The linear equations in NR steps were solved by ICCG solver under the convergence criterion $\|r_n\|_2 / \|r_0\|_2 < \varepsilon_{cg}$, where $\|r_n\|_2$ is a 2-norm of the residual of linear equation at the n -th iteration, here, ε_{cg} was set up as 10^{-2} . The line search technique (functional NR [0, 1.0]) [5], [6] is introduced to improve the nonlinear convergence characteristics. The Newton-Raphson iteration is terminated under the condition $|\delta B| < 10^{-3}$ T, where δB is the increment of magnetic flux density B on the element center. The waveform of current is sinusoidal with the frequency 50 Hz, and the current is imposed during two cycles.

B. Analyzed results

The numerical error and convergence characteristics in higher order time integration are compared with backward Euler method. The instantaneous eddy current loss ($t = t_0$) is computed by using

$$P_{Je}^{(t_0)} = \iiint_V \sigma \left| \frac{\partial A}{\partial t} \Big|_{t_0} + \nabla \phi^{(t_0)} \right|^2 dV. \quad (10)$$

Time step size Δt is set as 0.5556 ms, and number of time

Fig. 1. Finite element mesh (shield thickness: 1 mm).

Fig. 2. Behavior of instantaneous eddy current loss ($d = 1.0$ mm).

steps is 72. The temporal behavior of instantaneous eddy current loss is shown in Fig. 2. The standard solution is obtained from the 1,440 steps computation with the backward Euler method. Maximum value obtained from backward Euler method in steady state is improved by the utilization of 2nd or 3rd order time integration as shown in TABLE I. The nonlinear and ICCG convergence characteristics in using the higher order time integration are almost same as conventional 1st order characteristic as shown in TABLE II. It is shown that the accuracy of eddy current loss is improved by higher order time integration on the condition of nearly same CPU time.

IV. CONCLUSIONS

In this paper, GEAR's stiffly stable algorithm (2nd or 3rd order) is introduced to the time integration in the nonlinear eddy current analysis using finite element method. The accuracy of instantaneous eddy current loss is improved by utilization of higher order time integration, and convergence characteristics of ICCG and Newton-Raphson method is almost same as conventional backward Euler method. The effectiveness of GEAR's algorithm is more investigated in the practical analysis such as motor in the full paper.

Abstract — A novel meshfree point collocation method for the solving of electromagnetic potential problems with layered singularity is presented. The approximation based on the moving least squares technique is extended by introducing jump, scissor and wedge functions. It is able to model discontinuities electromagnetic potential and gradient fields. Discretization of the partial differential equations yields a linear system consisting of residual equations. Solving the system provides the nodal solutions together with jump strengths on the singular layer. Numerical experiments for electrostatic problems with layered singularity show that the developed method is highly efficient and reliable.

I. INTRODUCTION

The meshfree method [1] has been actively applied to singular problems like crack propagation problem because it has strong advantages in changing geometry modeling. It requires no connectivity among nodes in construction of the approximation function so that geometry change involves minimal node operation. However, the drawbacks such as expensive computational cost in derivative calculation, numerical quadrature and essential boundary treatment have been major obstacles to extension of the Galerkin based meshfree method to more various applications. Therefore, despite of the advantageous geometry modeling, application to the interface problems like electrostatic problem with layered singularity rarely appeared.

The meshfree point collocation method overcomes the drawbacks stated above. It was already applied to fluid and solid problems [2]-[3] and proved to be simple and fast in the formulation and computation, respectively. Kim and Kim [4] solved electromagnetic problem with complex geometry by using the meshfree point collocation method. Furthermore, heat conduction problem with interface has been successfully solved using only regular node set [5]; special functions generating derivative discontinuity across the interface was devised and immersed in the approximation so that numerical complexity due to the singularity was effectively eliminated.

This study presents a novel meshfree point collocation method for solving electrostatic problem with layered singularity. This work is an extension of [5]. New meshfree approximation to be proposed here is able to model jumps not only in the potential field but also in the normal and tangential derivative fields. Nodal operation is very easy since it does not require grid structure. The numerical scheme inherits the framework of the conventional meshfree point collocation method. The discretization of partial differential equation is

straightforward. In the next, the brief review and important numerical features of the method are presented.

II. EXTENDED MESHFREE APPROXIMATION

An electrostatic problem with layered singularity is considered. The layered singularity brings about jumps in the potential and the gradient fields. For easy awareness of the approximation, let us take one dimensional case into account. For a given function $u(\mathbf{x}) \in C^m(\bar{\Omega})$, m-th order Taylor polynomial at arbitrary position \mathbf{y} is given by

$$\begin{aligned} u_L(x, y) &= u(y) + \left(\frac{x-y}{\rho}\right) \frac{\rho}{1!} u^{(1)}(y) + \left(\frac{x-y}{\rho}\right)^2 \frac{\rho^2}{2!} u^{(2)}(y) \\ &+ \dots + \left(\frac{x-y}{\rho}\right)^m \frac{\rho^m}{m!} u^{(m)}(y) \\ &= \mathbf{p}_m^T \left(\frac{x-y}{\rho}\right) \mathbf{a}(y) \end{aligned} \quad (1)$$

which yields the local approximation of $u(\mathbf{x})$. The components of $\mathbf{a}(y)$ include the derivative of $u(x)$ at y up to m-th order and $\mathbf{p}_m^T \left(\frac{x-y}{\rho}\right) = \left(1, \left(\frac{x-y}{\rho}\right), \left(\frac{x-y}{\rho}\right)^2, \dots, \left(\frac{x-y}{\rho}\right)^m\right)$. ρ indicates the radius of influence; it turns into the radius of weight function in the Moving Least Squares procedure. The unknown vector $\mathbf{a}(y)$ is obtained from the stationary condition of the weighted residual constructed at each node as is in the conventional meshfree methods.

Let us consider the approximation near singular layer. For the jump modeling in potential field, heavy-side step function $b_\Gamma(\mathbf{x})$ is introduced into the approximation; for the jump modeling in the normal and tangential derivative fields, wedge function $b_n(\mathbf{x})$ and scissor function $b_t(\mathbf{x})$ are employed respectively. The regular approximation in (1) takes the form as following

$$\begin{aligned} u_L(x, y) &= \mathbf{p}_m^T \left(\frac{x-y}{\rho}\right) \mathbf{a}(y) + \frac{1}{2} [u]_\Gamma b_\Gamma(\mathbf{x}) \\ &+ \frac{1}{2} \left[\frac{\partial u}{\partial n} \right]_\Gamma b_n(\mathbf{x}) + \frac{1}{2} \left[\frac{\partial u}{\partial t} \right]_\Gamma b_t(\mathbf{x}) \end{aligned} \quad (2)$$

where $\frac{1}{2} [u]_\Gamma$, $\frac{1}{2} \left[\frac{\partial u}{\partial n} \right]_\Gamma$, and $\frac{1}{2} \left[\frac{\partial u}{\partial t} \right]_\Gamma$ stands for the strengths of the jumps in potential, normal derivative and tangential derivative fields, respectively. The strengths are obtained from the governing equations. \mathbf{n} and \mathbf{t} are the normal and tangential vector to the singular layer Γ . The mathematical background can be referred to [5]. The unknown vector $\mathbf{a}(y)$ can be

calculated by the same manner as in regular approximation. The derivative of the extended meshfree approximation can then be written as

$$\begin{aligned}
 D_x^\alpha u^h(\mathbf{x}) &= \sum_I \Phi_I^\alpha(\mathbf{x}) u_I \\
 &+ \frac{1}{2} [u]_\Gamma \left\{ D_x^\alpha b_\Gamma(\mathbf{x}) - \sum_I \Phi_I^\alpha(\mathbf{x}) b_\Gamma(\mathbf{x}_I) \right\} \\
 &+ \frac{1}{2} \left[\frac{\partial u}{\partial n} \right]_\Gamma \left\{ D_x^\alpha b_n(\mathbf{x}) - \sum_I \Phi_I^\alpha(\mathbf{x}) b_n(\mathbf{x}_I) \right\} \\
 &+ \frac{1}{2} \left[\frac{\partial u}{\partial t} \right]_\Gamma \left\{ D_x^\alpha b_t(\mathbf{x}) - \sum_I \Phi_I^\alpha(\mathbf{x}) b_t(\mathbf{x}_I) \right\}
 \end{aligned} \tag{3}$$

where multi-index notation is used for the sake of convenience.

The differential operator denotes $D_x^\alpha := \partial_{x_1}^{\alpha_1} \partial_{x_2}^{\alpha_2} \dots \partial_{x_n}^{\alpha_n}$; $\Phi_I(\mathbf{x})$ is the regular meshfree shape function; $\Phi_I^\alpha(\mathbf{x})$ is α -th derivative of the shape function.

III. DISCRETIZATION

The Poisson type partial differential equations for the electrostatic problem with layered singularity are given by

$$\nabla \cdot (\beta \nabla u) = f \text{ in } \Omega \setminus \Gamma \tag{4}$$

$$u = \bar{u} \text{ on } \partial\Omega \tag{5}$$

$$[u]_\Gamma = \bar{g} \text{ on } \Gamma \tag{6}$$

$$\left[\beta \frac{\partial u}{\partial n} \right]_\Gamma = \bar{h} \text{ on } \Gamma \tag{7}$$

where f and β denotes electromagnetic source and permeability, respectively. Discontinuous β generates jump across Γ in the potential and the gradient fields and f may be discontinuous. It should be noted that Laplace equation without permeability term can also be solved easier than the PDE given in (4)-(7).

The governing equations are discretized based on nodes. Difference equations (or residual equations) are constructed at each node. The equations involve the derivative approximation of (3) and set up the linear algebraic system. Solving of the system yields nodal solution and jump strengths.

IV. NUMERICAL RESULTS

For numerical validation of the developed method, an electric potential function $u(x, y)$ governed by (4)-(7). Fig. 1(a) depicts the geometry and boundary of the problem. In computing the meshfree shape function, we used second-order basis polynomial, i.e. $m=2$. The singular layer is discretized with sufficient number of points that are irrelative to nodes. Nodal solutions are obtained at the nodes together with the strength of jumps at the layer points. The conjugate gradient solver is used. As shown in fig 1(b), the number of CGM iterations for this problem with 6400 nodes is around 180, which achieve the successive tolerance implying that the stiffness matrix is well conditioned. Fig 2(a) shows the convergence rate of L^∞ relative error for the potential and gradient. The order of accuracy appears to be more than second order. Fig 2(b)-2(d) illustrates surface plots for the

electrostatic potential, x and y components of the gradient, respectively. Note that the jumps are captured sharply without smearing. These computational results reveal that the developed method is efficient, accurate and robust in solving electromagnetic problems with layered singularity.

ping@ansoft.com

Abstract — This paper details the derivation of the Jacobian matrix and the residual vector in terms of the T-Ω formulation. Then, a scheme is proposed to efficiently find the optimum relaxation factor for improving global convergence. Further, a local damping factor is introduced to address some local convergence issues by damping the updating of the nonlinear material property during nonlinear iterations.

I. INTRODUCTION

The Newton sequence with an arbitrary initial guess may converge at a very slow rate, or oscillate, or even diverge. It is also known that convergence is more difficult with the magnetic scalar potential than with magnetic vector potential [1]. Hence, under-relaxation is commonly used to improve convergence. If an optimum relaxation factor is used, convergent solution can always be obtained using a linear search algorithm [1]. However, it may take a very long time to find the optimum relaxation factor. [2] uses linearization to reduce the computation cost based on two values of the residual. However, the assumption that the residual changes quadratically with the relaxation factor is far from reality for most practical applications. In addition, the use of the optimum relaxation factor does not guarantee fast convergence because the “optimum” is only in the global sense and thus may not be suitable for some local elements. This may lead to poor local convergence due to large over-shoot correction or possible oscillation. This undesirable local convergence behavior may also have a significant impact on solution accuracy, such as in the case of considering eddy current in the nonlinear region.

In this paper, the Jacobian matrix and the residual vector are first derived in terms of the T-Ω formulation. Then, a method is proposed to efficiently find the optimum relaxation factor for improving global convergence performance. Further, to address the local convergence issue, a local damping scheme is introduced to damp the updating of the nonlinear material property for a small portion of elements that exhibit the largest changes in the equivalent dynamic permeability.

II. NEWTON NONLINEAR T-Ω FORMULATION

To apply Newton’s method, let us define

$$F_1(\Omega, \mathbf{T}) = \nabla \times \frac{1}{\sigma} \nabla \times \mathbf{H} + \frac{d\mathbf{B}}{dt} \quad (1.a)$$

$$F_2(\Omega, \mathbf{T}) = \nabla \cdot \mu \mathbf{H} = \nabla \cdot \mu (\nabla \Omega + \mathbf{T} + \mathbf{H}_p) \quad (1.b)$$

where \mathbf{H}_p is the source field component. The corresponding Newton iteration forms are

$$-F_{1(\partial T)}^k (\mathbf{T}^{k+1} - \mathbf{T}^k) - F_{1(\partial \Omega)}^k (\Omega^{k+1} - \Omega^k) = F_1^k \quad (2.a)$$

$$-F_{2(\partial T)}^k (\mathbf{T}^{k+1} - \mathbf{T}^k) - F_{2(\partial \Omega)}^k (\Omega^{k+1} - \Omega^k) = F_2^k \quad (2.b)$$

Taking the Frechet partial derivative of $F(\Omega, \mathbf{T})$ and performing some manipulations, we arrive at

$$\begin{aligned} F_{1(\partial T)}' &= \nabla \times \frac{1}{\sigma} \nabla \times () + \frac{1}{dt} [\hat{\mu}] () & F_{1(\partial \Omega)}' &= \frac{1}{dt} [\hat{\mu}] \nabla () \\ F_{2(\partial T)}' &= \nabla \cdot [\hat{\mu}] () & F_{2(\partial \Omega)}' &= \nabla \cdot [\hat{\mu}] \nabla () \end{aligned} \quad (3)$$

where tensor $[\hat{\mu}]$ can be considered as an equivalent dynamic permeability and derived by [3]

$$[\hat{\mu}] = \frac{\partial \mathbf{B}}{\partial \mathbf{H}} = \mu + \frac{\mu' - \mu}{H^2} (\underline{\mathbf{H}} \cdot \tilde{\mathbf{H}}) \quad (4)$$

where μ' is the permeability derivative. After discretization of (2), applying the Galerkin method, and integrating over the problem domain V , we have

$$J_{11} (\underline{\mathbf{T}}^{k+1} - \underline{\mathbf{T}}^k) + J_{12} (\underline{\Omega}^{k+1} - \underline{\Omega}^k) = \underline{\mathbf{R}}_1 \quad (5.a)$$

$$J_{21} (\underline{\mathbf{T}}^{k+1} - \underline{\mathbf{T}}^k) + J_{22} (\underline{\Omega}^{k+1} - \underline{\Omega}^k) = \underline{\mathbf{R}}_2 \quad (5.b)$$

where J_{11} , J_{12} , J_{21} and J_{22} are the blocks of the Jacobian matrix

$$J_{11} = \int \underline{\mathbf{t}} F_{1(\partial T)}^k \tilde{\mathbf{t}} dV \quad J_{12} = \int \underline{\mathbf{t}} F_{1(\partial \Omega)}^k \tilde{\alpha} dV \quad (6)$$

$$J_{21} = \int \underline{\alpha} F_{2(\partial T)}^k \tilde{\mathbf{t}} dV \quad J_{22} = \int \underline{\alpha} F_{2(\partial \Omega)}^k \tilde{\alpha} dV$$

and $\underline{\mathbf{R}}_1$ and $\underline{\mathbf{R}}_2$ are the residual vector

$$\underline{\mathbf{R}}_1 = - \int \underline{\mathbf{t}} F_1^k dV \quad \underline{\mathbf{R}}_2 = - \int \underline{\alpha} F_2^k dV \quad (7)$$

The details of derivation will be provided in the full paper. To consider the material property variations within the element, Gauss quadrature numerical integration is used in (6) and (7).

III. OPTIMUM RELAXATION FACTOR SEARCHING ALGORITHM

In order to reduce computation time, the following searching algorithm for the optimal under-relaxation factor is proposed: Let the relaxation factor α (between 1 and zero) be equally sampled with step of 0.2 as shown in Fig. 1. Here, $\alpha=0$ corresponds to the previous Newton iteration solution and $\alpha=1$ to the ordinary nonlinear Newton iteration scheme. The residuals at these two values of α are already available as part of the regular solution process. Thus, the evaluation of the residual can start from $\alpha=0.8$. For each α , after the solution candidate is obtained, we update the permeability and compute the residual. If the current residual is smaller than the previous one, we continue to the next value of α . If the current residual is greater, we use the current and the previous two values of α to construct a quadratic polynomial and find the optimal under-relaxation factor associated with the minimum residual value. If for $\alpha=0.2$, the corresponding residual value still does not increase, the sub-region of α between 0.2 and 0 is further sub-divided with a step of 0.05 and the search is continued.

Fig. 1 Search for the optimal under-relaxation factor

In order to improve efficiency, a large step size of 0.2 is used in the above algorithm. This has the added advantage of making the algorithm less sensitive to local minimum. However, the large step size may lead to a large error in the computed optimal under-relaxation factor. To address this, we can insert two additional α points in between the above obtained three points and compute corresponding residuals. This will effectively reduce the step size to 0.1 and the optimal under-relaxation factor will be determined based on the appropriately selected set of three points: the point with the smallest residual and two neighbouring points on each side.

IV. LOCAL MATERIAL UPDATE DAMPING ALGORITHM

A local damping factor β is introduced for updating $[\hat{\mu}]$

$$[\hat{\mu}]^{k+1}_{actual} = [\hat{\mu}]^k + \beta([\hat{\mu}]^{k+1} - [\hat{\mu}]^k) \quad (8)$$

It should be emphasized that this modification should be applied to only a very small percentage of elements with the highest rate of change in the equivalent dynamic permeability tensor. This ensures that the efficiency of Newton-Raphson approach will not be adversely affected. The number of elements to be damped can be determined by

$$n = 3 * \ln\left(\frac{N_e}{n_0}\right) \quad \text{when } N_e > n_0 \quad (9)$$

where N_e is the total number of nonlinear elements in the solved domain and n_0 is the nonlinear element size threshold. The local damping algorithm is only applied if the element size is greater than this threshold.

The first step is to identify the n elements with the highest values of k_e out of entire set of nonlinear elements, where k_e is the change rate of $[\hat{\mu}]$. Next, the smallest k_e in the list is used as the reference damping rate k_{ref} . Thus, the damping factor for each element of the n elements is determined by

$$\beta = 0.35 + 1.5e^{-\frac{k_e}{k_{ref}}} \quad (10)$$

The range of β from (10) is approximately between 0.35 and 0.9. The lower bound is used to avoid over damping; the upper bound is used to prevent altering of the convergence property of the Newton-Raphson method due to a trivial modification.

