}) dS. \quad (3)$$

By applying (3) to (2) and after some manipulations we obtain:

$$\int_\Sigma \tilde{\mathbf{m}} \cdot [(\alpha_1^{-1} C_1 + \alpha_2^{-1} C_2) \mathbf{m}_2 + (M_1 + M_2) \mathbf{j}_2] \times \hat{\mathbf{n}} dS + \int_\Sigma \tilde{\mathbf{j}} \cdot [(M_1 + M_2) \mathbf{m}_2 + (\alpha_1 C_1 + \alpha_2 C_2) \mathbf{j}_2] \times \hat{\mathbf{n}} dS = \mathbf{v}_0$$

where \mathbf{v}_0 is known and depends on \mathbf{m}_0 and \mathbf{j}_0 . The elementary contributions are $\int_\Sigma \tilde{\mathbf{a}} \cdot C_j \mathbf{a} \times \hat{\mathbf{n}} dS$ and $\int_\Sigma \tilde{\mathbf{a}} \cdot M_j \mathbf{a} \times \hat{\mathbf{n}} dS$ that, as shown in [16], are symmetric (i.e. $\int_\Sigma \tilde{\mathbf{a}} \cdot C_j \mathbf{a} \times \hat{\mathbf{n}} dS = \int_\Sigma \mathbf{a} \cdot C_j \tilde{\mathbf{a}} \times \hat{\mathbf{n}} dS$ and $\int_\Sigma \tilde{\mathbf{a}} \cdot M_j \mathbf{a} \times \hat{\mathbf{n}} dS = \int_\Sigma \mathbf{a} \cdot M_j \tilde{\mathbf{a}} \times \hat{\mathbf{n}} dS$).

Finally, the numerical models is obtained by a finite dimensional approximation of \mathbf{X} by means of div-conforming Whitney elements defined onto the surface Σ . One advantage for this formulation is that it is possible to adapt the existing preconditioners for the Electric Field Integral Equation (EFIE) as the one proposed in [18] and implemented and tested in [9]. Indeed, in (1), the operators C_i are the ones of the EFIE with coefficients from outside and from inside, whereas the operators M_i can be seen as compact perturbations. This last statement is valid in the case of sufficient regular dielectric interface, as it

is proved, e.g., in the book [8]. If we denote by A_h the matrix associated to the proposed numerical method, the construction given in [18] leads to a uniform multiplicative preconditioner i.e., to the construction of a matrix \mathcal{A}_h such that the spectral radius for $B_h^{*-1} \mathcal{A}_h B_h^{-1} A_h$ is uniformly bounded, where B_h denotes here a stable discretization of the bilinear form $B(\cdot, \cdot)$.

In the full paper we will discuss the details of the numerical formulation, together with its coupling with proper shape functions and the development of the preconditioner.

Abstract—A time integration scheme based on Taylor expansion using the higher order discontinuous Galerkin finite element method (DG-FEM) is presented. The special properties of the scheme allow for using explicit time integration as well as local timestepping. The algorithm is introduced, its characteristics are analyzed and first benchmarks are presented.

Index Terms—Time Domain, Local Timestepping, Discontinuous Galerkin, FEM.

I. INTRODUCTION

The simulation of radio frequency and microwave engineering problems requires the solution of the Maxwell equation. The semidiscrete formulation of DG-FEM allows for using explicit time integration schemes, which are more efficient compared to implicit implementations. However, explicit time integration is not unconditionally stable. The maximum stable time step can be computed by evaluating the Courant-Friedrichs-Lewy (CFL) condition for every finite element. To guarantee global stability, the smallest time step has to be used for the computation. Since grids of many physical applications have a diversity of element sizes, a local timestepping strategy provides the opportunity of minimizing computation time.

Local timestepping for DG-FEM has been published by Piperno [1], Warburton [2] and Montseny [3]. A 3D local timestepping scheme with the linear multistep method using DG-FEM was presented in [4] based on results in [5], where a third order Adams-Bashforth (AB) time integration method was used. In addition to the fixed AB order, the stability region is smaller than well-established explicit Runge-Kutta (ERK) methods [6], which are based on Taylor expansion.

In this paper a local timestepping algorithm based on a Taylor expansion is presented. Relevant results of using Taylor series have been published in [7]. This approach combines the larger time stability and a flexible scheme with a variable order.

II. DESCRIPTION OF THE MODEL

Starting from Maxwell's two curl equations the conversion in a weak formulation and DG-discretization, as published in [2], can be summarized as:

$$\frac{d}{dt} \varepsilon \mathbf{E} = \mathbf{M}^{-1} \mathbf{S} \mathbf{H} - \mathbf{M}^{-1} \mathbf{F} [\hat{n} \cdot (f_E - f_E^*)], \quad (1)$$

$$\frac{d}{dt} \mu \mathbf{H} = -\mathbf{M}^{-1} \mathbf{S} \mathbf{E} + \mathbf{M}^{-1} \mathbf{F} [\hat{n} \cdot (f_H - f_H^*)]. \quad (2)$$

Here, \mathbf{M} and \mathbf{S} denote mass- and stiffness-matrices. The numerical flux $\mathbf{F} [\hat{n} \cdot (f - f^*)]$ defines the integration over adjacent face values f^* of neighboring finite elements. The fields can be approximated by using local high-order multi-dimensional Lagrange polynomials. To simplify equations (1) and (2), \mathbf{Q} is defined as

$$\mathbf{Q} = \begin{pmatrix} \mathbf{E} \\ \mathbf{H} \end{pmatrix} \quad \text{resulting in} \quad \frac{d}{dt} \mathbf{Q} = \mathcal{L}(\mathbf{Q}). \quad (3)$$

The right-hand-side (RHS) terms of (1), (2) are summarized by the linear operator \mathcal{L} .

III. TAYLOR EXPANSION

A time integration scheme with Taylor expansion [2] has, in addition to the good stability properties, a further advantage: adaption to local timestepping. The temporal evolution of the electromagnetic fields can be approximated using Taylor series of order P

$$\mathbf{Q}(t) = \mathbf{Q}^n + \sum_{p=1}^P \frac{(t - t^n)^p}{p!} \mathcal{L}^p \mathbf{Q}^n : t \in [t^n, t^n + \Delta t]. \quad (4)$$

in the discrete time steps. To find a solution for (3) an explicit timestepping scheme, like

$$\mathbf{Q}^{n+1} - \mathbf{Q}^n = \int_{t^n}^{t^{n+1}} \mathcal{L}(\mathbf{Q}(t)) dt \quad (5)$$

is necessary. This method uses Taylor series with the derivatives $\mathcal{L}^p \mathbf{Q}^n$ of the order $P + 1$ for a time step from t^n to t^{n+1} . The straightforward implementation of the time discrete formulation

$$\mathbf{Q}^{n+1} = \mathbf{Q}^n + \sum_{p=1}^{P+1} \frac{(\Delta t)^p}{p!} \mathcal{L}^p \mathbf{Q}^n \quad (6)$$

is another advantage. The maximum stable time step is defined by the CFL condition as $\Delta t = C \cdot \left\{ \frac{\Delta x_{\min}}{v} \right\}$, with C being the Courant number, x_{\min} the characteristic size of the smallest element and v the wave speed.