V. BENCHMARK EXAMPLE

The benchmark problem No. 10 of TEAM Workshop is used here to check the nonlinear convergence and simulation accuracy [4]. The investigation includes three scenarios: constant under-relaxation factor; the adaptive optimal relaxation factor without local damping; and the adaptive optimal relaxation factor with local damping. Table 1 shows the comparison of the computation time for the three cases.

TABLE I. COMPUTATION TIME COMPARISON (37,385 ELEMENTS)

Relaxation algorithm	Time
Constant relaxation factor $\alpha = 0.1$ (greater than 0.1 does not converge)	32 hours 47 minutes
Optimal relaxation factor without local damping	3 hours 2 minutes
Optimal relaxation factor with local damping	2 hours 14 minutes

Fig. 2 shows the comparison of the computed average flux densities over the cross sections S_1 , S_2 , and S_3 [4] between the cases with local damping and without local damping. Fig. 3 compares the induced eddy current densities at the points P_1 , P_2 , and P_3 of the nonlinear conducting steel channels [4] for the cases with and without local damping. Measurement profiles for both average flux densities and the induced eddy current densities can be found in [4]. It is clear that while the local damping algorithm does not show obvious effects on the computed flux densities, it does have a significant impact on the more sensitive induced eddy current densities. The local damping algorithm has effectively eliminated the unphysical noises which also appeared in other researches' results [4]-[5].

yamazaki.katsumi@it-chiba.ac.jp

Abstract — A time-stepping adaptive finite-element method is proposed for shape optimization of rotating machines. In the proposed method, different mesh-modification procedures are applied to the core and the other regions, respectively, for the purpose of the fast iron-loss calculation. A method of automatic separation and connection between the stator and rotor meshes are introduced for the rotation. The proposed method is applied to the shape optimization of a permanent magnet motor for the loss reduction. The usefulness of the proposed method is clarified.

I. INTRODUCTION

It is well known that most of the electrical energy is produced by rotating generators and that nearly half of the energy is consumed by the rotating motors in industrialized countries. Owing to environmental problems, the optimization of the rotating machines from viewpoint of the loss minimization has become one of the important subjects.

In these cases, automatic mesh-generation techniques and time-stepping analyses that consider the harmonics in the machines are often required. The adaptive finite element method [1]-[5] must be effective in automatically obtaining the appropriate mesh for each shape. In the method, the finite elements are iteratively generated due to the error estimations of the electromagnetic field.

However, few papers applied the adaptive finite-element meshing to the optimization of the rotating machines using the time-stepping analysis. One reason is the vast computation time by the multiple loops of the time stepping and adaptive finite-element meshing. Reference [4] proposed the mesh modification at each time step. It can reduce the number of the iterative calculation. However, the estimation of the iron loss in the stator and rotor cores requires the fixed mesh during one time-period [6]. In addition, more generalized mesh-modification technique for the rotation of the rotor is desired.

From these viewpoints, we propose a novel procedure of

the time-stepping adaptive finite-element method for the shape optimization of the rotating machines. In the method, different mesh-modification procedures are applied to the core and the other regions, respectively, for the purpose of the fast iron-loss calculation. A method of automatic separation and connection between the stator and rotor meshes are also introduced in order to take the rotation into account. The proposed method is applied to the shape optimization of a permanent magnet motor for the loss reduction. The usefulness is confirmed.

II. MESH GENERATION PROCEDURE

A. Mesh modification due to rotation

Fig. 1 shows the modification method of the adaptive finite-element mesh due to rotation of the rotor. First, the stator and rotor meshes used in the last time-step are separated. After rotating the rotor, the stator and rotor regions are automatically connected. This mesh is used for the initial mesh of the adaptive-mesh iteration in the next time-step. In the separation of the stator and rotor regions, only the elements that cross the center line of the air gap are removed. By using this procedure, most of the elements in the last time-step can be utilized for the next time-step. As a result, the number of the adaptive-mesh iteration can be reduced because the difference in the electromagnetic field during one time-step is slight.

B. Mesh modification due to elemental error estimation

The error estimations of the finite elements [2] are carried out at each time-step. The finite element meshes at each part of the machine is modified due to the estimated errors. In the proposed method, different mesh-modification procedures are applied in the core and the other regions as shown in Table I.

In the core region, a fixed mesh during one time-period is required for the iron-loss calculation [6]. Therefore, following procedure are employed during two time-periods of the

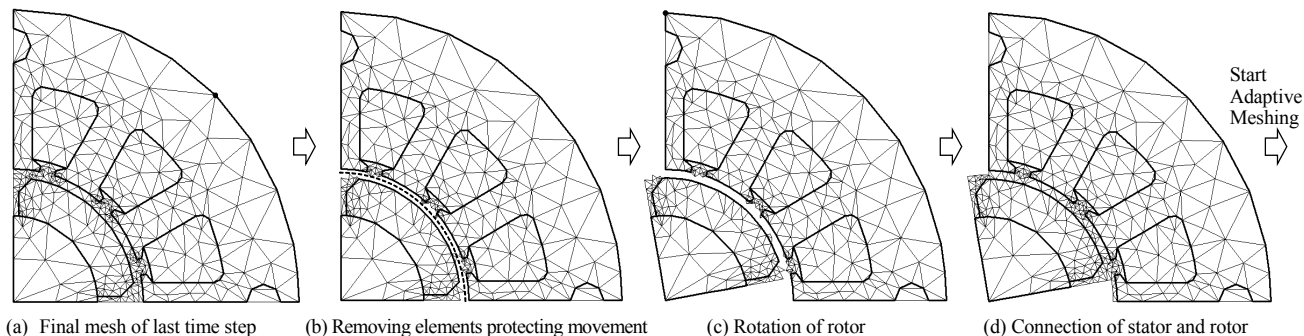

Fig. 1. Mesh modification due to rotation.

TABLE I

METHOD OF MESH MODIFICATION DUE TO ERROR ESTIMATION

	1 st time period	2 nd time period
Core region	Addition of nodes	Fixed
Other regions	Addition and cancellation of nodes	

Fig. 2. Number of elements during optimization.

Fig. 3. Fixing mesh in core for iron-loss calculation

rotation: In the first time-period, nodes are simply added on the elements whose estimated error is larger than the permissive error at each time-step. Consequently, the number of the finite elements in the core increases in this time-period. The final mesh obtained by this procedure can be regarded as satisfying the permissive error at any angle of the rotor. Therefore, in the second time-period, the mesh in the core is fixed to the final mesh of the first time-period. Then, the iron loss is obtained from the solution of the second time-period.

On the other hand, in the other regions including the air gap, the fixed mesh is not required. Therefore, not only the node addition but also the node cancellation [4] is applied to avoid increasing the number of the elements in both the first and the second time-periods.

Although the proposed method requires the analysis during the two time-periods, practical results and computation time are expected because the method can reduce the number of the adaptive-mesh iterations.

III. APPLICATION

The proposed method is applied to the shape optimization of an interior permanent-magnet motor. The Rosenbrock's method is combined with the proposed method. The design variables are the coordinates on the top of the stator teeth. The

(a) Conventional

(b) Optimized (106th optimization step)

Fig. 5. Experimental and calculated iron losses (Current 300 A, 80deg).

objective function is the efficiency of the motor. The total calculation time is 8h 48m using a Pentium 4, 3.6GHz PC.

Fig. 2 shows the number of the finite elements. It can be observed that the number of the elements increases in the first time-period and becomes constant in the second time-period. Fig. 3 shows the variation in the finite element mesh during the second time-period. It indicates that the meshes in the core are fixed during this period for the iron-loss calculation in the core.

Fig. 4 shows the conventional and optimized stator tooth. Fig. 5 shows the measured and calculated iron losses including the magnet eddy current loss. The loss is reduced to 70% by the optimization, while the torque is nearly the same. The usefulness of the proposed method is confirmed.

Abstract—This paper proposes a concurrent ray tracing algorithm for rotationally symmetric problems improving central parts from $O(\log(n))$ to $O(1)$ time complexity. Rotationally symmetric problems arise naturally when computing the heating generated by high frequency wake fields in cryogenic particle accelerator structures.

I. INTRODUCTION

Ray tracing methods are well researched for general three dimensional problems, but relatively little effort has been spend to develop improved ray tracing algorithms for purely rotationally symmetric cases. However, these cases do occur when computing the wall heating generated by high frequency wake fields in particle accelerator structures. For this purpose ray tracing has been used e.g. in [1].

Fig. 1. A modern particle accelerator structure

Modern particle accelerator structures require an elaborate cryogenic infrastructure [5]. To estimate the required cooling capacity, it is necessary to estimate all effects heating the structure. The algorithmic improvements proposed later in this paper are used to estimate the heating energy generated by high frequency wake fields. Wake fields are usually spurious electromagnetic fields generated by the accelerated particles. (For details see [2],[3] or [5]). Wake fields will lower the kinetic energy of the particles that get accelerated, heat the cryogenic structure and lower the efficiency of the accelerator.

II. LINEAR OPTICS

Using the Lorenz gauge, Maxwell's equations can be transformed into a set of wave equations (see e.g. [6][4]). Therefore every solution of Maxwell's equations can be constructed from plane waves. For sufficiently high frequencies the accelerator structures can be assumed being large in comparison to the wavelength. Therefore the approximations done by linear optics are applicable. As usual in linear optics the electromagnetic field is approximated by rays. These rays are interpreted as the trajectories of photons. It is further assumed that the shape of the accelerator structures is smooth and

Fig. 2. Example trace generated by the proposed algorithm

that its curvature is small in relation to the wave length. Reflections on the surface of the structure are then sufficiently approximated as reflections on a flat surface tangent to the reflection point. For an incoming ray with energy E_{in} and angle θ_{in} and the outgoing ray with energy E_{out} and angle θ_{out} the central equations are:

$$\begin{aligned}\theta_{in} &= \theta_{out} \\ E_{in} &= t(\omega) E_{out}\end{aligned}$$

where $t(\omega) \in [0, 1]$ is the energy transmission coefficient and $1 - t(\omega)$ is the energy heating the structure.

III. OPTIMIZED CONCURRENT RAY TRACING FOR ROTATIONALLY SYMMETRIC STRUCTURES

The first step in building an efficient algorithm for this problem is the development of an efficient representation of the rotationally symmetric cavity in which the wake field is propagating. Mathematically, the cavity is simply represented as a curve

$$\begin{aligned}\gamma : [0, e] &\rightarrow \mathbb{R}^2 \\ e &\in \mathbb{R}\end{aligned}$$

that will be rotated around the x-axis. For an efficient computational representation a curve should be build from simple predefined curves like lines or elliptical arcs. These curve building blocks are called segments. The curve is then constructed using the following concatenation rule where $\gamma_1 : [0, e_1] \rightarrow \mathbb{R}^2$ and $\gamma_2 : [0, e_2] \rightarrow \mathbb{R}^2$ with $\gamma_1(e_1) = \gamma_2(0)$:

$$\gamma := t \mapsto \begin{cases} \gamma_1(t) & \text{if } t \in [0, e_1] \\ \gamma_2(t - e_1) & \text{if } t \in [e_1, e_1 + e_2] \end{cases}$$

Using this rule is simple if all segment types (e.g. lines or elliptical arcs) are defined relative to a starting point. Building the curve of the structure becomes:

- 1) set current start point to initial start point
- 2) add new segment relative to current start point
- 3) set current start point to end point of new segment
- 4) if not finished repeat with 2.

This sequence resembles the building of a list of segments. Thus the most efficient way to store this list is as a plain array of an algebraic data type called segment. Algebraic data types are types that combine a finite number of parameterized choices. In our implementation a segment is either a line or an elliptical arc. Further details on algebraic data types can be found in [8]. Despite their usefulness algebraic data types are not directly supported by commonly used languages like C. However they can be easily expressed by using a union type:

Listing 1. Algebraic Data Type Mimicry in C

```

union segment_t {
  enum { ELLIPSE_SEG, LINE_SEG } type;
  struct {
    size_t padding; /*enum storage*/
    ... /* ellipse data */
  } ellipse;
  struct {
    size_t padding; /*enum storage*/
    ... /* line data */
  } line;
};

```

The code that generates the example trace in Fig. 2 uses this technique, which is more awkward to use than a natively supported algebraic data type, but works fine. With this type the whole geometry is storable as a compact array. For generic 3D ray tracers the best memory structure representing the scene is a tree structure. In this case we are able to use an array and therefore improve time complexity from $O(\log(n))$ to $O(1)$. Besides of having an $O(1)$ read and write time complexity the array has a higher locality of the data and is therefore more cache efficient as well.

To achieve an efficient concurrent implementation it is important to remember that data written by several threads should not be near each other since otherwise the requirement of cache coherency in concurrent systems will cause a lot of cache reloads. Therefore concurrency is exploited by assigning each thread the task to compute the trace of a given initial ray.

IV. THE TRACE OF A RAY

The trace of a ray is represented as an array of rays with some additional data, where the start point of each ray is the collision point of the previous ray with the structure. There are two additional values that should be recorded in the trace for fast trace analysis. First the index number of the segment a ray collides with, second the arc length from the beginning of the curve to the point of collision. If the collision is at $\gamma(t_{coll})$ it is necessary to compute the integral

$$s_{coll} = \int_0^{t_{coll}} \sqrt{\gamma'_x(t)^2 + \gamma'_y(t)^2} dt$$

where γ_x and γ_y denote the x and y component of the curve describing the whole structure. Even if it is not computationally cheap to integrate this for certain segments like for the elliptical segments of our code, it is straightforward to compute a numerically cheap approximation of this arc length function, when the geometry is build up. Thus, during the ray tracing process evaluation of the integral is computationally efficient.

V. OPTIMIZED TRACE ANALYSIS

Given several traces of rays, the next and final step is to count the rays hitting every surface element summing up the energy transferred onto these elements of the structure. For this part of the algorithm the computed arc length can be used cheaply to store this data in an array (Fig. 2) where again usually a tree structure would be required. This improves the time complexity from $O(\log(n))$ to $O(1)$ for this part of the algorithm.

Fig. 3. storage organisation of final result data

VI. CONCLUSION

Rigorously exploiting the benefits a rotationally symmetric problem allows strong simplifications for central parts of the ray tracing algorithm. Commonly required tree data structures can be replaced with arrays, improving time complexity from $O(\log(n))$ to $O(1)$ for operations on these structures. The upcoming full paper will contain more details on the algorithm, simulation results and benchmarks for realistic linear particle accelerator.

VII. ACKNOWLEDGEMENTS

The authors thank Prof. Dr. J. Struckmeier from the mathematics department and Prof. Dr. J. Roßbach from the physics department of the university of Hamburg for their kind cooperation.

Hierarchical Sparsified Models for the Substrate of Integrated Circuits

Daniel Ioan and Gabriela Ciuprina

”Politehnica” University of Bucharest, Electrical Engineering Faculty, Numerical Methods Lab.
Splaiul Independenței 313, 060042, Bucharest, Romania
lmm@lmm.pub.ro

Abstract—The paper proposes a new approach for the efficient modeling of the substrate in integrated circuits. The approach is valid at intermediate frequencies, the electroquasistatic field being used in conjunction with the magnetostatic field. The main idea is to perform a hierarchical sparsification based on an exponential partitioning scheme of the substrate with an impressive impact on the model extraction time. A circuit model of linear complexity is extracted.

I. INTRODUCTION

With the continuous downscaling of CMOS devices analog, RF and digital circuitry are integrated on a single chip. However, due to the conducting nature of the common substrate, noise generated by the digital circuitry can be easily injected into and propagate through the silicon substrate. Accurate and efficient modeling of the electromagnetic effects in the semiconductor substrate is an important still open problem for the EDA community [1], [2].

The IC substrate is a semiconductor body represented by computational domains of rectangular shapes. It is usually structured in homogeneous layers, with constant material parameters. The traces of the circuit devices on the top surface of the substrate are called *connectors* or *contacts*. The bottom surface of the substrate is the *backplane contact*, which is usually a grounded or a floating metallic layer [3]. The top surface of the computational domain and its lateral surfaces have a virtual character, being conventional cuts in the real semiconductor substrate body. The contacts are also conventional surfaces [1], [3]. The number, shapes and sizes of the contacts are very much dependent of the actual circuit layer as well as of the modeling approach. Inhomogeneous high-conductivity layers and structures such as the epi-layer, wells, diffusion gradients, and buried layers are usually included in the substrate models, but a simpler solution we will consider is the one in which the modeled substrate contains only the homogeneous Silicon bulk.

The substrate models are based on electromagnetic (EM) field modeling. The choice of the most appropriate EM field regime for a particular model of the substrate is dependent on the values of the material constants, as well as on the required operating frequency-range. In the low frequency case, the substrate behavior is well described by static regimes, the most appropriate model being obtained by using in conjunction electrostatics (ES), electric conduction (EC) and magnetostatics (MS). Only for inhomogeneous substrate structures the

use of electroquasistatic (EQS) in conjunction with MS can be justified. Numerical studies in [4] show that the EQS assumptions are not valid in the case of high-resistivity substrates at frequencies above 20 GHz. In the case of low-resistivity substrates EQS can be used at least for frequencies up to 100 GHz.

Even in the simplest static regimes, the complexity of the extracted model with n connectors is $O(n^2)$, since the number of lumped circuit elements linking the connectors is given by $n(n+1)/2$. For instance, millions of R, L or C elements are required to model 2000 connectors in EC, MS or ES regimes. RC ”equivalent” circuits are extracted from the EQS field solution. Fortunately, not all these elements have a similar importance in the model, as many of them describe weak interactions. Typical examples are links between far connectors or connectors screened by other connectors. The procedure to approximate a model with another of smaller size (with fewer elements) is called *sparsification*. The name is inspired by the fact that the admittance matrix of the new model is a sparse one, whereas the original matrix is dense. Several hierarchical approaches are described in [1], [5].

II. HIERARCHICAL APPROACH

The substrate modeling approach we propose is valid at frequencies where the EQS regime may be considered valid. In order to model also the magnetic/inductive field effects, we consider in the substrate the EQS field in conjunction with the MS one. Thus two independent models are extracted, to be connected in the global model of the IC. We use for this the domain partitioning (DP) technique as described in [6]. The IC devices and the substrate interact by means of EM *hooks* [6]. The hierarchical sparsification we propose is based on an exponential partitioning scheme of the substrate (Fig. 1).