IV. LOCAL TIMESTEPPING STRATEGY

Most physical applications have large aspect ratios in element sizes, shown in Fig. (1). The finest element dictates the global time step for the entirety of the mesh, however most numerical costs are contributed by considerably coarser elements. To simplify the investigation a less complicated

strategy is used. Domain decomposition is necessary for the local timestepping approach, splitting the set of all elements into two subsets, Ω_C and Ω_F , referring to the coarse and the fine elements, respectively. First all elements are classified

Fig. 1. Grid and histogram of an airplane with 227 960 elements and a aspect ratio of 634.

in levels of element size $2^{(\text{level}-1)} \cdot \Delta x_{\min}$ in Fig. 1. As preprocessing, an algorithm calculates the best position for the fine-to-coarse boundary, in this case between Level 4 and 5, to obtain minimal effort. All elements up to level 4 are summarized in Ω_F and advance in time with the microstep. All coarse elements advance in time every 16th microstep. The majority of the finite elements use a larger time step and a bulk of unnecessary computation is economized. In addition, problems of multi-level local timestepping with complex level coupling [4] are prevented.

$$Q_F^{n+1} - Q_F^n = \int_{t^n}^{t^{n+1}} (\mathcal{L}_{FF}Q_F + \mathcal{L}_{FC}Q_C) dt \quad (7)$$

$$Q_C^{n+1} - Q_C^n = \int_{t^n}^{t^{n+1}} (\mathcal{L}_{CC}Q_C + \mathcal{L}_{CF}Q_F) dt \quad (8)$$

In (7) and (8) a full time step $\Delta t_C = t^{n+1} - t^n$ is presented, whereas the integral in (7) has to be split up in microsteps. The RHS operation on the coarse and on the fine grid is denoted by \mathcal{L}_{CC} and \mathcal{L}_{FF} . The terms \mathcal{L}_{CF} and \mathcal{L}_{FC} adopt the coupling of both grids. The boundary of coarse and fine elements are the focus of further investigation and need a special implementation.

V. FIRST NUMERICAL RESULTS

First numerical results are presented for stability and accuracy of the Taylor time integration with order 4 and polynomial order 4 for a cavity, discretised with 398 tetrahedrons, in Fig. 2. The normalized energy at the top shows minimal dissipative behavior, resulting in a loss of 0.05% per 1000 periods and 1 329 673 micro time steps. The local timestepping scheme with $C = 2.124$, which equates 90% of the maximum stable time step, shows most dissipation. This effect is reducible in combination with an improvement of the maximum local error, if the Courant number C is decreased. The same accuracy of the global and local timestepping scheme with the same factor C is obvious in the diagram, highlighting the maximum E-field error. In Fig. 3 the maximum stable time step for the global and local timestepping algorithm for the cavity is illustrated. With higher Taylor order the stability of the scheme is increasing. The gap between the maximum local and global time step in Fig.3 was also encountered by Montseny et al. [3], who used a leapfrog scheme and proposed a factor of 0.8. For this academic example of a cavity a speedup of 1.3 is encountered, for further physical applications higher speed ups are estimated.

Fig. 2. Energy and accuracy of a cavity with 398 elements, the energy is normalized to the analytic solution. Due to an oscillatory behavior of both graphs, a fitting is used for better visibility.

Fig. 3. Maximum Courant number for a stable microstep of Taylor time integration method.

VI. CONCLUSION

In this paper, a local timestepping technique based on Taylor expansion was presented. The one step one stage method is more suitable for local timestepping than ERK methods. Additionally, better stability characteristics than previously used one stage methods like AB schemes have been encountered. First simulation results were shown for a cavity to validate the timestepping scheme. The full paper will provide a more detailed description of the algorithm as well as further simulations of realistic examples.

Abstract — The paper deals with the numerical prediction of the specific absorption (SA) of ultra wideband (UWB) radio systems for wireless body area network (BAN). The electromagnetic analysis is performed by the frequency-dependent finite difference time domain (FDTD) method in which the first order Debye approximation is used to model the frequency-dependent properties of the human body in the frequency range of the UWB signals. Different models of the human bodies are considered.

I. INTRODUCTION

Body Area Network (BAN), consists of a set of radio sensors, either wearable or implanted into the human body, which monitor body parameters and movements [1]. These devices, communicating through wireless technologies, transmit data from the body to a home base station, from where the data can be forwarded to a remote network.

The safety of radio sensors for BAN applications must be compliant with the IEEE standard C95.1 [2] in the USA and, up to now, with ICNIRP [3] in Europe. The IEEE 1-g specific absorption (SA) peak limit for a 6-min exposure is 576 J/kg, while 2 mJ/kg averaged over 10 g of tissue is settled in the ICNIRP safety guideline. Due to their characteristics, ultra wideband (UWB) radio sensors will be widely used in future BAN applications, and therefore they are analysed in this study to evaluate the critical aspect of safety. Different human head models excited by an UWB antenna are analyzed by the frequency-dependent finite difference time domain (FDTD) formulation ((FD)²TD) in order to predict the SA.

II. MODELS AND METHODS

A. Frequency-Dependent FDTD Method

Electromagnetic field in frequency domain are described by Maxwell's curl equations:

$$\nabla \times \mathbf{E}(\omega) = -j\omega\mu \mathbf{H}(\omega) \quad (1a)$$

$$\nabla \times \mathbf{H}(\omega) = j\omega\varepsilon_0\hat{\varepsilon}_r(\omega)\mathbf{E}(\omega) \quad (1b)$$

where $\mathbf{E}(\omega)$ is the electric field, $\mathbf{H}(\omega)$ the magnetic field, μ the permeability, ε_0 the free space permittivity, $\hat{\varepsilon}_r(\omega)$ the frequency-dependent complex relative permittivity given by:

$$\hat{\varepsilon}_r(\omega) = \varepsilon_r(\omega) - j\frac{\sigma(\omega)}{\omega\varepsilon_0} = \varepsilon_\infty - j\frac{\sigma_0}{\omega\varepsilon_0} + \chi(\omega) \quad (2)$$

with $\varepsilon_r(\omega)$ and $\sigma(\omega)$ the frequency-dependent relative permittivity and conductivity, respectively, ε_∞ the permittivity as $\omega \rightarrow \infty$, σ_0 the conductivity as $\omega \rightarrow 0$, and $\chi(\omega)$ the electric susceptibility. The dielectric properties of biological tissues vary with frequency owing to relaxation process [4]. In the frequency range of interest for UWB applications (i.e., 3.1-10.6 GHz), it is a satisfactory approximation to consider a single relaxation process that can be modelled by the first order Debye dispersion relation. For such a medium the electric susceptibility is given by [5]:

$$\chi(\omega) = \frac{\varepsilon_s - \varepsilon_\infty}{1 + j\omega\tau_0} \quad (3)$$

where ε_s is the static permittivity and τ_0 the relaxation time. Moving (1) to the time-domain, it yields:

$$\nabla \times \mathbf{E}(t) = -\mu \frac{\partial \mathbf{H}(t)}{\partial t} \quad (4a)$$

$$\nabla \times \mathbf{H}(t) = \sigma_0 \mathbf{E}(t) + \varepsilon_0 \varepsilon_\infty \frac{\partial \mathbf{E}(t)}{\partial t} + \varepsilon_0 \frac{\partial [\mathbf{E}(t) * \chi(t)]}{\partial t} \quad (4b)$$

where the symbol * denotes the convolution operator. Time-domain Maxwell's equations (4) can be numerically solved by the (FD)²TD method as described in [5].

B. Human Body Models

The electro-geometrical configuration of the human body is a critical point for the numerical analysis. The body models considered in the proposed investigation are (see Fig. 1):

- Visible Human Project (VHP) model, which is public and therefore has the advantage to be widely used and permits the benchmark of different numerical techniques [6];
- CAD model obtained by the atlas of the human body, which permits to modify in a simple way the electro-geometrical configuration (scaling, anatomical detail modification, ...) [7].
- Specific Anthropomorphic Mannequin (SAM) model, which is obtained by homogenizing the CAD model with a unique tissue of dielectric properties similar to the brain and therefore suitable for comparison with measurements.

C. SA Calculation

The field distribution calculated by the (FD)²TD is used to evaluate the SA by [8]:

$$SA = \int_0^{T_{max}} \frac{\mathbf{E}(t) \cdot \mathbf{J}(t)}{\rho} dt \quad (4)$$

where T_{max} is the maximum calculation time, ρ the mass density and $\mathbf{J}(t)$ the transient current density obtained by the inverse Fourier transform as [8]:

$$\mathbf{J}(t) = F^{-1}[\mathbf{J}(\omega)] \quad (5)$$

where

$$\mathbf{J}(\omega) = \sigma(\omega)\mathbf{E}(\omega). \quad (6)$$

It should be noted that the SA calculated by (4) must be averaged over a portion of tissue to be compared with the standard limits, as described in the Introduction Section.

III. NUMERICAL RESULTS

We consider the configuration of an UWB patch antenna whose characteristics are reported in [9]. It is placed at 2 mm from the ear of the three different human head tri-dimensional models (i.e., CAD, VHP and SAM), as shown in Fig. 1. These configurations are analyzed by the (FD)²TD when exciting the antenna by the UWB doublet signal shown in Fig. 2.

The presence of the human head affects the field radiated by the UWB patch antenna. The return loss $|S_{11}|$ calculated by the (FD)²TD for the three head models is reported in Fig. 3. It should be noted that the different geometries (see the simulations for the VHP and CAD models) influence the solution much more than the different tissue composition (see the simulations for the CAD and SAM models).

Finally, the SA distribution inside the human head is numerically calculated on the different models for a single UWB pulse, as shown in Fig. 4, where the SA maps are reported in dB defined as $SA_{dB} = 10 \log_{10}(SA / 1 \text{ pJ/kg})$. From this figure you can note as the higher values of SA are located in the human tissues characterized by higher water content or in close proximity to the UWB antenna. In the extended version of the paper, further human body-antenna configurations will be examined and several UWB modulation schemes will be considered. The SA calculated for a train of UWB pulses will be also presented under the IEEE and ICNIRP safety limits.

Abstract — In this paper, a detailed method for computing the transient voltage distribution in underground cables is described. The proposed model is based on RLCG lumped frequency-dependent parameters for time-domain analysis. The numerical Laplace transform in s -complex plane is used. The method is appropriate to solve underground cable systems at high frequencies (HFs) with lossy ground-return path included. Numerical results confirm good agreement with reference solutions taken from the literature.

I. INTRODUCTION

Computation of very fast electromagnetic transients (VFETs) plays a crucial role in the determination of overvoltage stresses on electrical equipment. Nowadays, special attention is paid to power transmission underground cables by utilities who are concerned with accurate and efficient computation methods for ensuring the insulation coordination and the mitigation of transients.

A large variety of computing programs for overhead lines based on very well established methodologies is readily available. There is no alternative for underground cables, since their electrical characteristics are significantly different from overhead lines. Their parameters have to be properly calculated from the cable geometry and frequency dependent. Proximity and skin effects, as well dielectric losses have to be taken into account with real lossy earth return path (ERP).

In this paper, modal analysis, numerical Laplace transform technique and lossy earth Machado's solution are applied to compute transient voltage and current oscillations in cable conductors. Numerical solutions at HF are more accurate than classical Pollaczek's approach when the outer cable radius and the influence of earth-air surface cannot be negligible.

II. CALCULATION OF PARAMETERS WITH LOSSY EARTH PATH

Maxwell's equations for power transmission system can be formulated in frequency domain by [1]

$$\frac{d}{dx}V = -ZI, \quad \frac{d}{dx}I = -YI, \quad (1)$$

where Z and Y are the frequency dependent (FD) series impedance and shunt admittance matrices per unit length, respectively, and V and I are the voltages and currents vectors at a distance x along the cable. For the case of underground cables system due to the soil acting as an electrostatic shield between cables, Y only represents the capacitive coupling between elements of each cable itself [2]. However, Z may be expressed according to [3] by

$$Z = Z_{ps} + Z_{soil}, \quad (2)$$

where Z_{ps} is obtained by Schelkunoff's [2] formulas and represents the FD series-impedance matrix under a perfect soil, which means a perfect conducting earth ($\sigma_{ps} = \infty$). Whereas the matrix Z_{soil} accounts for the influence of the lossy ERP due to a finite electric conductivity of the real soil. The form and dimensions of above matrices depend on the number of conducting cable system elements (core, sheath, armour, etc.).

The proposed model is valid for homogenous semi-infinite earth, where Machado's ground-return impedance approach was implemented [3]. Thus, the diagonal submatrix elements of Z_{soil} are the self-impedance of the ERP of each conductor calculated by

$$Z_{soil-self} = \left[-\frac{x_c J_o}{2J_1} - \frac{x_c^2 G_o}{2 C_o} \left(H_o - \frac{J_o H_1}{J_1} \right) \right] R_{dc}. \quad (3)$$

The non-diagonal submatrix elements of Z_{soil} represent the mutual impedance of ERP between conductors which are obtained by

$$Z_{soil-mutual} = \left[-\frac{x_c^2 G_o}{2 C_o} \left(H_o - \frac{J_o H_1}{J_1} \right) \right] R_{dc}, \quad (4)$$

where x_c , J_o , J_1 , G_o , C_o , H_o and R_{dc} are specified in [3]. Classical Pollaczek's approach is a particular solution when the outer cable radius is smaller than skin earth depth penetration.

III. MATHEMATICAL MODEL FOR MODAL APPROACH

From equations (1), a transmission system with N phases is partitioned as

$$\frac{d}{dx}V_i = -\sum_{j=1}^N Z_{ij} I_j, \quad \frac{d}{dx}I_i = -\sum_{j=1}^N Y_{ij} V_j, \quad i = 1, \dots, N. \quad (5)$$

Equations (5) are applied to discretize cables into sections in a equivalent π -circuit given by (6) and (7). The cables are divided into K homogenous sections according to

$$V_i(k) = V_i(K) + \sum_{r=k+1}^K \sum_{j=1}^N Z_{a,ij}(r) I_j(r), \quad k = 0, 1, \dots, K-1, \quad (6)$$

$$I_i(k) = I_i(K+1) + \sum_{r=k}^K \sum_{j=1}^N \left(Y_{b,ij}(r+1) + Y_{c,ij}(r) \right) I_j(r), \quad k = 0, 1, \dots, K, \quad (7)$$

where, $i=1, \dots, N$, $Z_{a,ij}$, $Y_{b,ij}$ and $Y_{c,ij}$ are the overall series impedance and overall shunt admittance of the r th section between i th and j th cables given by [4]. Operating (6) and (7) the following set of matrix equations are defined:

$$\begin{bmatrix} I_B \\ V' \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_B \\ V' \end{bmatrix}, \quad (8)$$

Fig. 1. Underground transmission system. a) Geometric configuration. b) Cable system connection diagram.

TABLE I
PHYSICAL DATA OF TESTED CABLE SYSTEM

Dimensions		Properties	
h	0.762 m	ϵr_1	3.5
d	0.1524 m	$\tan \delta_1$	0.002
r_0	0 m	ϵr_2	3.3
r_1	0.0127 m	$\tan \delta_2$	0.0005
r_2	0.0282 m	σ_{soil}	0.05 S/m
r_3	0.293 m	σ_{copper}	5.81E7 S/m
r_4	0.345 m	σ_{lead}	7.25E6 S/m

where V_B represents the voltage at cable terminals, I_B is the current entering each terminal of cable, and V' is the voltage at the internal nodes. The matrices A , B , C , and D are functions of the impedance $Z_{a,ij}$, and the admittances $Y_{b,ij}$ and $Y_{c,ij}$ as specified in [5].

Manipulating (8), the modal form of the solution is obtained from

$$\begin{aligned} V' &= C_L V_B + Q h P_t V_B, \\ I_B &= Y_{BB} V_B + P \xi h P_t V_B = Y_B V_B, \end{aligned} \quad (9)$$

where the matrices C_L , Q , h , P_t , Y_{BB} , P , ξ , h and Y_B are specified in [5]. The time domain solution is computed applying the numerical Laplace transform [6].

IV. TESTED CASES AND SIMULATION RESULTS

The proposed method is tested with underground cable system of the Fig. 1, applying a unit impulse to the core of phase 1 [7]. The data of the transmission line is given in Table I. Figure 2 shows the transient waveforms obtained for the remote node in core 1 of phase 1 for three different lengths of cable (10, 20 and 40 miles). Figure 3 shows the induced voltage obtained for the remote node in the sheath of each phase, evaluating the influence of the dc resistance of the lead sheath ($R_{dc-lead}$). Those numerical results are compared with the solution computed by Wedepohl & Wilcox [7] and Uribe [8].