Virtual contacts (hooks) are buried in the substrate at

Fig. 1. Partitioning of the substrates in macro-cells.

different depths (according to their levels), thus realizing a domain-partitioning of the substrate in horizontal layers structured in rectangular super-elements (macro-cells). The cell-walls generate thus an adapted *discretization macro-grid*, progressively refined from bottom to top. Unlike the literature, in our approach, the equivalent contacts have a physical meaning, being the terminals of the macro-cells. Thus, sparse hierarchical circuit-models with reduced number of lumped elements are generated. Moreover, since the macro-cells have similar geometries, the field has to be computed (and consequently the circuit model has to be extracted) only in one of them, *the standard cell*. For instance, considering such a cell with 14 terminals, 9 on the top face and one on bottom, the number of levels is $\ln(n)/\ln(9)$ and the total number of cells is $(n-1)/8$, while the complexity of the equivalent circuit is $O(11n)$. A model with six levels can handle about one million top-connectors, using about ten millions lumped elements. The linear order of the extracted model is another great advantage of this approach.

The main reason which makes our hierarchical sparsification approach valid is the exponential decay of the field variation on deeper horizontal planes. For instance, in EC, ES and MS field regimes, the scalar potential satisfies in homogeneous media the Laplace equation. By imposing zero Dirichlet boundary conditions on the bottom surface ($z = 0$), zero Neumann on vertical sides ($x = 0, x = a, y = 0, y = b$) and by using a double Fourier series, it can be proved that the Fourier coefficients of the solution $V(x, y) = \sum_{i=0}^n \sum_{j=0}^n V_{ij} \cos(\lambda_i x) \cos(\mu_j y)$ satisfy $|V_{ij}/V_0| \leq ab/(4\pi^2 ij) \exp\left(-\sqrt{\lambda_i^2 + \mu_j^2}(c-z)\right)$.

The Fourier series may be truncated, but in order to keep a minimal accuracy on the top surface ($z = c$), the number of retained terms (spatial harmonics along each direction) should be at least the total number of contacts in that direction. On deeper planes $z < c$, for same accuracy ε , only a lower number of terms n_z, m_z may be retained:

$$\varepsilon = \frac{ab}{4\pi^2 nm} \geq \frac{ab}{4\pi^2 n_z m_z} \exp\left(-\sqrt{\lambda_i^2 + \mu_j^2}(c-z)\right). \quad (1)$$

Going down in the substrate, the number of degrees of freedom (dofs) necessary to describe the solution decreases exponentially. A lower number of dofs means a lower number of hooks (contacts) on deeper layers. Hence, the grid necessary to describe field may be coarser, deeper in substrate. In any layer, the number of contacts can be decreased from its top to bottom q times:

$$q = \frac{n_c m_c}{n_0 m_0} = \exp\left(\pi \sqrt{(n/a)^2 + (m/b)^2} c\right). \quad (2)$$

For instance if $q = 9$, $a = b$ and $n = m$ it follows that $\Delta z \approx a/n$. Consequently, the standard cell of top layer should be a parallelepiped having its height at least the size of the top contacts. By increasing q , the approximation error of the hierarchical sparsification becomes higher.

III. RESULTS

In order to verify the proposed approach, a simple study case of a micro-strip dual conductor line in SiO₂ over a lossy Si

Fig. 2. Computational domain partitioned in three parts. Conform grids are shown.

Fig. 3. Hierarchical approach is as accurate as DP with conform grids.

substrate was considered. The line admittance was computed by FIT, using DP with conform grids (Fig. 2) and with the hierarchical modeling for the substrate. The result shown in Fig. 3 validates the latter approach.

The substrate was decomposed into 10 layers having progressive increasing thicknesses with a constant rate. The CPU time needed to extract the admittance matrix by hierarchical sparsification was 0.093 sec, whereas the same time when using DP with conform grids was 42.4 sec. This result illustrates the important reduction of the extraction time.

SUPG 3D vector potential formulation for electromagnetic braking simulations

François Henrotte¹, Enno Lange¹, Holger Heumann², Kay Hameyer¹

²ETH Zürich, Seminar for Applied Mathematics, CH-8092 Zürich, Switzerland

E-mail: fh@iem.rwth-aachen.de

Abstract—The calculation of motion-induced eddy currents in massive conductors yields a 3D convection-diffusion problem. Up-winding and SUPG formulations are well-established methods to obtain stable discretizations of the scalar convection-diffusion equations in the case of singular perturbation, but there is very little reported experience with the stability of convection in the vector case, i.e. in electromagnetism. Numerical experiments with the up-winding method proposed by Xu et al. [1] has proven its efficiency to be limited, and an alternative approach based on a consistent discretization within the finite element Galerkin context of the material derivative implied by the convection phenomenon is proposed.

I. INTRODUCTION

The problem of electromagnetic braking can be solved by a quasi-stationary approach by discretizing the model in the rest frame. According to e.g. [1], the governing equations are $\mathbf{b} = \nabla \times \mathbf{a}$, $\mathbf{e} = -\partial_t \mathbf{a} - \nabla V$ and $\nabla \times \mathbf{h} = \mathbf{j}$ with the material constitutive relations $\mathbf{b} = \mu \mathbf{h}$ and

$$\mathbf{j} = \sigma(\mathbf{e} + \mathbf{v} \times \mathbf{b}), \quad (1)$$

where the velocity field \mathbf{v} is different from zero in the moving domain. There are several interpretations found in literature for formulae like (1). The interpretations of Xu [1], Bossavit [5], Thorne [6] and Van Bladel [7] will be discussed and compared in the full paper.

On the other hand, it would seem natural, by analogy with mechanics to work with Eulerian coordinates, i.e. to replace the equation

$$\sigma \partial_t \mathbf{a} + \text{curl } \nu \text{curl } \mathbf{a} = \mathbf{j}_s \quad (2)$$

Fig. 1. Geometry of the 3D braking system.

valid when there is no motion, with the equation

$$\sigma D_t \mathbf{a} + \text{curl } \nu \text{curl } \mathbf{a} = \mathbf{j}_s \quad (3)$$

where D_t denotes the convective derivative. This would be a justification for importing stabilization SUPG scheme from Mechanics, in particular computational fluid dynamics [2], [3], into electromagnetic problems. We therefore have first to answer the question: Is electromagnetic braking a convection problem?

Given a placement map $p_t : M \mapsto N$, one can define the co-moving time derivative as the derivative operator that fulfills

$$\partial_t \int_{\Omega} \alpha = \int_{\Omega} \mathcal{L}_{\mathbf{v}} \alpha.$$

The co-moving time derivative of differential forms of various degrees write as follows

$$\mathcal{L}_{\mathbf{v}} f = \partial_t f + \mathbf{v} \cdot (\text{grad } f) \quad (4)$$

$$\mathcal{L}_{\mathbf{v}} \mathbf{a} = \partial_t \mathbf{a} + \text{grad } (\mathbf{a} \cdot \mathbf{v}) - \mathbf{v} \times \text{curl } \mathbf{a} \quad (5)$$

$$\mathcal{L}_{\mathbf{v}} \mathbf{b} = \partial_t \mathbf{b} + \text{curl } (\mathbf{b} \times \mathbf{v}) + \mathbf{v} \text{ div } \mathbf{b} \quad (6)$$

$$\mathcal{L}_{\mathbf{v}} \rho = \partial_t \rho + \text{div } (\rho \mathbf{v}) \quad (7)$$

in terms of classical vector and tensor analysis operators. The co-moving derivative of 0-forms (5) and 3-forms (7) are commonly used in computational fluid dynamics where they are called (amongst many other names) convective derivative, $\mathcal{L}_{\mathbf{v}} \equiv D_t$.

The electric field writes in the absence of motion $\mathbf{e} = -\partial_t \mathbf{a} - \text{grad } u$ becomes in an Eulerian representation,

$$\begin{aligned} \mathbf{e} &= -\mathcal{L}_{\mathbf{v}} \mathbf{a} - \text{grad } u \\ &= -(\partial_t \mathbf{a} + \text{grad } (\mathbf{a} \cdot \mathbf{v}) - \mathbf{v} \times \text{curl } \mathbf{a}) - \text{grad } u \end{aligned}$$

in the presence of motion. One observes the introduction through the co-moving time derivative of the classical $\mathbf{v} \times \mathbf{b}$ (1). But one observes also a motion induced correction to the electric scalar potential, $\text{grad } (\mathbf{a} \cdot \mathbf{v})$, which is not considered in the classical definition of motion induced eddy currents. The electric field can actually be rewritten

$$\mathbf{e}' = -\partial_t \mathbf{a}' - \text{grad } u'$$

with the auxiliary fields: $\mathbf{e}' = \mathbf{e} - \mathbf{v} \times \text{curl } \mathbf{a}$, $\mathbf{a}' = \mathbf{a}$ and $u' = u + \mathbf{a} \cdot \mathbf{v}$. The co-moving time derivative appears thus to be related with the Lorentz invariance of Maxwell's equations, as can be shown in a slightly extended theoretical context.

Fig. 2. Current density computed in the mover.

Fig. 3. Arbitrary finite element Ω and its upwind element Ω^- .

II. XU'S SUPG APPROACH

Assuming a stationary process, $\partial_t \mathbf{a} = 0$, the scheme proposed by Xu et al in [1], directly inspired from computational fluid dynamics, is as follows:

$$\int_{\Omega} \mu^{-1} \text{curl} \mathbf{a} \cdot \text{curl} \mathbf{w} \, d\Omega + \int_{\partial\Omega} (\mathbf{w} \times \mu^{-1} \text{curl} \mathbf{a}) \cdot \mathbf{n} \, d\Omega = - \int_{\Omega} \sigma (-\mathbf{v} \times \text{curl} \mathbf{a} + \text{grad} u) \cdot \mathbf{w} \, d\Omega$$

In analogy with the upwind scalar shape functions (with a free parameter τ):

$$w = w_0 + \tau \frac{\mathbf{v} \cdot \text{grad} w_0}{\|\mathbf{v}\|^2}, \quad \tau = \frac{\mathbf{v}h}{2} \left(\coth \frac{Pe}{2} - \frac{2}{Pe} \right)$$

upwind vector shape functions are defined as

$$\mathbf{w} = \mathbf{w}_1 - \tau \sigma \mathbf{v} \times \text{curl} \mathbf{w}_1$$

Numerical 3D simulations done with this approach, Fig. 2, show that a stabilization effect is indeed observed, but leaves still a severe limitation on the convection speed \mathbf{v} .

III. A GEOMETRICAL SCHEME

In their report [4], Heumann and Hiptmair have successfully exploited differential geometry concepts to obtain a geometrical discretization of the convection operator in 2D. Their approach is based on the extrusion operator introduced by

Bossavit [5]. The purpose of this paper is to generalize their 2D scheme to 3D finite element computations.

Consider the situation depicted in Fig. 3. Let Ω be an arbitrary finite element in a 3D mesh. A particular edge of that element e_i is considered, at both ends of which the velocity vector has been represented. This edge e_i represented in the figure is such that its upwind extrusion lays outside Ω , i.e. in a neighbour element $\Omega^- \neq \Omega$. For the FE discretisation, one has to evaluate:

$$\int_{\Omega} \sigma \mathcal{L}_{\mathbf{v}} \mathbf{a} \cdot \omega_i^e \, d\Omega = \sum_i \left\{ \int_{e_i} \mathcal{L}_{\mathbf{v}} \mathbf{a}(\Omega_i^-) \right\} \int_{\Omega} \sigma \omega_i^e \cdot \omega_i^e \, d\Omega, \quad (8)$$

where ω_i^e is an edge-based trial function. But the tangential component of $\mathcal{L}_{\mathbf{v}} \mathbf{a}$ is not continuous. The fact that the derivative $\mathcal{L}_{\mathbf{v}}$ is a limiting process involving the upwind extrusion of e_i , which lays in the upwind element Ω^- relative to the edge e_i under consideration, imposes thus to evaluate the circulation of $\mathcal{L}_{\mathbf{v}} \mathbf{a}$ in that element, i.e. $\int_{e_i} \mathcal{L}_{\mathbf{v}} \mathbf{a}(\Omega_i^-)$. In the evaluation of the residual (8) of the finite element Ω , the adjacent upwind elements Ω_i^- plays thus a role. This is incompatible with the classical element by element assembly of FE elementary matrices, hence an implementation difficulty.

An algorithm to evaluate $\int_{e_i} \mathcal{L}_{\mathbf{v}} \mathbf{a}(\Omega_i^-)$ will be described in the full paper. This expression has 3 terms (5). In particular, it will be shown that

$$\int_{e_i} \mathbf{v} \times \text{curl} \mathbf{a} = \sum_{jl} A_j \frac{V_1^l + V_2^l}{2} T_{ilj}$$

with

$$T_{ilj} = \mathbf{i}_{e_i} \mathbf{i}_{e_l} \text{curl} \omega_j^e(\mathbf{x})$$

a constant matrix with ± 1 and 0 elements that only depends on the topology of the tetrahedron.

IV. CONCLUSION

We have discussed the validity of introducing convection based concepts in context of electromagnetism, and shown that this is done by the co-moving time derivative. The concept of extrusion yields a geometrical upwind scheme without free parameter that can however not be assembled element by element. More numerical results will be given in the full paper.

e-mail: joerg.ostrowski@ch.abb.com, david.pusch@ch.abb.com

Abstract—This paper presents a method for the computation of magnetostatic problems based on finite element and boundary element coupling. In our method, we are introducing a reduced scalar magnetic potential in the unbounded air region. This enables the treatment of multi-connected domains in contrast to formulations based on total scalar magnetic potentials. Moreover, the computation of materials with high permeability is possible without stability problems, because of the usage of a vector potential in the solid parts.

I. INTRODUCTION

Similar methods have been proposed in the past. In [1] a vector potential is used in the solid parts and a total scalar approach for the unbounded domain, respectively. This approach is restricted to simple connected conductors. Other approaches are based only on total scalar potentials and/or reduced scalar potentials instead, see [2], [3], [4]. These methods suffer from cancellation errors and lack stability in presence of high permeability (e.g. $\mu_r = 500$) if the reduced scalar magnetic potential is used inside the permeable bodies, [6], [2]. Our proposed method circumvents these problems and enables simulations of highly permeable parts of general topology.

Thus, let us consider an inner domain Ω of general topology that consists of magnetic or non-magnetic parts. The unbounded outer air region is $\Omega^+ = \mathbb{R}^3 \setminus \bar{\Omega}$, with $\mu = \mu_0$. The interface boundary is assigned by $\Gamma = \partial\Omega$. We search a magnetic flux density \mathbf{B} that solves the magnetostatic field equations

$$\operatorname{curl} \frac{1}{\mu} \mathbf{B} = \mathbf{j} \quad \text{in } \Omega, \quad (1)$$

$$\operatorname{curl} \frac{1}{\mu_0} \mathbf{B} = \mathbf{j} \quad \text{in } \Omega^+, \quad (2)$$

$$\operatorname{div} \mathbf{B} = 0 \quad \text{in } \Omega \cup \Omega^+. \quad (3)$$

In order to solve the equations we are applying a finite element (FEM) formulation based on the magnetic vector potential for the inner domain. In the outer domain we are introducing a reduced potential, which is treated by a boundary element method (BEM). Taking into account the interface conditions, we are coupling both approaches and obtain an overall system of equations that has to be solved.

II. INNER DOMAIN Ω

In the inner domain Ω we are introducing the mentioned vector potential $\mathbf{B} = \operatorname{curl} \mathbf{A}$, and obtain

$$\operatorname{curl} \frac{1}{\mu} \operatorname{curl} \mathbf{A} = \mathbf{j} \quad \text{in } \Omega. \quad (4)$$

For regularization we apply Coulomb gauge

$$\operatorname{div} \mathbf{A} = 0. \quad (5)$$

In order to derive a variational formulation we multiply (4) and (5) with a testfunction v and q , respectively. After integration by parts and introducing a new variable p we obtain a weak formulation. Taking into account the correct function spaces, we have to find (\mathbf{A}, p) in $H(\operatorname{curl}) \times H^1(\Omega)$

$$\begin{aligned} \int_{\Omega} \frac{1}{\mu} \operatorname{curl} \mathbf{A} \cdot \operatorname{curl} v \, d\Omega - \int_{\Gamma} \left(\frac{1}{\mu} \operatorname{curl} \mathbf{A} \times \mathbf{n} \right) \cdot v \, d\Gamma \\ + \int_{\Omega} \nabla p \cdot v \, d\Omega = \int_{\Omega} \mathbf{j} \cdot v \, d\Omega \end{aligned} \quad (6)$$

$$\int_{\Omega} \mathbf{A} \cdot \nabla q \, d\Omega - \int_{\Omega} p \int_{\Omega} q \, d\Omega = 0. \quad (7)$$

for all (v, q) in $H(\operatorname{curl}) \times H^1(\Omega)$. It can be shown, that this new unknown function p has the property $p = \text{const} = 0$, see [1].

III. OUTER AIR DOMAIN Ω^+

Assuming that there are no magnetic materials, i.e. $\mu = \mu_0$ in the entire \mathbb{R}^3 , then a solution \mathbf{B}_0 of (1), (2) and (3) can be found by Biot-Savart integration. Considering the real configuration, we find the relation

$$\operatorname{curl} \left(\frac{1}{\mu} \mathbf{B} - \frac{1}{\mu_0} \mathbf{B}_0 \right) = 0 \quad \text{in } \mathbb{R}^3. \quad (8)$$

That means, we are now allowed to introduce a reduced scalar magnetic potential φ with

$$\nabla \varphi = \mathbf{B} - \mathbf{B}_0 \quad \text{in } \Omega^+ \quad (9)$$

without topological restrictions on Ω^+ . Considering equation (3) and taking into account that $\operatorname{div} \mathbf{B}_0 = 0$, the so-called reduced scalar potential φ can be found by solving a Laplace equation in the outer domain

$$\Delta \varphi = 0 \quad \text{in } \Omega^+. \quad (10)$$

It is well known that a solution for the Laplace equation can be obtained by an indirect single layer approach

$$\begin{aligned} \varphi = V\rho \quad \text{with} \quad (11) \\ (V\rho)(x) = \int_{\Gamma} \rho(y) G(x, y) ds_y \end{aligned}$$

and the kernel $G(x, y) = \frac{1}{4\pi} \|x - y\|^{-1}$. The normal derivative at the boundary Γ is given by

$$\begin{aligned} \nabla\varphi \cdot \mathbf{n} &= (K' - \frac{1}{2}I)\rho \quad \text{with} \quad (12) \\ (K'\rho)(x) &= \int_{\Gamma} \rho(y) \frac{\partial G}{\partial n_x}(x, y) ds_y \end{aligned}$$

where the appearing boundary integral operator K' is the adjoint double layer potential, I denotes the identity operator and \mathbf{n} is the outward unit normal vector. For mapping properties of the integral operators see e.g. [5].

IV. COUPLING FEM/BEM

At the interface between the solid parts Ω and the outer region Ω^+ we have to fulfill the interface conditions

$$[\mathbf{B}\mathbf{n}] = 0, \quad [\mathbf{H} \times \mathbf{n}] = 0. \quad (13)$$

If we are inserting the vector potential \mathbf{A} and the reduced scalar potential φ we obtain from the continuity of the normal component of the \mathbf{B} -field

$$\mathbf{curl} \mathbf{A} \cdot \mathbf{n} = \nabla\varphi \cdot \mathbf{n} + \mathbf{B}_0 \cdot \mathbf{n}, \quad (14)$$

and from the continuity of the tangential component of the \mathbf{H} -field

$$\frac{1}{\mu} \mathbf{curl} \mathbf{A} \times \mathbf{n} = \frac{1}{\mu_0} (\nabla\varphi + \mathbf{B}_0) \times \mathbf{n}. \quad (15)$$

Now we can replace the boundary integral in formula (6) with our boundary operators (11) and (12). Finally, we have to find a solution $(\mathbf{A}, p, \varphi, \rho)$ in $H(\mathbf{curl}, \Omega) \times H^1(\Omega) \times H^{1/2}(\Gamma) \times H^{-1/2}(\Gamma)$ that fulfills the final summarized system of equations

$$\begin{aligned} \int_{\Omega} \frac{1}{\mu} \mathbf{curl} \mathbf{A} \mathbf{curl} \mathbf{v} d\Omega + \int_{\Omega} \nabla p \mathbf{v} d\Omega - \\ \int_{\Gamma} \frac{1}{\mu_0} \varphi (\mathbf{curl} \mathbf{v} \mathbf{n}) d\Gamma = \int_{\Omega} \mathbf{j} \mathbf{v} d\Omega + \int_{\Gamma} \left(\frac{1}{\mu_0} \mathbf{B}_0 \times \mathbf{n} \right) \mathbf{v} d\Gamma \\ \int_{\Omega} \mathbf{A} \nabla q d\Omega - \int_{\Omega} p \int_{\Omega} q d\Omega = 0 \\ \int_{\Gamma} (\mathbf{curl} \mathbf{A} \mathbf{n}) w d\Gamma - \int_{\Gamma} (K' - \frac{1}{2}I) \rho w d\Gamma = \int_{\Gamma} (\mathbf{B}_0 \mathbf{n}) w d\Gamma \\ - \int_{\Gamma} \varphi \tilde{w} d\Gamma + \int_{\Gamma} (V\rho) \tilde{w} d\Gamma = 0 \end{aligned} \quad (16)$$

for all $(\mathbf{v}, q, w, \tilde{w})$ in $H(\mathbf{curl}, \Omega) \times H^1(\Omega) \times H^{1/2}(\Gamma) \times H^{-1/2}(\Gamma)$.

The corresponding discrete spaces are the standard space of edge elements \mathcal{W}_h , the space of piecewise linear elements \mathcal{V}_h , the space of piecewise linear and constant boundary elements \mathcal{X}_h and \mathcal{Y}_h , respectively. Hence, the resulting system in matrix notation is given as

$$\begin{pmatrix} A & B & C & 0 \\ B^{\top} & -P & 0 & 0 \\ C^{\top} & 0 & 0 & \frac{1}{2}I - K' \\ 0 & 0 & -I & V \end{pmatrix} \begin{pmatrix} \underline{A} \\ \underline{p} \\ \underline{\varphi} \\ \underline{\rho} \end{pmatrix} = \begin{pmatrix} \underline{f} \\ 0 \\ \underline{g} \\ 0 \end{pmatrix}. \quad (17)$$

V. NUMERICAL RESULTS

Our model problem consists of a cylinder made of copper ($\sigma = 5.7 * 10^7 (\Omega m)^{-1}$, $\mu = \mu_0$) with a current excitation of $I = 100A$. The surrounding core is non-conductive with a relative permeability $\mu_r = 500$. Let us remark, that the cylinder is not in the center of the core, but a bit moved towards a corner. In Fig. 1 the solution of the system of equations (16) for the \mathbf{B} -field is shown. The magnetic flux

Fig. 1. B-field, FEM-BEM, magnetostatic

density is concentrated in the high permeable core. At the reentrant corners we have singularities, which are difficult to compare with our reference solution, that has been computed by a pure FEM solver for magnetostatics, see Fig. 2. Note,

Fig. 2. B-field, FEM, magnetostatics

that the scale was set to the same range as in Fig. 1. The results of both methods match very well, which confirms the validity of our proposed general FEM-BEM approach. In order to compute using finer meshes we have to apply compression methods, which are currently under implementation.

Kopernikusgasse 24, 8010-Graz, Austria

Chao.Chen@tugraz.at

Abstract— A geometric multigrid method for the efficient solution of time-harmonic three-dimensional non-linear eddy-current problems is presented. A finite element method with scalar potentials and vector potentials is used to describe the problems. The iteration time of the multigrid solution is compared to a standard conjugate gradient with incomplete Cholesky factorization iteration.

I. INTRODUCTION

In recent years, edge elements have become state of the art for the calculation of linear or non-linear time-harmonic eddy-current problems with finite elements [1]. Particularly in the three-dimensional (3-D) case the finite element method (FEM) formulation results in a large system of equations. Iterative methods like the conjugate gradient method with incomplete Cholesky factorization (ICCG) as preconditioner are normally used for solving these systems of equations. However, the number of iterations increases substantially with the number of unknowns. A very fast method for solving a system of equations is the geometric multigrid (MG) method [2].

In this paper, the eddy-current problem is described by the FEM using the \mathbf{A} , V formulation. To decrease the solution time of non-linear problems we present a nonlinear geometric multigrid algorithm for edge elements which is based on a modified Picard-Banach method [3]-[4].

II. FEM-FORMULATION

An eddy current problem involves two regions: a conducting region Ω_c with an unknown current density distribution and a non conducting region Ω_n with a given source current density \mathbf{J}_0 .

In the non conducting region, the magnetic vector potential \mathbf{A} is defined as usual by $\mathbf{B} = \text{curl}\mathbf{A}$. Neglecting the dielectric displacement leads to the differential equation $\text{curl}(\nu\text{curl}\mathbf{A}) = \mathbf{J}_0$ in Ω_n , where $\nu = \nu(\mathbf{x})$ is the reluctivity of the material, \mathbf{J}_0 can be described as the curl of a vector potential \mathbf{T}_0 .

In the conducting region, an additional modified electric scalar potential V is introduced as $\mathbf{E} = -j\omega\mathbf{A} - j\omega\text{grad}V$ where ω is the angular frequency of the current excitation.

Since there are two unknowns, \mathbf{A} and V , an additional equation has to be used. It is common to use the divergence free property of the total current density, $\text{div}\mathbf{J} = 0$. This leads to the following system of differential equations:

$$\text{curl}(\nu\text{curl}\mathbf{A}) + j\omega\sigma\mathbf{A} + j\omega\sigma\text{grad}V = \text{curl}\mathbf{T}_0 \quad (1)$$

$$-\text{div}(j\omega\sigma\mathbf{A} + j\omega\sigma\text{grad}V) = 0 \quad (2)$$

where σ is the conductivity in the conducting region.

Using n_e edge basis functions N_i for the vector potential and n_n nodal basis functions N_i for the scalar potential, the Galerkin equations can be written as

$$\begin{aligned} (\text{curl}N_i, \nu\text{curl}\mathbf{A}_h) + j\omega(N_i, \sigma\mathbf{A}_h) + j\omega(N_i, \sigma\text{grad}V_h) = \\ (\text{curl}N_i, \mathbf{T}_0) \quad i = 1, 2, \dots, n_e \end{aligned} \quad (3)$$

$$j\omega(\text{grad}N_i, \sigma\mathbf{A}_h) + j\omega(\text{grad}N_i, \sigma\text{grad}V_h) = 0 \quad i = 1, 2, \dots, n_n \quad (4)$$

where $\mathbf{A}_h = \sum_{i=1}^{n_e} a_i N_i$ and $V_h = \sum_{i=1}^{n_n} V_i N_i$ are the approximations of the vector potential and scalar potential respectively. The resulting system of equations is singular, since applying the divergence operator to (1) will result in (2).

III. MULTIGRID

A geometric multigrid algorithm is used for solving this singular system of equations. One iteration step of the classical two-grid algorithm applied to the solution of the equation system $\mathbf{A}_h \mathbf{x}_h = \mathbf{b}_h$ can be described as follow

$$\begin{aligned} \tilde{\mathbf{x}}_h &= S^{n_1}(\mathbf{x}_h, \mathbf{b}_h) - n_1 \text{ pre-smoothing operations} \\ \mathbf{d}_h &= \mathbf{A}_h \tilde{\mathbf{x}}_h - \mathbf{b}_h - \text{calculation of the defect} \\ \mathbf{d}_H &= \mathbf{R}\mathbf{d}_h - \text{restriction of the defect on the coarser grid} \\ \mathbf{e}_H &= \mathbf{A}_H^{-1} \mathbf{d}_H - \text{solution of the coarse grid equation} \\ \mathbf{x}_h &= \tilde{\mathbf{x}}_h - \mathbf{P}\mathbf{e}_H - \text{correction of } \tilde{\mathbf{x}}_h \\ \mathbf{x}_h &= S^{n_2}(\mathbf{x}_h, \mathbf{b}_h) - n_2 \text{ post-smoothing operations} \end{aligned} \quad (5)$$

where S^{n_i} denotes n_i iterations using a smoother S , and the subscripts h and H refer to the fine and coarse grids, respectively. The linear mapping $\mathbf{d}_H = \mathbf{R}\mathbf{d}_h$ is called restriction and the coarse-to-fine interpolation $\mathbf{e}_h = \mathbf{P}\mathbf{e}_H$ prolongation. The multigrid algorithm can be obtained by replacing step 4 in the two-grid algorithm (5) by another two-grid step. This idea can be applied recursively, using coarser and coarser grids, generating a MG V-cycle.

For edge elements, the entry of the $n_h \times n_H$ prolongation matrix \mathbf{P}^e is defined as [4]

$$p_{ij}^e = \int_{\text{global edge}_{h,i}} N_{H,j}(x, y, z) \cdot dl \quad (6)$$

where $1 \leq i \leq n_h^e$ and $1 \leq j \leq n_H^e$.

Using nodal elements, the natural choice for the entries of the prolongation matrix P^n are the values of the coarse grid basis functions N_H at the fine grid nodes \mathbf{x}_{hj} :

$$p_{ij}^n = N_{H,i}(\mathbf{x}_{h,j}) \quad (7)$$

In a formulation using both nodal and edge elements, the prolongation matrix can be written as

$$P = \begin{bmatrix} P^e & 0 \\ 0 & P^n \end{bmatrix} \quad (8)$$

The transpose of P has been used as the restriction matrix R , i.e., $R = P^T$.

For the \mathbf{A} , V -formulation described in section II, a Gauss-Seidel type smoother can be applied to the nodal element and edge element space respectively. This is due to the fact that (4) takes care of the kernel of the curl operator [5].

In ferromagnetic materials the connection between \mathbf{B} and \mathbf{H} is nonlinear. For nonlinear problems, a modified Picard-Banach method has been used. This means a series of linear problems has to be solved

$$A_h(\mathbf{x}_{h,i})\mathbf{x}_{h,i+1} = \mathbf{b}_h \quad (9)$$

In each nonlinear iteration step, the nonlinear reluctivity ν has to be calculated in the Gaussian points of the finite elements, using the previous approximation for \mathbf{x}_h .

Since the matrices A_h depend on the reluctivity ν , they have to be reassembled in every nonlinear iteration step. For the MG method, the only meaningful solution for calculating ν is the solution \mathbf{x}_h on the finest grid, which is used to compute ν on a coarser grid as well. This yields the corresponding reluctivity at each MG level resulting in a proper hierarchy of finite element grids and systems of equations which can be described by the following algorithm [4]. It is assumed that the number of multigrid levels l and starting value ν_0 are given:

- Assemble the matrices $A_q(\nu_i)$, $q = 1, 2, \dots, l$;
- Solve $A_l(\nu_i)\mathbf{x}_{l,i+1} = \mathbf{b}_l$ with MG algorithm;
- Calculate $\nu_{i+1}(\mathbf{x}_{l,i+1})$;
- If $\|\nu_{i+1}/\nu_i\|_{\max} \geq \varepsilon$, $i = i+1$, back to step 2.

IV. NUMERICAL EXAMPLES

To demonstrate the applicability of the proposed scheme, a 3-D numerical example is considered. The geometry of the problem and the discretization of the coarse grid with hexahedral elements of second order can be seen in Fig. 1. The iron plate has conductivity of $\sigma = 4 \times 10^6$ S/m. Its nonlinear magnetization curve is depicted in Fig. 2. The current and frequency of the coil is 1×10^7 A/m² and 50Hz respectively.

In Table I, the solution time for solving the non-linear eddy-current problem, using ICCG and MG, have been compared. Especially for finer finite element mesh the multigrid method is faster than the ICCG.

Fig. 1. Geometry and discretization of 3-D problem.

Fig. 2. Non-linear magnetization of the iron plate.

TABLE I
COMPUTATION TIME OF ICCG AND MULTIGRID

Number of equations	Computation time (seconds)	
	ICCG	MG
275797	1318	1266
618657	4310	2374

V. CONCLUSION

In this paper we have presented a solution by an MG method for nonlinear eddy-current problems described by a system of nonlinear equations obtained by an edge finite element. Numerical results have shown the advantage of MG method for non-linear eddy-current problems.

Abstract— Magnetic particle is used in various areas from engineering to biomedical field. The particles are controlled by external magnetic field and the magnetized particles interact between themselves to show some interesting behaviors. Various computational analysis works have been recently presented. But, since most of them are based on a point-dipole model, the accurate effects of finite volume and mutual interactions are not calculated. In addition, full field analysis has serious problem in remeshing for moving particles. This paper propose a new approach, where the movement of particles is captured using level set function on a fixed background mesh for magnetic field analysis. The magnetic force on each particle by body force density are inserted into driving forces in dynamic equations.

I. INTRODUCTION

Recently, magnetic particle is attracting much attention because their role is increasing in various areas from engineering to biomedical field. Some typical examples include site-specific drug delivery, separation of tagged DNA, enhanced magnetic resonance imaging, hyperthermic cell treatment, magnetorheological fluids for controllable linear dampers, rotary brakes, and vibration dampers, etc. Therefore, the accurate analysis for their particle dynamics is required for appropriate estimation of the particle behaviors before a real test procedure, which needs a lot of cost and time. Applied magnetic field controls the particles in a fluid domain by exerting magnetic force on the particles. But, the magnetized particles also interact between themselves to produce other complex phenomena.

Various computational works have been presented recently for its characteristics analysis: molecular dynamics simulations, density functional theory, particle dynamics method, Monte Carlo method [1]. However, since they are based on a point-dipole model, the accurate effects of finite volume and mutual interactions are not calculated. So, it turns out that full magnetic field is required for accurate calculation of nonlinear dynamics with many particles. But, the existing finite element method has a serious problem of remeshing for evolving geometrical modeling for many moving particles. Therefore, in this paper we propose a new approach, where the movement of particles is captured using level set function on a fixed background mesh for magnetic field analysis. The magnetic forces on each particle are calculated by body force density and inserted into driving forces in dynamic equations. The proposed method is applied to estimation of chain aggregation of ferromagnetic particles under external magnetic field.

II. BOUNDARY AND MATERIAL SETTING

For arbitrary region Ω with boundary, the implicit function $\phi(\mathbf{x})$ is assumed as follow

$$\begin{aligned} \phi(\mathbf{r}) > 0 & \quad \mathbf{r} \in \Omega^+ & : \text{fluid} \\ \phi(\mathbf{r}) = 0 & \quad \mathbf{r} \in \partial\Omega & : \text{boundary} \\ \phi(\mathbf{r}) < 0 & \quad \mathbf{r} \in \Omega^- & : \text{particle} \end{aligned} \quad (1)$$

Magnetic particle region can be defined the boundaries of domain Ω^- via

$$\Omega^-(t) = \{ \phi(\mathbf{r}, t) < 0 \}. \quad (2)$$

The boundary $\Gamma(t)$ of $\Omega^-(t)$ is then given by the zero level set,

$$\Gamma(t) = \{ \phi(\mathbf{r}, t) = 0 \} \quad (3)$$

The boundaries of particles can be expressed the zero level set using the signed distance function and the boolean union function min. Fig. 1(a) shows the distributions of level set function [2].

$$\begin{aligned} \phi(\mathbf{r}) &= \min(\mathbf{r} - \mathbf{r}_i) \quad \text{for all } \mathbf{r}_i \in \partial\Omega \\ \phi(\mathbf{r}) &= 0 \quad \text{on the boundary where } \mathbf{r} \in \partial\Omega \end{aligned} \quad (4)$$

Fig. 1. (a) Level set function and (b) smeared Heaviside function.

Heaviside function is proper to set the material property of magnetic particle. It is not strict but continuously changes on the boundary in numerical processing because the boundaries can intersect an element. So, we used a smeared Heaviside function that gives a continuous permeability distribution near the zero level set. But, the material density near the boundary can be as abrupt as possible by regulating the tunable parameter h .

$$\mu = \mu_0 H(\phi, h) + (1 - H(\phi, h)) \mu_r \mu_0 \quad (5)$$

$$\mu(\phi, h) = \begin{cases} \mu_0 & \phi \leq 0 \\ \mu_r \mu_0 & \phi > 0 \end{cases} \quad (6)$$

where μ , μ_r and μ_0 denote permeability, relative permeability

and permeability of free space(fluid) respectively. Fig. 1(b) represents a smeared form of Heaviside function that is used in the proposed algorithm. By introducing the level set function to material setting process, we don't have to remesh the model geometry that is changed by moving objects.

The integration of surface and boundary integral are expressed using Heaviside function $H(\phi)$ and Dirac-Delta function $\delta(\phi)$.

$$\int_S f(\mathbf{r}) dS = \int_{\Omega} f(\mathbf{r}) H(\phi(\mathbf{r})) d\Omega \quad (7)$$

$$\int_{\Gamma} f(\mathbf{r}) d\Gamma = \int_{\Omega} f(\mathbf{r}) \delta(\phi(\mathbf{r})) |\nabla \phi(\mathbf{r})| d\Omega \quad (8)$$

III. FORCE ON PARTICLE AND DYNAMICS ANALYSIS

To calculate force on moving magnetic particles we employ a body force density that can be easily integrated for a total force using the level set function. The velocities and displacements of magnetic particles are calculated by the motion equation. Collision with other particles is assumed to be elastic and friction between particles is ignored to simplify the problem. The total forces on each particle are an integration of the force density [3].

$$\mathbf{F} = \int_{\Omega} \frac{\sigma_{m2}}{2} \left(\frac{\mathbf{H}_1 + \mathbf{H}_2}{2} + \frac{\sigma_{m2}}{2\mu_0} \mathbf{n}_2 \right) H(\phi) d\Omega \quad (9)$$

where, \mathbf{H} is field intensity of each side, σ_{m2} is magnetic charge of fluid, \mathbf{n}_2 is the normal unit vector on surface and Ω is a region of magnetic particles. The velocities and positions of particles are analyzed by the motion equation

$$m \frac{d^2 \mathbf{s}}{dt^2} + D \mathbf{v} = \mathbf{F} \quad (10)$$

where m is mass of a particle, D is damping coefficient such as viscosity or friction, and \mathbf{s} and \mathbf{v} denote position and velocity of particles.