Fig. 2. Voltages for the remote node in the core 1 of the phase 1.

Fig. 3. Voltage of the remote node in the sheaths for 10 miles.

V. CONCLUSION

The proposed method implements the lossy earth Machado's solution for computing VFETs in cable systems with success for firts time. While Ametani approach works up to 10 kHz, and Wedepohl & Wilcox method up to 100 kHz, the Machado's solution does up to 1-10 MHz. The proposed methodology becomes an alternative for solving cable systems with lossy ERP at VFETs.

FDTD Analysis of a Metamaterial with Particles Having O_h Point Group Symmetry

Tiago C. Martins and Victor Dmitriev

Department of Electrical Engineering, Federal University of Pará (UFPA)

Av, Augusto Corrêa nº 01, CEP 66075-900, Brazil

Email: tiagocm@ufpa.br, victor@ufpa.br

Abstract— In this work, we analyze a metamaterial with particles of cubic geometry described by O_h point group symmetry. We investigate the case of the negative refraction index, and we demonstrate that the material does not have isotropic behavior, when the dimensions of the particles of the metamaterial are of the order of the operating wavelength. The analysis is performed with FDTD method implemented in FORTRAN 90 code.

I. INTRODUCTION

Metamaterials are artificial media with the properties which are not met in natural substances. One of them intensively studied in the last years is the materials with negative refraction index. The electromagnetic response of such a material is characterized by simultaneously negative permeability and negative permittivity [1,2]. Some consequences of these unusual properties of the medium are the inverse Cherenkov and Doppler effects, negative refraction and a theoretical possibility of construction of a “perfect lens” [3]. However, a realization of such effects depends on the design of isotropic metamaterials. By using theory of groups [1,2], it was demonstrated that isotropic materials can be obtained using elements with cubic symmetries, such as the element with O_h symmetry shown in Fig. 1. This element is a cubic particle that has four-gap single-split-ring on each side.

Fig. 1. Particle with O_h symmetry

II. FDTD ANALYSIS OF PERIODIC STRUCTURES

The finite difference time domain (FDTD) method has been frequently used to analyze periodic structures. As a result, a variety of FDTD technique modifications to analyze

electromagnetic scattering for periodic structures in arbitrary incident angles are available in literature [4]. These techniques are divided in two classes: direct field methods (sine-cosine method, multiple unit cell method, and angle update method), and field transformation methods (multispatial grid method, and split-field method). Amongst these methods, split-field method is the most popular technique. Recently, F. Yang et al. [5] developed a new FDTD technique to analyze these structures and it is called as constant wavenumber method. In this work we implemented this technique in FORTRAN 90 code to simulate electromagnetic scattering for metamaterials.

In Fig. 2, it is shown the FDTD computational scheme used in our simulations. Note that the computational domain is truncate with convolutional perfectly matched layers (CPML) and periodic boundary conditions (PBC), respectively, in z and horizontal directions x and y. The periodicity of the structure is a , and the angle between the incident wave vector and the z direction is θ .

Fig. 2. FDTD computational domain

The periodic boundary condition in frequency domain is given by the expression (1)

$$\begin{aligned} \mathbf{E}(x=0, y, z) &= \mathbf{E}(x=a, y, z) \exp(jk_x a) \\ \mathbf{H}(x=0, y, z) &= \mathbf{H}(x=a, y, z) \exp(jk_x a) \end{aligned} \quad (1)$$

where k_x is the horizontal wavenumber, which is provided by the following equation:

$$k_x = k_0 \cdot \sin \theta = \omega \sin \theta / C \quad (2)$$

In the constant wavenumber method, (1) is not transformed in time domain, but instead both electric and magnetic fields are declared as complex variables, and the value of k_x is taken

as a constant. After the simulation is complete, we can choose a value for θ , and it will be possible to obtain the results in function of ω .

The main advantages of the constant wavenumber method are the simplicity of implementation (no change in the formulation of the conventional FDTD method is necessary) and computational efficiency (same stability condition of conventional FDTD, i.e, time step is independent of incident angle and horizontal wavenumber, which is not the case for other techniques).

III. RESULTS

In [2], the author suggested the use of particles with O_h symmetry, as shown in Fig. 1, to produce isotropic metamaterials with negative refractive index, however, we will demonstrate that the isotropy can not be realized when the dimensions of these particles are of the order of the operating wavelength. One layer of cubic particles was analyzed in this work; the unit cell of this structure is illustrated in Fig. 1. The edge size of cube is 1.8 mm, size gaps are 0.2 mm, and edge size of unit cell is 2.6 mm. The reflection coefficient in 85-95 GHz obtained with FDTD, for some values of k_x , and CST Microwave Studio for normal incidence is showed in Fig. 3. This structure presents negative refractive index in 83.3-92.5 GHz, and the periodicity is about 76% of the wavelength. In order to obtain the refractive index, we used the procedure proposed in [6].

Fig. 3. Reflection coefficient of the analyzed structure

In spite of cubic symmetry of the particles, the material does not have isotropy, it is observed in TABLE I, for angles greater than 10° , we obtained a difference of reflection coefficient above 10%, in relation to reflection coefficient for normal incidence. For the highest analyzed frequency (92.5 GHz), the structure has a less isotropic behavior.

TABLE I
REFLECTION COEFFICIENT FOR SOME VALUES OF k_x

k_x	Frequency (GHz)	θ	Reflection Coefficient	Difference from Normal incidence (%)
0	83.3	0°	0.9908	-
167.55	83.3	5.5°	0.9536	3.75
335.10	83.3	11.1°	0.88611	10.56
502.65	83.3	16.7°	0.75615	23.68
0	92.5	0°	0.61386	-
167.55	92.5	5.0°	0.61832	0.72
335.10	92.5	10.0°	0.49457	19.40
502.65	92.5	15.0°	0.12019	80.42

IV. CONCLUSIONS

When the wavelength is of the order of its dimensions, in spite of cubic symmetry of the particles, these structures does not have isotropy. In the full paper we will analyze isotropic metamaterials for other relations between the wavelength and the dimensions or periodicity of the structure.

Abstract—As a first step, we will investigate the extent of the consistency error for an hexahedral primal grid due to the use mass matrices of Finite Elements within the Discrete Geometric Approach (DGA) as discrete counterparts of the constitutive relations. Such matrices are constructed by resorting to *mixed elements* edge and face vector functions. Then we will propose a novel set of geometric vector basis functions for hexahedra which guarantee consistency and stability of the constitutive matrices for the DGA constructed according to the so called *energetic approach*.

Index Terms—Discrete geometric approaches, constitutive matrices, hexahedral meshes.

I. INTRODUCTION

The Finite Integration Technique (FIT) [1], the Cell Method (CM) [2] and the geometrical reinterpretation of Finite Elements demonstrated by A. Bossavit [3] suggest a Discrete Geometric Approach (DGA) for discretizing an electromagnetic field problem with respect to a pair of interlocked grids in the spatial domain of interest.

A grid is a collection of oriented nodes, edges, faces and volumes [2]. The grids are one dual of the other, since the oriented nodes, edges, faces and volumes of the primal grid one-to-one correspond with the oriented volumes, faces, edges and nodes of the dual grid respectively. Now, integral variables can be univocally associated with the geometric elements of the pair of dual grids [2]. For instance, circulations of electric field are associated with the primal edges, while electric currents are associated with the faces of the dual grid.

The fundamental laws of electromagnetism, formulated as *balance equations*, are discretized into sets of *exact* equations relating circulations and fluxes associated with the geometric elements of each of the grids [2], [4]. For instance, Ampere’s law relates the current through a dual face with the circulations of the magnetic field along the dual edges forming the boundary of that dual face. The discrete counterparts of the constitutive relations are introduced as *approximate* algebraic equations which relate either the circulations along the primal edges with the fluxes through the dual faces or viceversa. For instance, the magnetic constitutive relation is a matrix mapping the fluxes of magnetic induction through primal faces to the circulations of magnetic field along dual edges [2], [5].

As a known result [4], in order to ensure the consistency and the stability of the overall final system of algebraic equations, the discrete constitutive relations have to satisfy

both *stability* and *consistency* requirements. The stability requirement prescribes that the constitutive matrix is symmetric and positive definite. The consistency requirement prescribes that the constitutive matrix *exactly* maps either circulations along primal edges into fluxes through dual faces or viceversa, at least for element-wise *uniform* fields.

Stable and consistent discrete constitutive matrices can be easily obtained for pairs of grids in which the primal grid is composed of tetrahedra and the dual grid is obtained according to the barycentric subdivision of the primal. The recipe is to construct the so called “Galerkin Hodge”, where Whitney’s edge and face basis functions are used to compute the mass matrices [3]; for such a pair of grids, where the primal is simplicial, both Whitney’s basis functions and the Galerkin Hodge admit a simple geometric interpretation, [5], [6]. Alternatively, we proposed in [6] novel constitutive matrices not only for tetrahedra but also for (oblique) prisms with triangular base; this result was achieved with the introduction of a novel set of purely geometric edge and face vector functions combined with an energetic approach.

Therefore, if we limit to tetrahedra, Finite Elements and DGA are akin each other, so that the mass matrices of Finite Elements can be borrowed as constitutive matrices for the DGA.

However difficulties arise when discrete constitutive matrices for hexahedral primal grids need to be considered within the DGA. A simple theoretical counter-example, described in [7], shows that the mass matrices constructed by means of the *mixed elements* edge and face vector functions [8] for hexahedra, do *not* satisfy the consistency property for any choice of the dual grid. Thus, such mass matrices *cannot* be borrowed as constitutive matrices for the DGA. In this paper the consistency error of mass matrices introduced by the mass matrices of Finite Elements will be evaluated by numerical investigations. Moreover, to overcome this difficulty, a novel set of edge and face basis vector functions, suited for hexahedral primal grids, will be presented, capable to exactly represent a uniform field and satisfying a geometric consistency property. In this way, novel stable and consistent constitutive matrices can be easily derived, resorting to the energetic approach.

II. INCONSISTENCY OF MASS MATRICES OVER HEXAHEDRAL GRIDS

We will present a numerical study to evaluate the extent of the consistency error when the standard mass matrices of

Finite Elements are used in DGA as discrete counterparts of the constitutive relations over an hexahedral primal grid.

In a domain D , consisting of a cube of unitary edge, we consider a primal grid made of nodes n_i , edges e_j , faces f_h and hexahedra v_k , Fig. 1. A dual grid is constructed from it according to the barycentric subdivision of the *boundary* of the primal grid: a dual node \tilde{n}_k is chosen¹ within v_k , a dual edge \tilde{e}_h is a broken line joining the pair of dual nodes, within the pair of hexahedra having the primal face f_h in common, and passing through the *barycenter* g_{f_h} of the primal face f_h . A dual face \tilde{f}_j is a non planar surface consisting of the union of four portions; each of the portions is tailored inside an hexahedron and it has the *barycenter* g_{e_j} of edge e_j as common vertex. We will consider a pair of reference

Fig. 1. On the left side: Grid of hexahedra filling the domain of interest D . On the right side: An hexahedron v_k is shown, together with a primal face f_h , a primal edge e_j , a primal node n_i ; a dual face \tilde{f}_j , a dual edge \tilde{e}_h and a dual node \tilde{n}_k . Moreover the barycenters g_{e_j} of edge e_j and g_{f_h} of face f_h are shown.

static problems characterized by a uniform field solution: a magnetostatic (MS) and a current conduction (CC) problems, which can be formulated in a discrete way [9] as

$$\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A} = \mathbf{0} \quad (\text{MS}), \quad \mathbf{G}^T \boldsymbol{\sigma} \mathbf{G} \mathbf{V} = \mathbf{0} \quad (\text{CC}), \quad (1)$$

where \mathbf{C} , \mathbf{G} are the faces-edges and edges-nodes incidence matrices of the primal complex respectively, \mathbf{A} is the array of the circulations of the magnetic vector potential associated with the primal edges and \mathbf{V} is the array of the electric scalar potentials associated with the primal nodes. The sources are assigned by specifying proper boundary conditions; for this reason the right hand sides in (1) are null. Finally, $\boldsymbol{\nu}$, $\boldsymbol{\sigma}$ are matrices representing discrete counterparts of the constitutive relations, of dimension $\dim(\boldsymbol{\nu}) = \mathcal{F}$ and $\dim(\boldsymbol{\sigma}) = \mathcal{E}$ respectively, where \mathcal{F} , \mathcal{E} are the number of faces or edges of the primal grid. The matrix $\boldsymbol{\nu}$ or $\boldsymbol{\sigma}$ is obtained by assembling local constitutive matrices computed for each hexahedron v_k of the grid. The entry of a local constitutive matrix is now computed by forming the mass matrices with an element-wise uniform reluctivity ν or conductivity σ as

$$\boldsymbol{\nu}_{ij}^{km} = \int_{w_k} w_i^f \cdot \nu w_j^f dv, \quad \boldsymbol{\sigma}_{ij}^{km} = \int_{w_k} w_i^e \cdot \sigma w_j^e dv, \quad (2)$$

¹In the full paper, we will see that \tilde{n}_k can be in an *arbitrary* location inside v_k .

where w_i^f , w_i^e are the *mixed elements* edge and face vector functions [8] for hexahedra. The boundary conditions have been set in order to generate in D a uniform magnetic induction field of amplitude $B=1$ T and a uniform current density field of amplitude $J = 4 \cdot 10^7$ A/m² respectively, both directed as the z axis.

Correspondingly, the consistency error for volume v^k is computed as follows

$$e^{kMS} = \boldsymbol{\nu}^{km} \mathbf{C}^k \mathbf{A}^k - \mathbf{F}^k, \quad e^{kCS} = \boldsymbol{\sigma}^{km} \mathbf{G}^k \mathbf{V}^k - \mathbf{I}^k, \quad (3)$$

where the subscript k attached to an array, represents the local subarray for volume v^k and $(\mathbf{F}^k)_i = \int_{\tilde{e}_i} \mathbf{H} \cdot d\mathbf{l}$, $(\mathbf{I}^k)_i = \int_{\tilde{f}_i} \mathbf{J} \cdot d\mathbf{s}$ are the circulations and fluxes of the actual uniform magnetic field \mathbf{H} or uniform current density \mathbf{J} in v^k respectively. Considering the primal grid presented in Fig. 1, the maximum extent of $|e^{kMS}|$, $|e^{kCS}|$ is about 5.5 %.

III. NEW VECTOR BASE FUNCTIONS

In order to guarantee consistency of the constitutive matrices $\boldsymbol{\nu}$ or $\boldsymbol{\sigma}$ at least for element wise uniform fields, we will propose a novel set of vector base functions v_i^e , v_i^f attached to a primal face or to a primal edge of hexahedron v_k respectively. These vector base functions will be described in detail in the full paper, can be constructed in purely geometric way and comply with the following properties: *i*) they form a base, *ii*) they can represent a uniform field (magnetic induction \mathbf{B} , electric field \mathbf{E}) from the Degrees of Freedom (fluxes or voltages) and *iii*) they comply with the following geometric consistency properties [4]

$$\int_{v_k} v_i^f dv = \tilde{e}_i, \quad \int_{v_k} v_i^e dv = \tilde{f}_i, \quad (4)$$

where \tilde{e}_i , \tilde{f}_i are the edge and face vectors associated with \tilde{e} , \tilde{f} respectively.

 peng.98@osu.edu

Abstract— Non-overlapping domain decomposition (DD) methods with complex first-order Robin-type transmission conditions (TCs) provide an efficient iterative solution for Maxwell's equation. Unfortunately, the first order TCs do not effectively account for some eigenmodes of the system matrix, which limits the scalability of the methods. In this work, we derive a new type of Robin TCs with second order tangential derivatives to improve the performance. We then investigate the use of this new second order TCs for non-conformal and non-overlapping DD methods. Numerical results illustrate their effectiveness of the proposed methods on some model problem and on several large scale problems of practical interest.