Fig. 2. Collision diagram between particles.

When the particles come into collision with other particle or boundary wall, collision involves forces that are a change in velocity as in (11) and (12). Collision is assumed to be elastic, meaning they conserve energy and momentum. The magnitude of the velocity difference at impact is called the closing speed. The state variables of dynamics are concerned with moving and colliding objects. The above analysis procedure is executed until movement of particle is small enough for convergence.

$$m_1 \mathbf{v}_1 + m_2 \mathbf{v}_2 = m_1 \mathbf{v}_1' + m_2 \mathbf{v}_2' \quad (11)$$

$$\frac{1}{2} m_1 \mathbf{v}_1^2 + \frac{1}{2} m_2 \mathbf{v}_2^2 = \frac{1}{2} m_1 \mathbf{v}_1'^2 + m_2 \mathbf{v}_2'^2 \quad (12)$$

The overall flow chart of this procedure is shown as in Fig. 3. The dynamic equations of particles are numerically solved using Runge-Kutta algorithm for nonlinear ordinary differential equations.

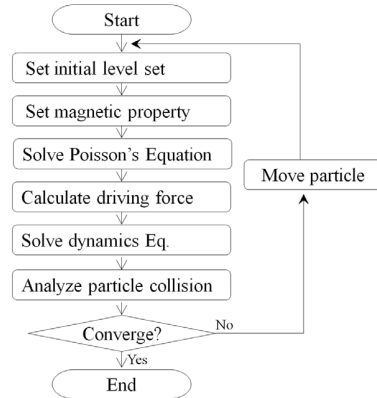

Fig. 3. Flow chart of particle dynamics analysis.

IV. NUMERICAL RESULTS

The proposed modeling method for evolving geometry is numerically tested for a magnetic particle dynamics analysis. The test problem is dynamics of 228 magnetic particles in a box as Fig. 4(a) which shows the initial distributions of particles in absence of external field. After a uniform magnetic field of 1(T) is applied, the particles are redistributed and clustered to form long chains along the applied field direction as in Fig. 4(b). Using this model we can also predict the changed material property of the system in the presence of interactions. These results are consistent with experimental data [4].

Fig. 4. Magnetic particles in (a) zero field and (b) a uniform field

Abstract — This paper presents a progress in the development of a recent and promising wavelet-based Algebraic Multigrid method with the use of the lifting technique. This new approach allows creating an algorithm with smaller memory requirement and a reduced number of floating point operations, if long filters are used, keeping the efficiency of the multigrid technique. The performance of the proposed approach is verified by solving the three-dimensional Poisson equation defined in a uniform grid and also in the TEAM 28 Problem. The standard Incomplete Cholesky Conjugate Gradient solver and the Incomplete LU preconditioner are used for comparison.

I. INTRODUCTION

A combination of the Discrete Wavelet Transform (DWT) and the Algebraic Multigrid method (AMG) was introduced recently in [1] producing a new method called WAMG. In that new approach a modified DWT, using only low-pass filter bank, was applied to the original matrix to produce an approximation of it in each level of the multiresolution process.

The WAMG has revealed to be a very efficient and promising method for several problems related to computation of electromagnetic fields, in both serial and parallel computation [1],[2]. The method can be either used as an iterative solver or as a preconditioning technique, presenting in many cases a better performance than some of the most advanced and current AMG algorithms.

Due to the WAMG efficiency and potentiality further researches have been carried out for its improvement and this paper is part of this effort. In order to accomplish this task this work build a modified discrete wavelet transform using the tool called the lifting scheme [3]. The lifting technique is a method introduced by W. Sweldens [4], which allows some improvements on the properties of existing wavelet transforms. The technique has some numerical advantages as a reduced number of floating point operations which are fundamental in the context of the iterative solvers. Actually, it is known that the lifting algorithm is asymptotically twice as fast as the standard algorithm for long filters [2].

II. THE WAVELET-BASED ALGEBRAIC MULTIGRID

The key point of the WAMG is the application of a modified (incomplete) DWT, as a filter bank with only low-pass filters, to generate the hierarchy of matrices in the AMG method.

This approach is very interesting mainly because it avoids the coarsening process and the heuristic parameters present in

the standard AMG, simplifying the use of the method as well as its parallel implementation in distributed memory computers [1],[2].

III. THE IMPLEMENTATION USING THE LIFTING TECHNIQUE

In [5] Daubechies and Sweldens have shown that every wavelet filter can be decomposed into lifting steps. Therefore, all discrete wavelet transforms used for WAMG can be implemented with the lifting scheme. The main algorithmic advantages of this technique are:

a) Smaller memory requirement – the calculations can be performed in-place;

b) Efficiency: reduced number of floating point operations;

c) Parallelism –inherently parallel feature;

More details about these advantages as well as others important structural advantages of the lifting can be found in [3],[4].

In fact, there are basically three forms for representing a wavelet transform: equation form (lifting), filter form (filter bank) and matrix form. However, only the first two are appropriate in the multigrid implementation.

The representations of the Daubechies 4 wavelet in the lifting form and in the filters form are presented in (1)-(3). These representations were extracted from [3], which shows the details for converting between these two forms (one can also see [4]).

A. Lifting form

$$\begin{aligned} s^{(1)}[n] &= S[2n] + \sqrt{3}S[2n+1], \\ d^{(1)}[n] &= S[2n+1] - \frac{1}{4}\sqrt{3}s^{(1)}[n] - \frac{1}{4}(\sqrt{3}-2)s^{(1)}[n-1], \\ s^{(2)}[n] &= s^{(1)}[n] - d^{(1)}[n+1], \\ \tilde{s}[n] &= \frac{\sqrt{3}-1}{\sqrt{2}}s^{(2)}[n], \quad \tilde{d}[n] = \frac{\sqrt{3}+1}{\sqrt{2}}d^{(1)}[n]. \end{aligned} \quad (1)$$

B. Filter Form

$$h_4 = \frac{1}{4\sqrt{2}}[1 + \sqrt{3}, 3 + \sqrt{3}, 3 - \sqrt{3}, 1 - \sqrt{3}], \quad (2)$$

$$g_4 = \frac{1}{4\sqrt{2}}[1 - \sqrt{3}, -3 + \sqrt{3}, 3 + \sqrt{3}, -1 - \sqrt{3}]. \quad (3)$$

The coefficients $s[n]$ and $d[n]$ in (1) are, respectively, the approximation and the details coefficients of the input signal S . Therefore, for the multigrid implementation in the Lifting

form the last equation in (1) is not necessary. In (2) and (3) h_4 and g_4 are the low-pass and high-pass filter bank, respectively.

IV. THE NUMERICAL TEST PROBLEM

The performance of the proposed approach is verified by solving the three-dimensional Poisson equation defined in a uniform grid on the cube $[-1,1]^3$. The spatial discretization of the Poisson equation uses Lagrange finite-element functions and second order elements, both implemented in the C++ Finite Element Library - LibMesh [6]. The resulting symmetric positive definite matrix has 29791 rows and 1771561 nonzero entries.

The WAMG method with the lifting implementation (LAMG) was used as a stand-alone solver and as a preconditioner for Bi-Conjugate Gradient Stabilized (BiCGStab). The results are shown in Table I. For comparison, the standard Incomplete Cholesky Conjugate Gradient (IC-CG) solver is used.

TABLE I
RESULTS FOR THE TEST PROBLEM

Method	Number of steps	Time in seconds		
		Setup	Solver	Total
LAMG	5	3.65	3.85	7.50
LAMG-BiCGStab	3		4.58	8.23
LAMG-CG	3		4.04	7.69
IC-CG	10	6.78	2.59	9.37
IC-BiCGStab	5		2.08	8.86

V. APPLICATION IN THE TEAM 28 PROBLEM

The performance of the LAMG is also verified in the steady-state analysis of Compumag TEAM 28 Problem. This problem relates to the modeling of an electrodynamic device which consists of two stationary concentric exciting coils interacting with a moveable round conducting plate. The used model, which was created using the Finite Element Method Magnetic (FEMM) [7], applies the Kelvin transformation [8] for investigating the steady-state levitation height of the plate. The resulting complex symmetric matrix has 54723 rows and 380957 nonzero entries.

The LAMG method was used as a preconditioner for BiCGStab. Again, the Incomplete Cholesky and the Incomplete LU preconditioners were used for comparison. The results are shown in Table II.

TABLE II
RESULTS FOR THE TEAM 28 PROBLEM

Method	Number of steps	Time in seconds		
		Setup	Solver	Total
LAMG-BiCGStab	42	1.11	15.92	17.03
ILU-BiCGStab	244	0.36	81.17	81.53
IC-BiCGStab	223	0.58	33.99	34.57

The Magnetic flux density B (module) for this problem is presented in Fig. 1.

VI. CONCLUSION

The proposed approach seems to be very promising. The numerical advantages of the lifting technique allow an efficient computational implementation of the method, as can be seen from the setup time for the test problem in Table I. On the other hand, the LAMG presented a small convergence rate for the TEAM 28 problem, especially when it is used as a preconditioner, when compared with the incomplete Cholesky and incomplete LU preconditioners. The number of steps in Table II illustrates this superiority. This LAMG performance for this problem is especially interesting because the corresponding matrix is complex symmetric and, curiously, there is not much literature available on iterative solvers for complex symmetric problems, given the number of diverse applications in which these problems arise.

Fig. 1. Magnetic flux density B (module).

Abstract— A method to solve stochastic partial differential equations in random domains consists in using a one to one random mapping function which transforms the random domain into a deterministic domain. The randomness is then supported by the behavior law of the material. This paper addresses an application of this method for an electrokinetic problem with uncertain dimensions. An example is presented to illustrate the method.

I. INTRODUCTION

In several models used to predict the behavior of a physical phenomenon, the available information is known with a finite level of confidence. Since the numerical models are more and more accurate thanks to the availability of new numerical methods (in 3D for example) and also to the increasing of computer performances, some of these uncertainties can not be considered negligible any longer. In several works, random variables were used in order to taking into account of these uncertainties. There are three kinds of uncertainties: Those on the terms sources, those on the material behavior and those on the dimensions. In [2], methods proposed in literature [4] to account for uncertainties on the material behavior were used to solve static field problems. However, the case of uncertainties on the geometry is much less studied. In [1], a method to solve differential equations in random domains based on a one to one random mapping function which transforms the random domains to a deterministic one is proposed.

In this paper, we propose to use such approach to solve a static field problem with random dimensions. In the first part of this paper, we present the approach that consists in transferring the randomness on the dimensions on the material behaviors. Then, known methods can be used to solve the stochastic problem. A numerical example will be presented in the second part.

II. PROBLEM DESCRIPTION

A. Deterministic problem

The electrokinetic problem defined in domain D can be written:

$$\begin{cases} \operatorname{div} \mathbf{J}(x) = 0 \\ \operatorname{curl} \mathbf{E}(x) = 0 \end{cases} \quad (1)$$

with \mathbf{J} the current density and \mathbf{E} the electric field. The constitutive law is given by $\mathbf{J}(x) = \sigma(x) \cdot \mathbf{E}(x)$, where $\sigma(x)$ is

the conductivity of the domain D . If we denote $\varphi(x)$ the scalar potential such that $\mathbf{E} = -\operatorname{grad} \varphi(x)$, equation (1) can be written:

$$\operatorname{Div}(\sigma(x) \cdot \operatorname{grad} \varphi(x)) = 0 \quad (2)$$

We assume that the domain D is bounded by the surface $\Gamma = \Gamma_1 \cup \Gamma_2 \cup \Gamma_3$ where the boundary conditions are given by:

$$\begin{cases} \mathbf{J}(x) \cdot \mathbf{n} = 0 & \text{on } \Gamma_1 \\ \varphi(x) = 0 & \text{on } \Gamma_2 \\ \varphi(x) = V & \text{on } \Gamma_3 \end{cases} \quad (3)$$

where \mathbf{n} is normal unity vector and V the imposed voltage. A weak formulation is used to solve numerically (2):

$$\int_D \operatorname{grad}^T \varphi(x) \cdot \sigma(x) \cdot \operatorname{grad} \lambda(x) \cdot d\Omega = 0 \quad (4)$$

where $\lambda(x)$ is a scalar test function that is equal to zero on Γ_2 and Γ_3 . To approximate the scalar potential and also for the test functions, nodal shape function are used.

III. PROBLEM WITH UNCERTAINTIES ON THE BEHAVIOR LAW

As will be shown later, the solution of a problem with random dimensions can be equivalent to a problem with random behavior laws. In the following, we will recall shortly how this kind of randomness can be taken into account. The uncertainties on behavior law can be modeled by the random fields $\sigma(x, \theta)$, where θ is the outcome. The scalar potential becomes now a random field $\varphi(x, \theta)$. The weak formulation becomes:

$$\int_D \operatorname{grad}^T \varphi(x, \theta) \cdot \sigma(x, \theta) \cdot \operatorname{grad} \lambda(x) \cdot d\Omega = 0 \quad (5)$$

This problem can be studied using Monte Carlo Simulation Method (MCSM) that is a very reliable method but very time consuming. Alternative methods can also be used that were studied in [2-4]: Spectral Stochastic Finite Element Method (SSFEM) and Non-Intrusive Method (NIM). SSFEM and NIM consist in projecting the field $\varphi(x, \theta)$ on space $K(x, \theta) = S(x) \otimes H(\theta)$ where $S(x)$ is spatial space spanned by the set of nodal shape functions $\lambda(x)$ (see section II) and $H(\theta)$ is spanned by a set of orthogonal polynomials $\{H_i(\theta)\}$. The main difference between SSFEM and NIM is that with SSFEM, the projection $\varphi(x, \theta)$ is undertaken simultaneously

on $S(x)$ and $H(\theta)$ while with NIM we project $\varphi(x, \theta)$ firstly on $S(x)$ and secondly on $H(\theta)$.

IV. PROBLEM WITH UNCERTAINTIES ON GEOMETRY

In SSFEM, MCSM and NIM, one difficulty in case of random domains compared to the case with random behavior law is that, a priori, geometric variation leads to the re-meshing of the system. Furthermore, the space S is no longer independent on $H(\theta)$, therefore the random scalar potential $\varphi(x, \theta)$ can not be directly approached by the projection in these spaces. To overcome that difficulty, an idea based on a one to one random mapping function that transforms the random domain to a deterministic domain is proposed in [1]. We will clarify this in following part. We use a one to one random mapping function $X = X(\theta, x)$ which transforms the random domain D to deterministic domain E . Thus, formulation (5) becomes:

$$\int_E \text{grad}^t \varphi(X, \theta) \frac{T^t(X, \theta) \cdot \sigma(X) \cdot T(X, \theta)}{|\det(T(X, \theta))|} \text{grad} \lambda(X) d\Omega = 0 \quad (6)$$

where T is the Jacobian matrix of the transformation. If we denote the conductivity:

$$\sigma'(X, \theta) = \frac{T^t(X, \theta) \cdot \sigma(X) \cdot T(X, \theta)}{|\det(T(X, \theta))|} \quad (7)$$

the problem with geometric uncertainties on the domain D can be considered equivalent to a problem with uncertainties on a modified behavior law with a conductivity $\sigma'(X, \theta)$ on the domain E . Methods have been already proposed to solve such kind of problems. One can note that to use the method, a one to one random mapping function has to be defined that is not necessarily always obvious.

V. NUMERICAL APPLICATION

We focus now on the following electrokinetic problem presented in figure 1. It is a cubic domain D_2 with a conductivity $\sigma_2 = 1 (\Omega.m)^{-1}$ with an edge length ($2a = 4m$). This domain surrounds another cube D_1 with random dimensions (l_1, l_2, l_3) with a conductivity $\sigma_1 = 10 (\Omega.m)^{-1}$. $l_1(\theta), l_2(\theta)$ and $l_3(\theta)$ are independent uniform random variable in the interval $[1; 1.5](m)$. On two opposite sides of the domain D_2 a voltage difference $V = 2$ (Volt) is prescribed. Since the dimensions of D_1 are random so does the energy.

We define a transformation $X = X(\theta, x)$ to transform the domain D into a domain E with $l_1 = l_2 = l_3 = 1m$. On the domain E , the conductivity is then random and given by (7). To determine the Jacobian transformation matrix (6), we divide the domain D into several sub-domains. We apply a linear transformation (dilation) in each sub-domain which leads to a constant Jacobian transformation matrix.

To study the problem, we use both the NIM and the MCSM. In MCSM, we use a sample of length 10000. With NIM we use an expansion of order 4 for the multivariate

Legendre polynomials. The Legendre Gauss quadrature method is used to calculate the coefficients of the polynomial expansions ($4^3 = 64$ points are calculated).

We compared the statistical moments of a global random variable (energy) given by the two methods. The statistical moments are reported in the Table I. We notice that the NIM gives statistical moments that belong to the 95% confidence interval obtained with the MCSM.

Fig. 1. Electro-kinetic system

TABLE I
MONTECARLO SIMULATION METHOD COMPARED WITH NON-INTRUSIVE METHOD

Information	Monte Carlo method (95% confidence interval)	Non-intrusive method
	Energy (J)	Energy (J)
Mean	[28.86 : 28.99]	28.91
Standard deviation	[3.34 : 3.42]	3.38
Skewness	[0.43 : 0.56]	0.49
Kurtosis	[2.40 : 2.69]	2.55

VI. CONCLUSION

We have presented a method to treat the problem with uncertainties on the geometric dimensions. This method consists in using a geometric transformation that allows transferring the randomness on the behavior law. The choice of the transformation is however a delicate point of this method. Further investigations should be undertaken to find and to specify this transformation in a simpler way.

Quality Evaluation of Automatically Generated Hexahedral Mesh for FEA

Yuichiro Motooka, So Noguchi, and Hajime Igarashi
 Graduate School of Information Science and Technology, Hokkaido University
 Kita 14 Nishi 9 Kita-ku, Sapporo, 060-0814, JAPAN
 noguchi@ssi.ist.hokudai.ac.jp

Abstract— We have previously proposed an automatic hexahedral mesh generator. It is necessary to understand about the quality and characteristic of mesh to perform hexahedral edge finite element analysis in electromagnetic. Therefore, we have compared high-quality mesh with poor-quality mesh, and investigated about the factors that affect the accuracy and the computation time. We will conclusively apply the result to improving the automatic hexahedral mesh generator.

I. INTRODUCTION

In order to perform a finite element analysis (FEA), the analysis domain has to be divided into finite elements. Hexahedral mesh has advantages over others at accuracy and speed. Therefore, we have previously proposed an automatic hexahedral mesh generator [1], [2]. The quality of mesh generated by the proposed mesh generator is affected by the smoother, i.e. the *Laplacian* smoothing in [2].