I. INTRODUCTION

Finite Element based DD methods have recently garnered considerable attention due to their ability to accurately and efficiently solve large and multiscale electromagnetic radiation and scattering problems [2]-[4]. The methods are attractive because they allow the solution of large problems with only modest computational resources. They are also inherently parallel, an important consideration in keeping with current trends in computer architecture. In general, the DD method derives its efficiency by modifying the original large FEM problem by decomposing it into several smaller, more manageable sub-domains. The sub-domains are solved individually and the interactions between the sub-domains are communicated through a proper transmission condition (TC). TCs not only enforce the continuity of tangential fields on the interfaces, but also play a crucial role in the convergence performance of DD method.

For the vector wave equation, the majority of non-overlapping DD methods employ complex first-order Robin-type transmission conditions (FOTCs). The FOTCs provide a simple, efficient, and parallel preconditioner for the DD matrix equation that yields fast and robust iterative solution. Unfortunately, it is recognized that there are two types of eigenmodes of the DD system matrix, which are propagative and evanescent modes. the FOTCs provide a convergent solution for propagative modes, but do not effectively account for evanescent modes of the system matrix. This limits the scalability of the method and one must turn to higher order TCs to further improve the performance. Similar to the higher absorbing boundary conditions, the complete second order TCs and higher order TCs are hard to implement and the reason of that is the surface divergence terms. Instead of complete second order TCs, this work adds a second order tangential differential operator to the FOTC. We refer this

family of TCs as second order TCs (SOTCs). Here we investigate non-conformal, non-overlapping DD methods with the use of SOTCs at the interfaces of sub-domains. Numerical results demonstrate that by using the SOTCs, the convergence of DDM can be greatly improved.

II. DDM BOUNDARY VALUE PROBLEM

For simplicity, we consider only partitioning the problem domain into two sub domains. The particular DDM that we are interested in this application is the non-overlapping DDM. Thus the problem domain Ω is partitioned into two non-overlapping sub-domains, Ω_1 and Ω_2 . We shall denote the boundary that separates Ω_1 and Ω_2 by Γ_{12} . Thus, the proposed non-overlapping DDM can be formulated through the following iteration process: given \vec{E}_1^0 and \vec{E}_2^0 , for $n \geq 1$ solve

$$\begin{aligned} \nabla \times \frac{1}{\mu_{r_1}} \nabla \times \vec{E}_1^n - k^2 \epsilon_{r_1} \vec{E}_1^n &= 0 && \text{in } \Omega_1 \\ \vec{n}_1 \times \frac{1}{\mu_{r_1}} \nabla \times \vec{E}_1^n + \alpha \vec{n}_1 \times \vec{E}_1^n \times \vec{n}_1 + \gamma \nabla_\tau \times \frac{1}{\mu_{r_1}} \nabla_\tau \times \vec{E}_1^n \\ &= -\vec{n}_2 \times \frac{1}{\mu_{r_2}} \nabla \times \vec{E}_2^{n-1} + \alpha \vec{n}_2 \times \vec{E}_2^{n-1} \times \vec{n}_2 + \gamma \nabla_\tau \times \frac{1}{\mu_{r_2}} \nabla_\tau \times \vec{E}_2^{n-1} && \text{on } \Gamma_{12} \\ \nabla \times \frac{1}{\mu_{r_2}} \nabla \times \vec{E}_2^n - k^2 \epsilon_{r_2} \vec{E}_2^n &= 0 && \text{in } \Omega_2 \\ \vec{n}_2 \times \frac{1}{\mu_{r_2}} \nabla \times \vec{E}_2^n + \alpha \vec{n}_2 \times \vec{E}_2^n \times \vec{n}_2 + \gamma \nabla_\tau \times \frac{1}{\mu_{r_2}} \nabla_\tau \times \vec{E}_2^n \\ &= -\vec{n}_1 \times \frac{1}{\mu_{r_1}} \nabla \times \vec{E}_1^{n-1} + \alpha \vec{n}_1 \times \vec{E}_1^{n-1} \times \vec{n}_1 + \gamma \nabla_\tau \times \frac{1}{\mu_{r_1}} \nabla_\tau \times \vec{E}_1^{n-1} && \text{on } \Gamma_{21} \end{aligned} \quad (1)$$

α and γ are parameter to choose. It is straightforward to show that the two TCs imply the needed field continuities on the interface. Compare to the FOTC in [2], the new interface conditions add two second order tangential differential operators.

III. CONVERGENCE ANALYSIS

By using Fourier analysis [3], we can obtain the following convergence factors for the new SOTCs.

$$|\rho_{TE}| = \left| \frac{j k_z + \alpha + \gamma(k^2 - k_z^2)}{j k_z - \alpha - \gamma(k^2 - k_z^2)} \right|^2 \quad (2)$$

for the TE modes, and

$$|\rho_{TM}| = \left| \frac{\frac{j k_z^2}{k_z} + \alpha}{\frac{j k_z^2}{k_z} - \alpha} \right|^2 \quad (3)$$

for the TM modes, where we have made use of the dispersion relation $k^2 = k_x^2 + k_y^2 + k_z^2$. k_z^2 is the z-directed wave number.

By choosing $\gamma = 0$, we will obtain the first order Robin type TC. Normally we will choose $\alpha = -jk_0$ to guarantee all the TE and TM propagating modes converge. However, for the evanescent modes, $|\rho_{TE}| = |\rho_{TM}| = 1$. This is the reason FOTC has the issue of scalability with respect to mesh density or polynomial order.

Fig. 1. Convergence factor of first order Robin TC

For the new SOTC, we still choose $\alpha = -jk_0$ to obtain the same convergence rate for all the TE and TM propagating modes. Now we have an additional degree of freedom for the second order tangential differential term. This parameter is chosen to accelerate the convergence for the TE evanescent modes. We refer this type of SOTC as SOTC-TE.

Fig. 2. Convergence factor of second order TC TE

There are other forms of SOTC [5,6] by choosing different value of α and γ . The details are omitted here and will report in the future.

IV. NUMERICAL EXPERIMENT

A. Eigenspectra of DD Matrices

The first numerical experiment involves a small cubical waveguide with size of 0.5λ , which is partitioned into two sub-domains. We use it to examine the eigenspectra produced by the DD methods using the FOTC, SOTC. From Fig. 3(a) we can see that many eigenvalues lie on the shifted unit circle, which are the evanescent modes. The remaining eigenvalues within the unit circle are the propagating modes. As the mesh is refined, the number of evanescent modes increases and the eigenvalues quickly approach zero. These small but non-zero eigenvalues will significantly degrade the performance of iterative Krylov subspace method. It is clearly seen from Fig. 3(b) the eigenspectra of the SOTC shows improvements over FOTC. The evanescent modes which are nearest to zero are brought well within the shifted unit circle and the eigenvalues are clustered in the center. We also note that some eigenvalues remains unchanged and these correspond to the TM modes. However, as SOTC take care of the most troublesome evanescent modes, it is very effective in improving the condition number of the DD matrix.

Next we use an "COBRA" cavity [7] excited by plane wave and operating at 4GHz to examine the accuracy and scalability of the methods with respect to mesh size. The mesh size decreases from $h = \lambda/5$ to $\lambda/12$. Fig. 4 shows the

convergence of the FOTC and SOTC for different mesh size. We see that the performance of FOTC significantly degrade as the mesh is refined. The SOTC however, provides a near constant number of iterations as the mesh is refined.