The quality and density of mesh are the most important factors to perform FEA in electromagnetic. In order to achieve highly accurate analysis and short computation time, a high-quality hexahedral mesh with graded mesh densities should be employed. In common, it is known that the regular hexahedral element is the best. However, the generation of mesh with only regular hexahedron is very difficult under various conditions. Therefore, we have to investigate about the characteristic of generated mesh.

In this paper, some evaluation functions are defined to check the element shape. It was investigated whether those evaluation functions correlate with the accuracy and the computation time. The result of this paper helps to improve the smoothing process in the proposed automatic hexahedral mesh generator [2].

II. EVALUATION METHOD

A. Orthogonality Evaluation

It is empirically known that the regular hexahedron and the rectangular parallelepiped are the high-quality element. Therefore, the orthogonality of element is an important factor. The orthogonality evaluation value ϕ is defined as follows:

$$\phi = \sum_{i=1}^N \phi_i / N, \quad \phi_i = \sum_{j=1}^{24} \phi_{ij} / 24, \quad \phi_{ij} = \cos^{-1}(\mathbf{e}_a \cdot (\mathbf{e}_b \times \mathbf{e}_c)), \quad (1)$$

where N is the number of elements, and \mathbf{e} is the unit vector along the edge, as shown in Fig. 1. When ϕ_i is 0 deg., the element is a rectangular parallelepiped. On the other hand, when ϕ_i is large, the element is distorted with poor quality.

Fig. 1. Conceptual Illustration of Orthogonality Evaluation Method.

B. Planarity Evaluation

In the method proposed in [2], the conclusive position of nodes depends on the smoothing arrangement. Then, 4 nodes of a hexahedral facet might not be on plane. Therefore, the planarity evaluation function δ is defined as follows:

$$\delta = \sum_{i=1}^N \delta_i / N, \quad \delta_i = \sum_{j=1}^6 \delta_{ij} / 6, \quad (2)$$

$$\delta_{ij} = \frac{|(\mathbf{P}_b - \mathbf{P}_a) \cdot [(\mathbf{P}_c - \mathbf{P}_a) \times (\mathbf{P}_d - \mathbf{P}_b)]|}{|(\mathbf{P}_c - \mathbf{P}_a) \times (\mathbf{P}_d - \mathbf{P}_b)|^2}, \quad (3)$$

where \mathbf{P} is the located vector of the node, as shown in Fig. 2. When δ_i is large, the facet of the element is curved.

Fig. 2. Conceptual Illustration of Planarity Evaluation Method.

C. Diagonal Length Ratio Evaluation

The diagonal length ratio evaluates the distortion of element. The evaluation function of the ratio between the longest and the shortest diagonal of the element, λ , is defined as follows:

$$\lambda = \sum_{i=1}^N \lambda_i / N, \quad \lambda_i = 1 - \frac{l_{i,\max}}{l_{i,\min}}, \quad (4)$$

where l is the length of the diagonal, as shown in Fig. 3. When λ_i is large, the element is distorted.

Fig. 3. Conceptual Illustration of Diagonal Length Ratio Evaluation Method.

D. Volume Ratio Evaluation

The ratio between the volume of the element and the cube, whose edge length is that of the longest edge of the element, is defined as the volume ratio evaluation ε . It is calculated as follows:

$$\varepsilon = \sum_{i=1}^N \varepsilon_i / N, \quad \varepsilon_i = 1 - \left(\frac{V_i}{h_i^3} \right)^{\frac{1}{3}}, \quad (5)$$

where h is the length of the longest edge and V is the volume of the element, as shown in Fig. 4. When ε_i is large, the element is flat or slender.

Fig. 4. Conceptual Illustration of Volume Ratio Evaluation Method.

III. EVALUATED MODEL AND MESHES

In this paper, a simple model consisting of a permanent magnet (1.0 T) and an iron is tested, as shown in Fig. 5. The ICCG is used as a solver. The properties of the generated mesh are shown in Table I. The Mesh (A) consists of only regular hexahedron, as shown in Fig. 6(a). For comparison, some distorted meshes are prepared. The Mesh (B) is generated by randomly moving the nodes of Mesh (A), as shown in Fig. 6(b). The Meshes (C) and (D) are generated by zigzag moving the nodes of Mesh (A) into z - and x -direction, respectively, as shown Figs. 6(c) and (d).

Fig. 5. Test Model consisting of a permanent magnet and an iron.

TABLE I
MESH PROPERTIES

Nodes	Elements	Edges of Unknown
438,976	421,875	1,232,100

Fig. 6. Conceptual Illustrations of Meshes.

IV. EVALUATION OF MESH QUALITY

First, the convergence properties of ICCG are investigated, as shown in Fig. 7, where “Mesh (B)-5” means that the randomly moving distance of nodes is 5.0 mm at longest in Mesh (B). In Fig. 7(b), the degradation of convergence properties of Mesh (C) is prominence. Secondly, the

correlativity between the evaluation values of mesh quality and the number of ICCG iteration is investigated, as shown in Fig. 8, where the convergence criterion of ICCG is 1.0×10^{-6} . In Fig. 8(c), the diagonal length ratio is strongly correlated. Finally, the error of the solution is compared. The maximum error values are 0.0433 T at Mesh (B), 0.0374 T at Mesh (C) and 0.0215 T at Mesh (D) as compared with Mesh (A). All the solutions are accurate enough.

The mesh quality strongly affects the ICCG convergence. To decrease the diagonal length ratio λ leads to the speed-up. Therefore, in the smoothing process of the proposed mesh generator [2], the nodes should move so as to decrease the diagonal length ratio λ .

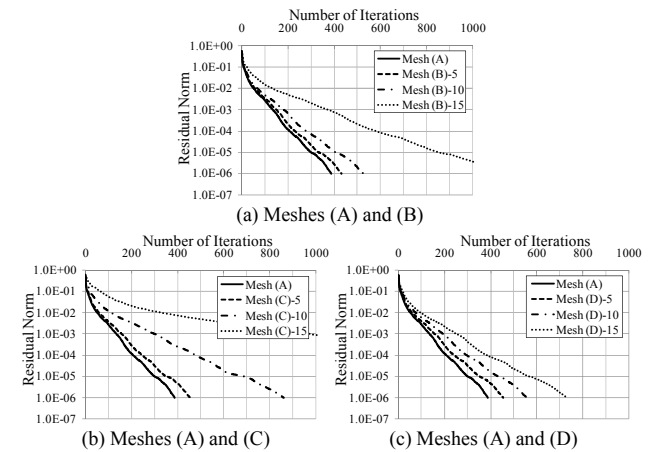

Fig. 7. ICCG Convergence Properties.

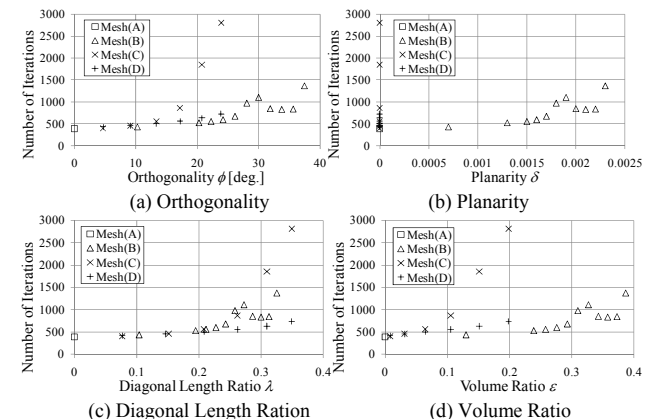

Fig. 8. Evaluation of Mesh Quality.

V. SUMMARY

It was clarified that the diagonal length ratio evaluation correlates with the ICCG convergence. In the future, the smoothing process in the proposed mesh generator [2] has to be developed to decrease the diagonal length ratio.

Abstract—Nowadays, several industrial applications are being ported to parallel architectures. In fact, these platforms allow acquire more performance for system modelling and simulation. In the electric machines area, there are many problems which need speed-up on their solution. This paper examines the parallelism of sparse matrix solver on the graphics processors. More specifically, we implement the conjugate gradient technique with input matrix stored in CSR, and Symmetric CSR and CSC formats. This method is one of the most efficient iterative methods available for solving the finite-element basis functions of Maxwell's equations. The GPU (Graph Processing Unit), which is used for its implementation, provides mechanisms to parallel the algorithm. Thus, it increases significantly the computation speed in relation to serial code on CPU based systems.

I. INTRODUCTION

An electromagnetic field analysis is one of the most complex problems of physics. And, the modeling and simulation of electrical systems use a very large computational algorithms to solve their problems. One of this algorithms is based on the conjugate gradient (CG) method [2]. The CG method is an effective technique for symmetric positive definite systems. It is suitable for systems of the form $Ax=b$, where A is a known, square, symmetric, positive-definite matrix, x is a unknown solution vector and b is a known vector. Iterative methods like CG are suited for use with sparse matrices.

The solution of large, sparse linear systems of equations is the single most computationally expensive step. Thus, any reduction in the linear system solution time will result in a significant saving in the total process time. This need demands for algorithms and software that can be used on parallel processors.

This paper describes the use of the GPU as platform to implement a CG method to solve a linear system. The sample inputs are matrix stored in Symmetric CSR (compressed sparse row) [2] format obtained from a simulation of electric machines. The algorithms use standard BLAS library and two implemented kernels for matrix-vector product (SpMV). The next section describes the GPU which is the platform used and how to program it with CUDA. Section 3 depicts the matrix used and how to implement the solver. A execution performance is discussed in following section. Finally, some concluding remarks are made about obtained results.

II. GPU

GPU (Graphics Processing Unit) is a manycore processor attached to a graphics card dedicated to calculating floating point operations. Even if GPUs are a manycore processors, their parallelism continues to scale with Moore's law. It is necessary to develop application software that transparently scales its parallelism. CUDA (Compute Unified Device Architecture) [3] is a parallel programming model and software environment designed to overcome this challenge while maintaining a low learning curve for programmers familiar with standard programming languages such as C.

A. Processor Architecture

The GPU devotes more transistors to data processing rather data caching and flow control. This is the reason why the GPU is specialized for compute intensive. NVIDIA GPU, specifically, is composed of array of SM(Streaming Multiprocessors), each one is equipped with 8 scalar cores (the SP or Streaming Processors), 16834 32-bit registers, and 16KB of high-bandwidth low-latency memory shared for up to 1024 co-resident threads. GPUs such as the NVIDIA GeForce GTX 280 contain 30 multiprocessors, so 30K threads can be created for a certain task. Further, each multiprocessor executes groups, called *warps*, of 32 threads simultaneously.

B. Memory Architecture

In the NVIDIA GPU memory model, there are per-thread local, per-block shared, and device memory which comprehends global, constant, and texture memories. Shared Memory can be only accessed by threads in the same block. Because it is on chip, the Shared Memory space is much faster than the local and Global Memory spaces. But only 16KB of shared memory are available on each SM.

C. CUDA Programming Model

CUDA is a C language extension developed by NVIDIA to facilitate writing programs on GPUs. It allows the programmer to define C functions, called *kernels*, that, when called, are executed N times in parallel by N different *CUDA threads*, as opposed to only once like regular C functions. One of the main features of CUDA is the provision of a Linear Algebra library(CuBLAS) and an Fast Fourier Transform library

(CuFFT) [3]. The next section describes the implementation of CG on the GPU and the use of CuBLAS library.

III. IMPLEMENTATION

The Conjugate Gradient was applied to 30880x30880 symmetric sparse matrix A with 449798 nonzero double precision elements. It is stored in full or symmetric CSR format files which include the unknown elements vector x and the result vector b . The CG algorithm used to implement the program is below.

Require: init variables

- 1: **for all** k such that $1 \leq k \leq N$ **do**
- 2: $\alpha \leftarrow \frac{(r^T r)}{(p^T A p)}$
- 3: $x \leftarrow x + \alpha p$
- 4: **break if convergence**
- 5: $r \leftarrow r - \alpha A p$
- 6: $\beta \leftarrow \frac{(r_k^T r_k)}{(r_{k-1}^T r_{k-1})}$
- 7: $p \leftarrow r + \beta p$
- 8: **end for**

All the internal loop operations are executed on GPU. The scalar product and $axpy$ functions on lines 3,5,7 use CuBLAS functions. Since BLAS is only for dense matrix, naturally it is necessary to create a *CUDA kernel* for sparse matrix. For that reason, a SpMV algorithm for matrix-vector multiplication should be implemented to execute the $A p$ product on line 2. Let $A = (L + D + U)$, where D is the main diagonal part of A , L is its strictly lower triangular part and U is its strictly upper triangular part. Since A is symmetric, $U^T = L$. Thus, A can be stored in CSR format of $(L + D)$.

Three algorithms were implemented in this work. The first one is a trivial solution of $y = Ax$ in which each thread executes $y[tid] += A[i-1] * x[jA[i-1] - 1]$, where tid is the thread identify, and $[i,jA]$ are obtained from vectors of the stored matrix. The two other solutions explore the symmetry characteristic. The aim is to cut down the time and memory allocation cost. The figure 1 shows the procedure of algorithm conception. The *kernels* are composed of blocks and each block has certain threads. Only one kernel can execute in same time on same device and there are a few blocks in execution simultaneously in each SM. Sequentially the *kernel 1*(SCSR) and *kernel 2*(SCSC) are executed and they take care of $L + D$ and U respectively. To avoid writing conflicts on y vector in global memory, the *kernel 2* calls *atomic functions* and that allows just one thread write in a memory address at given moment. As the number of elements of a column or a row can be greater than the number of threads in a block, it is necessary that the algorithm calculates the quantity of elements for each thread.

IV. RESULTS

A double precision version of CG was created on a contemporary conventional CPU and this one was used as a reference to calculate the speed-up. Two other versions were developed on the GPU. The first one is a single precision version which was tested on a NVIDIA Tesla C870 card. The second one is

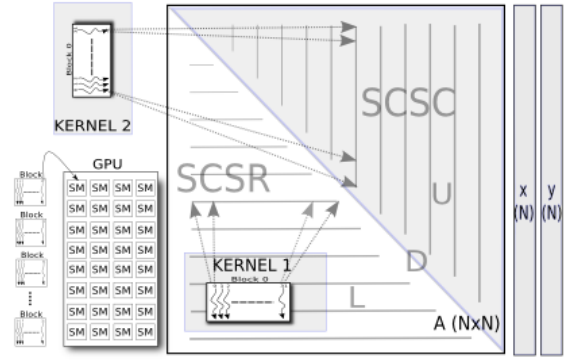

Fig. 1. SpMV on Symmetric CSR and CSC storage format

a double precision version which was executed on a NVIDIA GeForce GTX 280.

The matrix reading from files takes time to be done properly. Approximately 6ms in our tests. Because this operation is basic for all experiments, it is not necessary to evaluate it. It is important to examine the *Scalar Product*, *AXPY*, and *SpMV* execution time because these functions are called repetitively in each loop interaction. Yet, all the time that the interactive CG loop takes. The table I shows the operations and their respective spent time values. The application not use the *sym SpMV*, its times are there just for benchmarking.

TABLE I
SPEED-UP RESULTS

Operation	CPU Time	Single Prec. C870	Double Prec. GTX280
dotProd	0.290ms	0.529ms	0.450ms
AXPY	0.109ms	0.014ms	0.008ms
SpMV	5.966ms	0.013ms	0.005ms
SpMV(sym)	-	0.040ms	0.035ms
CG/ # int	2392ms/328	400ms(5.8x)/324	370ms(6.4x)/323

V. CONCLUSION

This approach issues the viability of using GPU on sparse matrix solvers. The obtained results allow us to evaluate two important impacts in finite-element method of Maxwell's equations using Conjugate Gradient algorithm. The first one is concerned to speed gain. On the GPU, the CG arrives faster than on the CPU due its parallel architecture. The second one is the impact of storing symmetric matrix in memory. Although it can store in memory almost half of the matrix, the performance of algorithm decreases as shown in table of speed-up results. This is due the repetitive way that the *kernel* computes and accumulates the $y = Ax$ result. However, both cases contribute significantly to accelerate the computation of basis functions.

Design of Conventional C-core Magnets Using a Multi-Step Optimization Procedure

Felipe Campelo^{1,2}, Jaime A. Ramírez² and Hajime Igarashi¹

¹Laboratory of Hybrid Systems, Hokkaido University, Sapporo 060-0814, Japan.

²Departamento de Engenharia Elétrica, Universidade Federal de Minas Gerais, Belo Horizonte 31720-901, Brazil.

We consider, in this work, the design of conventional C-core magnets for particle accelerators, focusing primarily on the shape design of the iron core. We propose an integrated technique that uses topology and parameter optimization, which are connected by a model generation module. Specific characteristics of this kind of device are also considered in the definition of the final shape, particularly in the final parameterization of the pole shape.

Index Terms—C-core magnet, multi-step optimization, electromagnetic design.

I. INTRODUCTION

Conventional C-core dipole magnets are important components in the design of some particle accelerators, where this kind of device is employed for changing the trajectories of charged particle beams [1]. Such devices usually consist of one or more excitation coils, or in some cases, permanent magnets, placed around a C-shaped core, hence the name, of ferromagnetic material, shaped in a way such as to provide a highly homogenous magnetic field within a certain region where the charged particles are to pass. Particles moving at high speeds through this region are subject to the magnetic component of the Lorentz force,

$$\mathbf{F} = q(\mathbf{v} \times \mathbf{B}) \quad (1)$$

where \mathbf{F} is the force vector, q and \mathbf{v} are respectively the charge and speed vector of the particle, and \mathbf{B} is the magnetic flux density vector. The trajectories of the particles are bent perpendicularly to their speed and the direction of the field, and a ring arrangement of several magnets is capable of maintaining the particle beam in a stable circular trajectory.

Despite the lower field intensities of conventional electromagnets, when compared to the more impressive superconducting ones, conventional, copper-coil C-core magnets still provide an interesting alternative to the superconducting solution. First, the costs involved in building, maintaining, operating, and replacing conventional magnets are sensibly smaller than those of a superconducting one; also, in cases where multi-Tesla magnetic fields are not required, conventional C-core magnets are capable of providing the intensities and performance needed. One such example is the Large Electron-Positron (LEP) collider from CERN, predecessor to the current Large Hadron collider (LHC) [1], with its 3,280 dipole magnets. Better designs for C-core dipoles can, therefore, lead to cheaper or more efficient particle accelerators, two interesting goals for organizations developing such experiments.

II. DESIGN REQUIREMENTS

It is regarded that one of the most important requirement of a C-core dipole in an accelerator is field homogeneity within the target region (see figure 1), which must be within a few parts per million in order to keep the particles in stable trajectories. Matematically, the design problem can be stated as:

$$\begin{aligned} \text{minimize: } f &= \frac{\max(|\mathbf{B}_m - \mathbf{B}_{ref}|)}{10^{-6}} + V_{core} \\ \text{subject to: } \max|\mathbf{B}_m - \mathbf{B}_{ref}| &\leq 10^{-5} \end{aligned} \quad (2)$$

where \mathbf{B}_m and $\mathbf{B}_{ref} = [0.0, 0.13]^T$ are respectively the observed and ideal magnetic flux densities within the target region (in Tesla); and V_{core} is the observed volume (in m^3) of the variable portion of the core, figure 1. While the reduction of the volume is not an essential requirement in this particular problem, a volume term is included in the objective function as a regularization term.

In this particular design case, the core is manufactured as series of laminated low-carbon steel plates embedded in cement mortar, following the LEP design [2]. The excitation of the magnet is provided by two solid copper bars carrying a total current of 4480A. A detailed description of the device, along with the specifications of all materials used, will be provided in the full paper.

III. DESIGN PROCEDURES

In order to obtain an optimal shape for the magnet core a multi-step optimization procedure [3] is performed. These design steps are briefly presented in this section, and will be discussed in depth in the full paper.

A. Topology optimization

The design process starts with the topology optimization (TO) step to find a rough estimate of the size and shape of material required for the fulfillment of the design requirements. An evolutionary TO algorithm [3] is, then, applied on the design model shown in figure 1, in order to obtain a good initial distribution of steel within the L-shaped *design region*.

Fig. 1. Design layout (upper half) for the C-core dipole magnet, showing the fixed and variable portions of the core, the coils, and the design region (30mm half circle under the magnet pole). This device presents linear symmetry, with a depth of 3000mm. All units are in millimeters.

Fig. 2. Rough shape obtained after topology optimization

B. Shape refinement

The result obtained by the topology optimization algorithm is used to generate a parametric model of the device, in order to allow for further refinement of the shape. The parameterization of the TO result is done by means of an automated feature-recognition routine, based on simple edge- and corner-detection techniques [3]. This parameterization routine is able to represent the shape obtained by the TO process by means of a series of connected lines and Bézier splines.

Fig. 3. Core shape after parameterization and parametric shape optimization.

The parametric model is, then, optimized by means of a regular evolutionary algorithm, yielding the shape shown in figure 3.

C. Pole Design

It has been shown that optimal pole shapes for C-core dipoles present shims in order to compensate for the effects of finite pole length. Following the recommendations given by Russenckuck [1], the dimensions of the pole shims were

obtained by means of numerical algorithm, in this case an evolutionary method. The final pole shape obtained is shown in figure 4.

Fig. 4. Detailed view of the pole after shim optimization.

Table I describes the characteristics obtained at the end of each step in the design process for the device of interest.

TABLE I
RESULTS OBTAINED AFTER EACH STEP OF THE DESIGN PROCESS

	$\max \mathbf{B}_m - \mathbf{B}_{ref} $ [T]	V_{core} [m ³]
Topology Optimization	2.11×10^{-5}	0.2532
Shape refinement	1.68×10^{-5}	0.2762
Pole design	1.25×10^{-5}	0.2764

The results in Table I show that the use of a multi-step design methodology was able to yield progressively better characteristics for this particular device, considering the magnetic field characteristics that are the main focus of the current design procedure. While the final result obtained after the optimization of the pole shims is still slightly over the $10\mu T$ threshold, this small constraint violation should be within the tolerance limits for the intended application. The full paper will discuss the results in greater depth.

IV. CONCLUSIONS

In this paper the design of a conventional C-core dipole magnet was considered. A multi-step optimization procedure was employed, including the initial topological design; the parameterization of the topology obtained; the refinement of the parametric model; and the determination of the pole shims. The characteristics obtained at each of the design steps illustrate the potential of this multi-step methodology to generate progressively better designs for the dipole under consideration. A discussion on the manufacturability of the shapes obtained and on the optimization techniques employed are included in the full paper.

 angelo@ieav.cta.br

Abstract — This work presents a self-consistent optimization approach of multi-quantum well structures. A Genetic Algorithm meta-heuristic is used for the search mechanism. The computer code, based on the solution of both the Poisson and the Schrödinger equations self-consistently by using the Finite-Element Method, obtains the characteristics of each individual. The results of two tests are presented and discussed.

I. INTRODUCTION

Commercial CAD tools for simulating semiconductor devices usually do not deal with the quantizing effects of nanometric heterostructures. When they deal with heterostructures, they do it in a quite limited way. A number of commercially available or developing devices, such as quantum-well infrared photodetector [1], QWIP, quantum dot infrared photodetector [2], QDIP, and quantum cascade laser [3], QCL, depend on a detailed design of its band structure, in what has become known as band engineering [4]. Many structures of academic interest have also been intensively studied, in the past decades, improving the understanding of fundamental physics involved in such devices [5]-[9]. Since many of the used heterostructures have free charges from doping, a more precise calculation of the quantum levels should include the effect of charge distribution, solving the Poisson and Schrödinger equations self-consistently.

More recently, computational optimization techniques have been used to the design of nanostructured semiconductor devices. A brute force technique was employed to optimize an InGaAsN/GaAs multi-quantum well structure, MQW, in order to obtain a QCL of high operation frequency [3]. The simulated annealing meta-heuristic was used to maximize the optical rectification of an AlGaAs/GaAs MQW, varying the Al concentration of each barrier [10].

In this work, we present the optimization of MQW structures by using the Genetic Algorithm meta-heuristic, GA.

II. OPTIMIZATION APPROACH

The design optimization is an iterative process in which candidate solutions are successively generated by an optimization, or search, algorithm and evaluated by an analysis tool.

In this work, the GA selects tentative solutions, i.e., design parameters of the quantum wells that are responsible for specific characteristics of the structure. Each design parameter is represented by a binary code and the number of bits of this code is associated to the search space of the parameter. The binary codes of each design parameter are appended one after another to form the individual, or chromosome. The individuals of the initial population are

generated randomly. The core of the optimization tool used in this work has been used in the optimization of electrooptic modulators and of electrooptic sensors [11].

When analyzing periodic semiconductor MQW, the calculation of energy levels without taking into account charge redistribution usually gives reasonable results [8],[9], since the changes in the relative energy position of the subbands are not dramatic. Otherwise, if the periodicity is broken with a well of different width, charge separation increases and a self-consistent calculation becomes essential even for a qualitative understanding of electrical dynamics in the structure [12]. In this work, the analysis tool is based on the Finite Element Method, FEM, and solves the Poisson and Schrödinger equations self-consistently. The complete formulation is presented in [13] and the computational tool we developed was already presented in [14]. This tool is already in use for research purposes [12], [15].

III. RESULTS

In this section, results from two cases are presented. The genetic operators used in the test cases are: elitism of one individual, the roulette wheel technique for the reproduction operator with one crossover point chosen randomly, the occurrence probability for the crossover is set to 0.8 and for the mutation is set to 0.05.

The first case is a very simple problem: a symmetric heterostructure of GaAs/Al_xGa_{1-x}As, composed by two wells surrounding a third, larger one. A doped barrier is allowed between the external wells and the substrate. Fig. 1 illustrates the structure. In a periodic MQW, the current at low bias is believed to occur via tunneling between the first subband of adjacent wells [9],[8]. A larger well introduced in the structure should generate a charge accumulation and consequently a potential increase. The final subband alignment between the larger well and neighbor wells is important for understanding the charge transport in the structure.

The exercise is to choose design parameters to obtain a symmetric structure in which the energy of the second subband of the central well, E_{2c} , is equal to the energy of the first subbands of the right and left lateral wells, E_{1r} and E_{1l} . The objective function is given by:

$$F = |E_{2c} - E_{1l}| - \alpha * |E_{1l} - E_{1r}| \quad (1)$$

where α is a constant. Therefore, we try to minimize the difference among the energy of these subbands. As additional constraints, we impose that the structure has to be symmetric in terms of the thickness of the layers with respect to the central one. Also, all barriers must have the same concentration of aluminum. The doping concentration can be

different in each well and barrier. Additional penalty is imposed if there is less than 2 subbands in the central well. The range of variation of each design parameter is:

$$\begin{aligned} 0.2 \leq x \text{ (aluminum concentration)} &\leq 0.5, \\ 1 \text{ nm} \leq \text{thickness of the lateral well} &\leq 10 \text{ nm}, \\ 10 \text{ nm} \leq \text{thickness of the central well} &\leq 50 \text{ nm}, \\ 5 \text{ nm} \leq \text{thickness of the inner barriers} &\leq 10 \text{ nm}, \\ 1 \text{ nm} \leq \text{thickness of the doped external barriers} &\leq 5 \text{ nm}, \\ 10^{15} \text{ cm}^{-3} \leq \text{doping concentration} &\leq 9.0 \times 10^{16} \text{ cm}^{-3} \text{ or zero, and} \\ \text{thickness of the non doped substrate layer} &= 50 \text{ nm}. \end{aligned}$$

Fig. 1 shows the best individual obtained after 100 generations of 26 individuals each. As expected, the best individual presents almost a symmetric doping concentration.

Fig. 1. The best solution is almost symmetric in terms of the doping concentration.

The second case is also a symmetric structure, a MQW composed by ten identical internal wells, surrounded by larger wells. The larger well aims to simulate the effect of the electric contact on MQW structures, which is an acceptable approximation if the number of subbands confined is high enough. In this case, the objective is to obtain a structure in which the energy of the first subband of each internal well, E_i , is as close as possible to the Fermi energy, E_F :

$$F = \sum_{i=1}^n |E_i - E_F| \quad (2)$$

where n is the number of inner quantum wells. In this example, $n = 10$. The alignment is a necessary condition to obtain a device presenting a quasi-ohmic behavior when submitted to low (quasi-zero) voltages.

In this case the aluminum concentration, the thickness of the non doped substrate layer, the thickness of the inner barriers, and the thickness of the inner wells are kept constant. The range of variation of the other design parameters is:

$$21 \text{ nm} \leq \text{thickness of the lateral wells} \leq 50 \text{ nm}, \\ 10^{16} \leq \rho_{in} \leq 9.9 \cdot 10^{18} \text{ cm}^{-3} \text{ or zero, and } \rho_{in} \leq \rho_{la} \leq 9.9 \cdot 10^{18} \text{ cm}^{-3},$$

where ρ_{in} and ρ_{la} are the doping concentration of the inner wells of the lateral wells, respectively.

Fig. 2 shows one of the best solutions found that minimizes the objective function (2). The contact layers (the larger wells) are strongly doped with respect to the MQW inner structure.

The main objective of the test was to verify the convergence of the GA for this problem. The test is very hard, because the self-consistent computation converges rapidly when doping concentrations are lower than $5.0 \cdot 10^{17} \text{ cm}^{-3}$, but the time of convergence increases for higher doping

concentrations and it is very high for concentrations about 10^{18} cm^{-3} .

Fig. 2. One of the best solutions obtained.

IV. FINAL COMMENTS

The module of optimization of nanostructured semiconductors based on quantum wells is operational and in the early stage of testing. The optimizations process was executed in a distributed computational environment with up to nine processing units. Nowadays, the main effort is to improve the convergence process of the self-consistent computation for structures with high doping concentrations, characteristic desired for the design of QWIPs. In the next steps, we intend to optimize structures minimizing or maximizing some features of interest for QWIPs.

Impact of Wave Propagation Effects in Electrical Tomography

M. Neumayer and G. Steiner

Institute of Electrical Measurement and Measurement Signal Processing
Graz University of Technology, Kopernikusgasse 24/IV, A-8010 Graz, Austria
Email: neumayer@tugraz.at

Abstract—Algorithms and methods to solve inverse problems in Electric Field Tomography (EFT) often use a quasi-static model assumption. At higher measurement frequencies where wave propagation effects appear these simplifications of the model could lead to corrupted reconstruction results. In this work we investigate the impact of unmodeled physical effects in electrical impedance tomography. We recapitulate physical considerations about the emerge of wave propagation effects and perform simulations to verify these results.

I. INTRODUCTION

The usability of electric fields for industrial and medical tomography applications is commonly known and for a longer period a field of applied and theoretical research. By measurements of electrical impedances these methods aim at the reconstruction of the spatially distributed electrical material parameters and present them as an image. Typically the electric conductivity σ or the relative permittivity ϵ_r are reconstructed. Also methods that evaluate the both quantities together have been implemented [1], [2]. These methods aim at the complex impedance $\sigma + j\omega\epsilon_0\epsilon_r$ which is appropriate if the ohmic current and the displacement current are in the same order of magnitude. For the physical modeling of the problems in most cases an elliptic differential equation for the electric scalar potential is used. However, in the case of high working frequencies also wave propagation effects could appear. If these effects are not negligible in their amplitude the relatively simple models fail and a loss in the quality of the reconstruction results has to be expected. In this paper we investigate the physical effects within the sensor and give a statement about the choice of a model. For this we recapitulate the theoretical background and compare our considerations with previous results. We perform field simulations to compare the electrical quantities of different models and monitor the impact of un-modeled physical effects on reconstruction tasks.

II. SENSOR SETUP

Figure 1 depicts a possible hardware scheme for complex electrical impedance tomography. 16 electrodes are mounted equidistantly on the exterior of a plastic pipe. The sensor is based on current measurements which means that the electrical potential on the electrode is fixed. It is aimed to reconstruct material distributions with relative permittivities up to $\epsilon_r = 80$ and conductivity values of about $\sigma = 0,2 \text{ Sm}^{-1}$ (saline water). The measurement frequency of the sensor is 40 MHz. For this

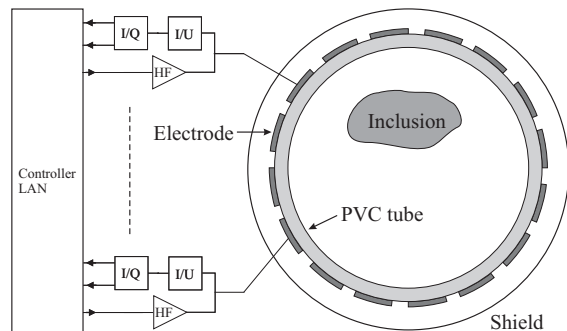

Fig. 1. Schematic of the sensor system.

frequency σ is in the same order of magnitude as $\omega\epsilon_0\epsilon_r$, which is a precondition for complex impedance tomography [3].

III. PHYSICAL CONSIDERATIONS ABOUT WAVE PROPAGATION

A decision rule for the consideration of wave propagation is given by [3]

$$\omega\mu\sigma L_c \left(1 + \frac{\omega\epsilon}{\sigma}\right) \ll 1, \quad (1)$$

where L_c is defined as a characteristic distance over which the electric field \vec{E} varies significantly. If equation (1) is satisfied then a quasi-static formulation can be used. From transmission line theory it is known that a criterion for the occurrence of wave propagation effects is given by the ratio of object size to wavelength λ . Typically at a ratio of one over ten of object size to wavelength it is said, that wave propagation effects can not be neglected. The wavelength λ of an electromagnetic wave can be calculated by the complex propagation constant

$$p = \sqrt{j\omega\mu(\sigma + j\omega\epsilon)} = \alpha + j\beta, \quad (2)$$

which ends up in

$$\lambda = \frac{2\pi}{\beta} = \frac{2\pi c}{\omega} = \frac{2\sqrt{2}\pi}{\sqrt{\omega\mu(\sqrt{\sigma^2 + \omega^2\epsilon^2}) + \omega\epsilon}}. \quad (3)$$

Table I lists the results of the left hand side of equation (1) and (3) for different materials. The parameter L_c has been set to $L_c = 0,01 \text{ m}$. This value was found by the evaluation of field simulations. The results in table I give a hint that already for distilled water wave propagation effects should not be neglected.

TABLE I
WAVELENGTHS AND THE LEFT HAND SIDE OF EQUATION (1) FOR DIFFERENT FILLINGS AT A FREQUENCY OF $f = 40$ MHz ($\mu_r = 1$).

Nr.	Filling	σ Sm ⁻¹	ϵ_r 1	λ m	Equation (1) 1
1	Air	0.0	1	7.49	0.007
2	Distilled water	0.0	80	0.84	0.562
3	Saline water	0.2	80	0.75	1.194
4	Sea water	5	80	0.22	16.354

IV. FIELD SIMULATIONS

To give precise statements about the appearance of wave propagation the sensor has been modeled with a finite element software tool. For a saline water filled sensor ($\sigma = 0,2 \text{ Sm}^{-1}$, $\epsilon_r = 80$) a quasi-static and a full simulation of the Maxwell's equations have been performed for a shielded and a unshielded sensor. Figure 2 depicts the ratio of the induced current density to the potential driven current density in the interior of the sensor. One can see that the induced current density is almost a tenth of the potential driven current density. The impact sounds not to be negligible. Bode diagrams figured a first significant spread between the quasi-static and the full simulations at a frequency of 30 MHz.

Fig. 2. Ratio of the induced to the potential-driven current for a saline water ($\sigma = 0,2 \text{ Sm}^{-1}$, $\epsilon_r = 80$) filled sensor at $f = 40$ MHz.

V. RECONSTRUCTION ALGORITHM

For the reconstruction a Gauss-Newton formulation is used. The inverse problem is solved by

$$\arg \min_{\sigma, \epsilon_r} \mathbf{r}_c^H \mathbf{r}_c + \alpha_\sigma \|\mathbf{L}\sigma\|_2^2 + \alpha_{\epsilon_r} \|\mathbf{L}\epsilon_r\|_2^2, \quad (4)$$

where \mathbf{r}_c denotes the complex-valued residual vector. The vectors σ and ϵ_r contain the material values of the finite elements which are in the interior of the pipe. The parameters α_σ and α_{ϵ_r} are regularization parameters. A detailed description of the algorithm and the used calibration method can be found in [2].

VI. RECONSTRUCTION RESULTS

Figure 3 depicts the result of a reconstruction task for a material distribution of two oil bubbles ($\sigma = 0 \text{ Sm}^{-1}$, $\epsilon_r = 2$)

Fig. 3. Reconstruction of the measurement data obtained by a simulation of the full Maxwell's equations.

within saline water ($\sigma = 0,3 \text{ Sm}^{-1}$, $\epsilon_r = 80$). The positions of the two inclusions are marked by dashed circles. The measurement data was obtained by a full simulation of the Maxwell's equations. By defining the error measure

$$\epsilon_x = \frac{\int_{\Gamma} |x_{Wave} - x_{Qstat}| d\Gamma}{\int_{\Gamma} |x_{Qstat}| d\Gamma} \times 100, \quad (5)$$

the impact of wave propagation effects amounts $\epsilon_\sigma = 8,89\%$ and $\epsilon_{\epsilon_r} = 7,87\%$ compared to a reconstruction of measurement data which was obtained by a quasi-static simulation.