Abstract— The meshless local Petrov–Galerkin method (MLPG) with a mixed formulation to impose Dirichlet boundary conditions is investigated in this paper. We propose the use of Shepard functions for inner nodes combined with the radial point interpolation method with polynomial terms (RPIMp) for nodes close to the Dirichlet boundaries. Whereas the Shepard functions have lower computational costs, the RPIMp imposes in a direct manner the essential boundary conditions. Results show that the technique leads to a good trade-off between computational time and precision.

I. INTRODUCTION

Meshfree methods do not need any connectivity structure among nodes, avoiding the mesh generation problem. It is a very attractive choice, especially when solving problems that involve movement, boundary and shape deformation. However, because of the absence of a mesh, a few drawbacks are introduced such as neighbour search, local matrix inversions and other computations that ultimately increase the computational cost. Consequently, in order to increase the methods efficiency special techniques should be employed. Other problem with meshless methods is the imposition of the essential boundary conditions since some of the meshless shape functions do not satisfy the Kronecker delta condition.

In [1] a mixed formulation to impose boundary conditions is presented. The moving least squares (MLS) is used for inner nodes and the radial point interpolation method with polynomial terms (RPIMp) is used for boundary nodes. However, the MLS functions are more expensive than RPIMp when the number of neighbors is low. To reduce the computational time, in this work we propose a faster shape function instead of MLS, namely Shepard functions.

In 1968 Shepard introduced shape functions in the context of data interpolation that can be interpreted as an inverse distance weighting [2]. Actually, Shepard's method is a subcase of the MLS procedure with 0th order consistency. Using the Shepard method to construct shape functions has the important advantage of low computational cost and simplicity of computation. However, the low order of consistency makes the Shepard shape functions fail for the solution of even second order boundary value problems [2]. Moreover, both MLS and Shepard have low precision when the essential boundary conditional is not well imposed. In this paper we show that when using the penalty method [3] to impose boundary conditions the results present high oscillation over the whole domain. When using the proposed mixed

formulation, the results show that the mixed method is still faster than using only RPIMp and maintains good precision. This is true even in cases where a few nodes are used for the integration of subdomains.

II. MLPG

MLPG uses a procedure named local weak form [3]. In this technique, each node defines its own sub-domain that is independent from the remaining. Those sub-domains are allowed to have any size and shape (Fig. 1) and they eliminate the need of a grid for numerical integration. Furthermore, the Petrov–Galerkin method allows the trial and shape functions to be chosen from different spaces. These two features make this method very flexible and distinguishes MLPG as a truly meshfree method.

Fig. 1. Domain representation

For electrostatic problems, the local weak form can be written as

$$\int_{\Omega_q} w(\nabla \cdot (\varepsilon \nabla V^h)) d\Omega + \alpha \int_{\Gamma_q} w(V^h - V_u) d\Gamma = 0 \quad (1)$$

where w is the test function chosen to be the Heaviside step functions which leads to a MLPG5 variant of MLPG [4]. The second integral is used to enforce Dirichlet boundary conditions by the penalty method, where α is a constant with high value (10^6).

III. SHAPE FUNCTIONS

In a broad sense, shape functions are interpolation functions [3]. The approximation function V^h is obtained by taking the sum of the known values at some points weighted by their respective shape functions. Therefore, at any point of the domain, the approximated value of the function is given by

$$V^h(\mathbf{x}) = \sum_{i=1}^n \phi_i V_i \quad (2)$$

where V_i is the fictitious nodal value of the unknown function at \mathbf{x}_i , n is the number of known points and ϕ_i is the shape function of node \mathbf{x}_i .

A. Radial point interpolation method with polynomial terms

Amongst the approximation techniques commonly used in meshless methods, the RPIMP is one of the few that will lead to a shape function that possess the Kronecker delta property [1]. However, its computational cost is higher if compared with the other approaches:

$$\phi_i(\mathbf{x}) = \mathbf{R}^t(\mathbf{x})\mathbf{S}\mathbf{a}_i + \mathbf{p}^t(\mathbf{x})\mathbf{S}\mathbf{b}_i \quad (3)$$

$$\mathbf{S}\mathbf{a} = \mathbf{R}_0^{-1}[1 - \mathbf{P}\mathbf{S}\mathbf{b}] = \mathbf{R}_0^{-1} - \mathbf{R}_0^{-1}\mathbf{P}\mathbf{S}\mathbf{b} \quad (4)$$

$$\mathbf{S}\mathbf{b} = [\mathbf{P}'\mathbf{R}_0^{-1}\mathbf{P}]^{-1}\mathbf{P}'\mathbf{R}_0^{-1} \quad (5)$$

$$\mathbf{P} = [\mathbf{p}(\mathbf{x}_1)\mathbf{p}(\mathbf{x}_2)\cdots\mathbf{p}(\mathbf{x}_n)]^t \quad (6)$$

$$\mathbf{R}^t(\mathbf{x}) = [w(\mathbf{x} - \mathbf{x}_1)w(\mathbf{x} - \mathbf{x}_2)\cdots w(\mathbf{x} - \mathbf{x}_n)] \quad (7)$$

$$\mathbf{R}_0^t = [\mathbf{R}(\mathbf{x}_1)\mathbf{R}(\mathbf{x}_2)\cdots\mathbf{R}(\mathbf{x}_n)] \quad (8)$$

where $w(\mathbf{x} - \mathbf{x}_i)$ is some weight function centered at \mathbf{x}_i , usually a Radial Basis Function (RBF), and $\mathbf{p}(\mathbf{x})$ is a vector containing monomials of a complete polynomial basis with m terms. In this work we used $\mathbf{p}^t(\mathbf{x}) = [1 \ x \ y]$.

B. Moving least squares [1]

MLS shape functions are given by:

$$\phi_i(\mathbf{x}) = \mathbf{p}^t(\mathbf{x})\mathbf{A}^{-1}(\mathbf{x})\mathbf{B}_i(\mathbf{x}) \quad (9)$$

$$\mathbf{A}(\mathbf{x}) = \sum_{k=1}^n w(\mathbf{x} - \mathbf{x}_k)\mathbf{p}(\mathbf{x}_k)\mathbf{p}^t(\mathbf{x}_k) \quad (10)$$

$$\mathbf{B}_i(\mathbf{x}) = w(\mathbf{x} - \mathbf{x}_k)\mathbf{p}(\mathbf{x}_k) \quad (11)$$

C. Shepard

The Shepard functions can be interpreted as a MLS simplification with $\mathbf{p}(\mathbf{x}) = [1]$ which leads to

$$\phi_i(\mathbf{x}) = \frac{w(\mathbf{x} - \mathbf{x}_i)}{\sum_{k=1}^n w(\mathbf{x} - \mathbf{x}_k)} \quad (12)$$

IV. MIXED FORMULATION

The mixed formulation [1] uses RPIMP to define the approximation for the nodes along the boundaries (boundary nodes) with Dirichlet boundary conditions and those close to them, and a faster shape function for the remaining nodes (inner nodes). This approach eliminates the need of using the penalty method to enforce essential boundary conditions.

Fig. 2. Mixed Formulation: black nodes are classified as boundary nodes and white nodes are classified as inner nodes. Integration of inner nodes uses a faster shape function and integration of boundary nodes uses a shape function with Kronecker delta property.

V. RESULTS

To test the approach, the problem described by Fig. 3a was simulated with an uniform 100x100 node distribution. Table I shows the relative times for the various shape functions. Using only Shepard functions we obtain the best times but due to the lower consistence order and the penalty method to impose boundary conditions, the result has lots of oscillation (Fig. 3c). The same problem occurs with MLS but in minor scale. When using mixed formulation with RPIMP + Shepard functions, the time consuming is a little higher than using only Shepard but the precision is much better (Fig. 3d).

TABLE I
COMPARISON AMONG METHODS, BASED ON RELATIVE TIMES

n	9	16
RPIMP	1.94	7.54
MLS	2.26	3.25
Shepard	1.00	1.21
RPIMP + MLS	2.20	3.86
RPIMP + Shepard	1.07	2.15

n is the number of neighbour nodes used to build the shape function approximation in a sub-domain.

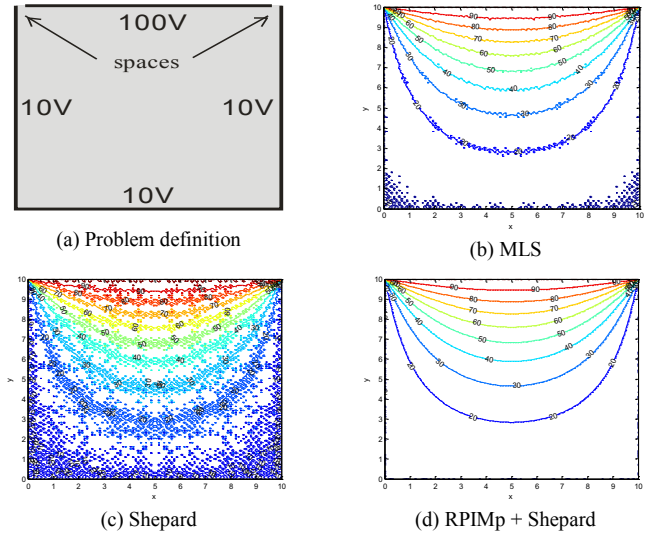

Fig. 3. Sample results. (a) defines de test problem. (b) result using MLS (c) results using Shepard (d) results using mixed formulation with RPIMP and Shepard. An uniform grid of 100x100 nodes over the domain and 9 nodes in the neighborhood of each domain (1st column of Table I) were used for all tests.

Abstract— The accuracy of the time domain magnetic field analysis occasionally dropped when the first order backward difference (backward Euler) is adopted as time integration technique. Backward Euler technique is widely applied to the analysis of various electrical machines. In this paper, the effectiveness of higher order time integration is investigated against the time domain analysis using finite element method.

I. INTRODUCTION

The magnetic field analysis in time domain is indispensable to the practical design of electric machines. The first order backward difference technique (Backward Euler method) is widely applied to the magnetic field analysis [1], [2] according to the stable characteristic in the time domain. However, the computation accuracy occasionally gets worse.

In this paper, we applied the GEAR's stiffly stable algorithm [3] to the eddy current analysis of magnetic shielding model with magnetic nonlinearity [4]. The accuracy of the higher order time integration is compared with the one of backward Euler method.

II. FORMULATION

The weighted residual G_e and G_n in the time $t = t_0$ is given as follows:

$$G_{ei}^{(t_0)} = \iiint_V (\nabla \times N_i) \cdot (\nu \nabla \times \mathbf{A}^{(t_0)}) dV - \iiint_V N_i \cdot \mathbf{J}_0^{(t_0)} dV + \iiint_V N_i \cdot \left\{ \sigma \left(\frac{\partial \mathbf{A}}{\partial t} \Big|_{t_0} + \nabla \phi^{(t_0)} \right) \right\} dV = 0, \quad (1)$$

$$G_{ni}^{(t_0)} = \iiint_V \nabla N_i \cdot \left\{ \sigma \left(\frac{\partial \mathbf{A}}{\partial t} \Big|_{t_0} + \nabla \phi^{(t_0)} \right) \right\} dV = 0, \quad (2)$$

where \mathbf{A} is the magnetic vector potential, ϕ is the electric scalar potential, N_i is the edge-based vector shape function, N_i is the nodal scalar shape function, the material constant ν and σ are the magnetic reluctivity and conductivity, \mathbf{J}_0 is the source current density, respectively. The boundary integral term can be omitted here.

The time derivative term using backward Euler method is given as follows:

$$\frac{\partial \mathbf{A}}{\partial t} \Big|_{t_0} = \frac{\mathbf{A}^{(t_0)} - \mathbf{A}^{(t_0 - \Delta t)}}{\Delta t}, \quad (3)$$

where Δt is the time step size. Introducing GEAR's stiffly stable algorithm (2nd or 3rd order) to the implicit time

integration, and then the time derivative term is expressed by multi magnetic vector potentials obtained in past several time steps as follows:

$$\frac{\partial \mathbf{A}}{\partial t} \Big|_{t_0} = \frac{3\mathbf{A}^{(t_0)} - 4\mathbf{A}^{(t_0 - \Delta t)} + \mathbf{A}^{(t_0 - 2\Delta t)}}{2\Delta t}, \quad (4)$$

$$\frac{\partial \mathbf{A}}{\partial t} \Big|_{t_0} = \frac{11\mathbf{A}^{(t_0)} - 18\mathbf{A}^{(t_0 - \Delta t)} + 9\mathbf{A}^{(t_0 - 2\Delta t)} - 2\mathbf{A}^{(t_0 - 3\Delta t)}}{6\Delta t}. \quad (5)$$

The \mathbf{A} - ϕ formulation of Newton-Raphson method in each time step is given as follows:

$$\begin{bmatrix} \mathbf{S}_{AA} & \mathbf{S}_{A\phi} \\ \mathbf{S}_{\phi A} & \mathbf{S}_{\phi\phi} \end{bmatrix} \begin{Bmatrix} \delta \mathbf{A} \\ \delta \phi \end{Bmatrix} = - \begin{Bmatrix} G_{ei} \\ G_{ni} \end{Bmatrix}, \quad (6)$$

where $\delta \mathbf{A}$ and $\delta \phi$ are the increment of \mathbf{A} and ϕ , and $\mathbf{S}_{AA} - \mathbf{S}_{\phi\phi}$ are the components of the Jacobian matrix. In the case of second order, left side matrix of (6) becomes symmetry when (2) is multiplied by $2\Delta t / 3$ in both sides. For example, components of $\mathbf{S}_{\phi A}$, $\mathbf{S}_{\phi\phi}$, and G_{ni} are described as follows:

$$\mathbf{S}_{\phi A} \Big|_{i,j} = \iiint_V \sigma \nabla N_i \cdot \nabla N_j dV, \quad (7)$$

$$\mathbf{S}_{\phi\phi} \Big|_{i,j} = \iiint_V \frac{2}{3} \sigma \Delta t \nabla N_i \cdot \nabla N_j dV, \quad (8)$$

$$G_{ni}^{(t_0)} = \iiint_V \nabla N_i \cdot \sigma \left(\frac{3\mathbf{A}^{(t_0)} - 4\mathbf{A}^{(t_0 - \Delta t)} + \mathbf{A}^{(t_0 - 2\Delta t)}}{3} + \frac{2}{3} \Delta t \nabla \phi^{(t_0)} \right) dV. \quad (9)$$

In the case of third order, left side matrix of (6) becomes symmetry when (2) is multiplied by $6\Delta t / 11$ in both sides. The components $\mathbf{S}_{\phi\phi}$ and G_{ni} are transformed as follows:

$$\mathbf{S}_{\phi\phi} \Big|_{i,j} = \iiint_V \frac{6}{11} \sigma \Delta t \nabla N_i \cdot \nabla N_j dV, \quad (10)$$

$$G_{ni}^{(t_0)} = \iiint_V \nabla N_i \cdot \sigma \left(\frac{11\mathbf{A}^{(t_0)} - 18\mathbf{A}^{(t_0 - \Delta t)} + 9\mathbf{A}^{(t_0 - 2\Delta t)} - 2\mathbf{A}^{(t_0 - 3\Delta t)}}{11} + \frac{6}{11} \Delta t \nabla \phi^{(t_0)} \right) dV. \quad (11)$$

Above formulation is same applied into more higher order time integration.

At the 1st step computation using GEAR's 2nd order, backward Euler method is adopted. Similarly, at the use of

GEAR's 3rd order computation, 1st order and 2nd order time integrations are adopted as the 1st and 2nd step computation.

III. VERIFICATION

A. Analyzed model and condition

The finite element mesh of magnetic shielding model [4] is shown in Fig. 1. The shield thickness is 1 mm, and the magnetic material is SS400. The nonlinear magnetic property of SS400 is considered. The number of elements, nodes, and unknowns of the edge-based first order hexahedral elements are 60,950, 65,753, and 185,276, respectively.