VII. CONCLUSION

Although the obtained reconstruction result looks quite accurate an appreciable difference appears. To demonstrate the impact of unmodeled effects a synthetic setting of calibration and measurement data has been used. In the normal case better reconstruction results can be achieved as all measurements imply the same characteristics. The results about the appearance of wave propagation in section III are a hint that wave propagation effects should not be neglected. Especially equation (1) suggests an evidence for wave propagation effects. An explanation for the small impact in the reconstruction results is the geometry of the sensor. Considerations about wave propagation are typically for free space propagation. Due to the large cover angle of the electrodes the sensor is nearly completely screened. The results of the simulations of the unshielded sensor confirm this. The shielding causes a suppression of wave propagation effects. Conventional rules of thumb for a prognosis of the model have therefore be handled carefully. In combination with a suitable calibration an expansion of the frequency range or the dimensions of the sensor should be possible by a retention of a quasi-static model.

Abstract — This paper presents the design optimization of new electromagnetic engine valve in a limited space of the entire by multidisciplinary simulation using MATLAB and MAXWELL. This aims to maximize the frequency of vibration in order to reduce the transition time of engine valve. The results show the enhanced performance of optimized actuator.

I. INTRODUCTION

The variable valve timing is a key technology in combustion engine of automobile to improve fuel efficiency up to 15%, enhance torque output up to 10% and reduce CO2 emission up to 15% because VVT makes possible the optimization of these outputs at different engine operating conditions [1][2]. Kim and Lieu introduced a new design of electromagnetic engine valve actuator using permanent magnet [3] to achieve VVT in combustion engine. It saves a large amount of electric power for operation compared with conventional solenoid-driven actuator two main advantages. First, the residual induction of the permanent magnet can hold the valve at the closed position at the initial stage. In addition, no power is needed between valve events and current is only fed into system at each valve transition period.

Fig. 1 shows the schematic diagram and operating principle of newly suggested actuator. This actuator is composed of two pieces of permanent magnet, electromagnetic coil (solenoid), a laminated steel core and armature, two springs and valve body. The armature and the valve are one continuous body. Accordingly, the engine valve closes and opens as the armature moves up and down. The total travel distance of armature is 8 mm. The solid arrows show the magnetic flux generated by the permanent magnets and the dotted arrows show the flux generated by the electromagnetic coil. At start, the permanent magnets latch the armature at the upper position, i.e. the valve is closed because the magnetic force exceeds the spring force. To open the engine valve, the coil is energized. As the flux of permanent magnets is partially cancelled, the spring force exceeds the magnetic force and the armature is released and accelerated by the stored energy in the springs. Thus, the engine valve starts opening. After the armature passes neutral position of stroke, the electromagnetic coil is reversely energized. Then, the permanent magnets and the electromagnetic coil catch the armature at the lower end position. The motion from the lower end to the upper end is the inverse operation of the steps above.

Fig.1. Schematic diagram and operating principle of suggested actuator (a) at the upper end (b) at starting and (c) at the lower end

The transition time is defined as the duration for the valve to move from closed position to opened position or from opened position to closed position and as the transition time is smaller, the engine valve actuator can accomplish higher maximum engine speed. The transition time of valve is shortened by the increment of the frequency of vibration because the actuator is mainly operated by mass-spring oscillation. The frequency of vibration is called by natural frequency (ω_n) that is defined by $\sqrt{k/m}$. Here, k is the equivalent spring stiffness and m is the moving mass.

In this paper, actuator design is optimized to maximize the frequency of vibration, which results in the reduction of the transition time of stroke.

II. DESIGN OPTIMIZATION

Fig. 2 shows design variables for optimization and the goal of this structure is to maximize the frequency of vibration expressed by (1).

$$\omega_n = \sqrt{\frac{k}{m}} = \sqrt{\frac{(F_{Latching} - 100) / x_{max}}{v_a \times \rho_s + m_v}} \quad (1)$$

where,

k : Spring stiffness

m : Moving mass including armature and engine valve

ω_n : Frequency of vibration (natural frequency)

- $F_{Latching}$: Magnetic latching force
- x_{max} : Distance from neutral to lower end of stroke
- v_a : Volume of armature
- ρ_{steel} : Mass density of steel
- m_v : Mass of engine valve

Fig. 2. Design optimization variables for maximizing frequency of vibration at bottom end position of armature

The optimization is achieved by multidisciplinary simulation of MAXWELL and MATLAB based on finite element analysis (FEA) that is widely used in design of electromagnetic devices and the generic algorithm (GA) that is a robust stochastic search methods based on natural selection and mutation which drives biological evolution [4]. First, a population of actuator is randomly generated. Each individual in the population is a series of binary string (chromosome) that representing one complete actuator. Then, each gene in the chromosome is decoded to actual parameters using a binary-decoding method. The decoded parameters are passed to the Maxwell for evaluation. The goodness of each chromosome is determined by MAXWELL. In the simulation platform, MATLAB writes a VBScript to execute MAXWELL for electromagnetic simulation and reads the value of latching force to determine the frequency of vibration. Upon the completion of simulation for a given population, GA acts on the chromosomes to generate a new population through crossover and mutation operation. Several independent runs are performed varying population sizes, ratio of crossover and mutation to assure the convergence to the optimal design. Fig. 3 shows a good convergence to some optimal values.

III. OPTIMIZATION RESULTS

Table I shows the optimized dimension of actuator and Table II shows the comparison of characteristics of existing design and optimal design. The magnetic latching force at end position of stroke falls from 1525 N to 1262 N that reduces the obtainable maximal stiffness of spring by 18.4 % from 358 kN/m to 292 kN/m and at the same time, the moving mass

including armature and engine valve falls by 52.1 % from 284 gram to 136 gram. In results, the natural frequency is improved by 30 %.

Fig. 3. The best fitness values in each generation

TABLE I
COMPARISON OF EXISTING DESIGN AND OPTIMAL DESIGN

Characteristics	Existing design	Optimal design
Magnetic latching force	1525 (N)	1262 (N)
Available Spring stiffness	358 (kN/m)	292 (kN/m)
Moving mass	0.284 (kg)	0.136 (kg)
Natural frequency	1123	1465

TABLE II
ACTUATOR DIMENSIONS (ALL DIMNENS IN MILLIMETERS)

Symbol	Quantity	Exiting dimensions	New optimized dimensions
L_{ac}	Thickness of actuator	38.1	38.1
W_{ac}	Width of actuator	120.65	120.65
H_{ac}	Height of actuator	93.34	95

Abstract — The main targets of a Multi-Objective Evolutionary Algorithm (MOEA) is to find a uniformly distributed and well-spread non-dominated solution set (NDSS) close to the true Pareto optimal front (TPOF). This paper presents a new MOEA called Niched Pareto-Archived Evolutionary Programming (NPAEP). It is able to find a good NDSS with few objective function evaluations. During the selection and reproduction processes it uses information about the uniformity distribution and extension of the NDSS. Comparisons were made with other well-known MOEAs on different test problems.

I. INTRODUCTION

In industrial applications optimized design is often problematic because of the simultaneous occurrence of many conflicting targets. Real-world optimization problems, in fact, often exhibit multiple optima, hence it is suitable to give the decision maker a wide range of solutions to choose from. Some optimization methods solve a single multi-objective function obtained by a weighted sum of targets [1]-[2]. The main difficulty in using this approach is setting a good value for the weights so as to scale the objectives appropriately [1]. Other MOEAs search for a set of multiple equivalent solutions, called a non-dominated solution set [1]-[3]. Unfortunately, they can be extremely expensive. This is especially harmful in the optimization of electromagnetic devices, where each estimation of the objective function calls for a numerical solution by means of the Finite Element Method (FEM) [4].

In this paper we present a new MOEA called Niched Pareto-Archived Evolutionary Programming that is able to obtain the same results as well-known MOEAs with fewer objective function evaluations.

II. THE NPAEP ALGORITHM

The main target of a MOEA is to find an NDSS close to the TPOF, uniformly distributed and maximally extended. During the selection and reproduction processes, NPAEP uses information about the degree of satisfaction of these targets and it maintains an archive of the best solutions found so far.

Fig. 1 shows the pseudo-code of the algorithm, where Q is the set of dominated individuals, P is the archive of the best solutions, n_{pop} is the population size, n_{gen} is the number of generations and n_Q is the number of individuals in Q at generation t .

Fig. 2 shows the pseudo-code for the fitness assignment, where n_P is the number of individuals in P at generation t , $df_{i,j}$ is the normalized [0,1] Euclidean distance between individuals

```

begin
  Create  $n_{pop}$  random solutions
  Move the non-dominated individuals to  $P$  and the others to  $Q$ 
  Set the age of every individual belonging to  $Q$  to zero
  do  $t=1$  to  $n_{gen}$ 
    Increase the age of individuals belonging to  $Q$ 
    Compute the fitness  $F$  of each individual
    Select one parent among them by means of a roulette wheel
    if then (parent belonging to  $Q$ ) then
      Reset the age of the parent to zero
    endif
    Mutate  $x_{offspring} = m(x_{parent})$ 
    if (offspring dominates some individuals of  $P$ ) then
      Move them to  $Q$  and their ages are set to zero
      Move offspring to  $P$ 
    elseif (offspring and  $P$  are non-dominated by each other) then
      Move offspring to  $P$ 
    else
      Move offspring to  $Q$  and set its age to zero
    endif
    if ( $n_Q > n_{pop}$ ) Delete the eldest  $n_Q - n_{pop}$  individuals of  $Q$ 
  enddo
end

```

Fig. 1. Pseudo-code of NPAEP algorithm

i and j in the search space, OP is the subset of P containing the best solutions of every objective function, $rand$ is a random number $\in [0,1]$ and it has a uniform probability density function, $n_{DOM,i}$ is the number of individuals that dominate i . The fitness is assigned to an i -individual of P as follows:

$$F_i = \begin{cases} 1 & \text{if } (dfm = d \min_i) \\ \frac{1}{n_i} \left(\frac{1}{n_i \cdot dfm} \sum_{j=1}^{n_i} df_{i,j} \right) & \text{if } (dfm > d \min_i) \end{cases} \quad (1)$$

where n_i is the number of j -individuals belonging to P for whom $df_{i,j}$ is less than dfm and dfm is $\max(\min(df))$.

The NPAEP algorithm uses a maximum mutation displacement computed as follows:

$$\sigma_{i-k} = \frac{1}{2} \frac{\rho_k}{1 + n_P} \left(1 + n_P \frac{F_{max} - F_i}{F_{max} - F_{min}} \right) \left(1 - \frac{0.75 * t}{n_{gen}} \right) \quad (2)$$

where ρ_k is the range of the k -th design parameter, F_{min} and F_{max} are the minimum and maximum values of F respectively. Hence, the mutation operator is obtained as:

$$x_{offspring-k} = m(x_{parent-k}) = x_{parent-k} + rand * \sigma_{parent-k} \quad (3)$$

where $rand \in [-1, 1]$ and has a uniform probability density.

```

begin
do i=1 to nP (xi∈P)
  dmini = 1
  do j=1 to nP (xj∈P, i≠j)
    if (dmini > dfi,j) dmini = dfi,j
  enddo
enddo
dfm = max(dmini) (xi∈P)
do i=1 to nP (i∈P)
  use (1) to compute Fi
  if (i∈OP) then
    if (Fi==1) then
      Fi = Fi + rand
    else
      Fi = Fi + (1-Fi)* rand
    endif
  endif
enddo
nT = nP + nQ
do i=1 to nQ (xi∈Q)
  Fi = min(Fj)*(nT - nDOM,i) / nT (xj∈P and xj dominates xi)
enddo
end

```

Fig. 2. Pseudo-code of the fitness assignment

Fig. 3. Non-dominated solution set obtained by means of NPAEP on the SCH function

NPAEP	0.003266	0	0.002439	0
NPAEP 2500	0.003559	0	0.006126	0

III. MATHEMATICAL RESULTS

In multi-objective optimization there are several performance metrics [5]. We adopt the metrics and objective functions described in [3] to compare NPAEP with the results given in the same paper. The convergence metric Υ measures the degree of convergence to a known TPOF. The diversity metric Δ measures the extent of spread achieved among the NDSSs obtained.

Tables I and II show the mean value and variance of the convergence metric Υ and the diversity metric Δ respectively: a lower value means better performance. Performance was obtained with 25000 function evaluations averaged over 10 runs, as in [3]. Moreover, in the last row we show the NPAEP performance with only 2500 function evaluations.

Fig.3 shows the true Pareto optimal set for the SCH function [3] and the non-dominated solution set obtained by means of NPAEP using 25000 function evaluations.

IV. CONCLUSION

Many MOEAs exist in the literature but they can be extremely expensive. This is especially harmful in electromagnetic problems, where each estimation of the objective function calls for a numerical solution by means of

TABLE II
DIVERSITY METRIC Δ

	SCH		FON	
	mean	variance	mean	variance

Abstract — The aim of this paper is to propose a methodology to optimize the design of cylindrical electromagnetic devices regarding to the vibration phenomena. This approach combines the Artificial Intelligent (AI) and Finite Element (FE) analysis to solve the electromechanical inverse problem for identifying the material proprieties (Young modulo and mass density) in different regions of the studied system. Thus, a multilayer perceptron neural network (MLP) is used as forward model and Genetic Algorithm (GA) is used to solve the Optimization Problem (OP) in the Inverse Problem (IP).

I. INTRODUCTION

IPs in electromagnetic are usually formulated and solved as OPs, so iterative methods are commonly used approaches to solve this kind of problems [1]. The numerical models such as FE model are used to represent the forward process. However, iterative methods using the numerical based forward models are computationally expensive. Neural networks (NNs) are utilized for solving the forward process in the iterative methods [2]. Parameters identification using NNs can be recast as a problem in multidimensional interpolation, which consists of finding the unknown nonlinear relationship between inputs and outputs in a space spanned by the activation functions associated with the NN nodes. The input space corresponds to the material characteristics (Young modulo and mass density) and the output corresponds to the dynamic response of the electromagnetic device [3]. This paper proposes a GA based inverse algorithm for parameters identification of electromagnetic devices, witch induce a minimum level of vibration (noise). In the proposed algorithm, a MLPNN is used as forward model, and GA is used to solve the OP in the IP.

II. NEURAL NETWORK ARCHITECTURE

An ANN is an information processing system that has certain performance characteristics in common with biological neural networks and therefore, each network is a collection of neurons that are arranged in specific formations. The basic elements of neural network comprise neurons and their connection strengths (weights). One of the attractive features of ANNs is their capability to adapt themselves to special environmental conditions by changing their connection

strengths or structure. One of the most influential developments in ANN was the invention of the back-propagation algorithm, which is a systematic method for training multilayer ANNs [4]. The standard back-propagation learning algorithm for feed-forward networks aims to minimize the mean squared error defined over a set of training data. In feed-forward ANNs neurons are arranged in a feed-forward manner, so each neuron may receive an input from the external environment or from the neurons in the former layer, but no feedback is formed. The network always has an input layer, an output layer and at least one hidden layer. In our case, there is only one hidden layer. A neuron's activity is modeled as a function of the sum of its weighted inputs, where the function is called the activation function, which is typically nonlinear, thus giving the network nonlinear decision capability. Each layer is fully connected to the succeeding layer. The arrows indicate flow of information (Fig.1) [5].

Fig. 1 Feed forward neural network

where n_l is the number of neurons in the input layer, n_H is the number of neurons in the hidden layer, n_O is the number of neurons in the output layer, x_l are the inputs to the input layer where $l=1, \dots, n_l$, y_k is the value of the hidden layer where $k=1, \dots, n_H$, z_m is the value of the output layer where $m=1, \dots, n_O$. $w_{lk}^{[1]}$ is the weight connecting the l th neuron in the input layer to k th neuron in the hidden layer, and $w_{km}^{[2]}$ is the weight connecting the k th neuron in the hidden layer to the m th neuron in the output layer. The nodes of the hidden and output layer are:

$$y_k = f\left(\sum_{l=1}^{n_l} w_{lk} x_l\right) \quad k = 1, \dots, n_H \quad (1)$$

and

$$z_m = f\left(\sum_{k=1}^{n_k} w_{mk} y_k\right) \quad m = 1, \dots, n_O \quad (2)$$

where the activation function f is traditionally the Sigmoid function defined as

$$f(x) = \frac{1}{(1 + e^{-x})} \quad (3)$$

The back-propagation method is based on finding the outputs at the last (output) layer of the network and calculating the errors or differences between the desired outputs and the current outputs. When the outputs are different from the desired outputs, corrections are made in the weights.

III. GENETIC ALGORITHM

GAs are probabilistic parallel search algorithms based on natural selection. GAs are capable of finding a global optimum among multiple local optima. A GA usually begins with a randomly generated set of potential solutions, called the initial population [6]. A fitness function is used as a measure of the closeness of each member in the population to the global optimum solution. Then, members from the population are selected to produce new members, called descendents or children, by applying stochastic operators to the selected members. The most common genetic operators are crossover and mutation. A crossover operator combines the features presented in parents to produce descendents. A mutation operator slightly perturbs a selected member in a random manner. Crossover operations ensure that the new population inherits highly fit features while mutation operations may add previously unexploited features into the population.

IV. STUDIED ELECTROMAGNETIC DEVICES

Two electromagnetic cylindrical devices are studied in this paper. So, the first one consists on the determination of the optimal mechanical parameters of the ferromagnetic cylinder shown in fig. 2, regarding to the vibratory behavior. The second one is an application of the developed model on an electrical machine. The data are generated by means of a 2D FE model, implemented under Matlab software. Fig 3 and 4 show respectively the evolutions of the objective function and the mass density with respect to the identification iterations.

Fig.2 geometry of the studied cylinder

Fig.3 Evolution of the objective function

Fig.4 Evolution of the mass density with iterations

The obtained results for the studied electrical machine and their validation will be presented in the full paper.

V. CONCLUSION

Material approach is advantageous because it offers the possibility to optimize mostly a given geometry. In fact, in the case of electrical machines, the geometry is usually determined after an optimization process. The combination finite element-neural network has permitted to reduce the computing time needed to resolve the electromechanical problem. The obtained results are satisfactory and open interesting prospects for the vibratory optimisation in electrical machines. In the full paper, more details will be given on the finite element model, the optimization method and the obtained results.

Abstract—This work presents an improved genetic algorithm (GA) applied for electromagnetic optimization. A real-value mutation operator is proposed to improve the algorithm convergence. The well-established theory of capacitive mesh filter is revisited for application of the proposed algorithm. Modeling of mesh filters is accomplished with an equivalent-circuit, a numerical analysis with Ansoft Designer™ method of moments software, and a multi-layer perceptrons neural network. A comparative study between the improved-GA and continuous-GA was done. The obtained results show the superior performance of the proposed genetic algorithm.

I. INTRODUCTION

Natural optimization algorithms, such as, the simulated annealing (SA) and genetic algorithm (GA) are stochastic population-based global search methods inspired in the nature. They are effective for optimization problems with a large number of design variables and inexpensive cost function evaluation. However, the main computational drawback for electromagnetic (EM) optimization relies on the repetitive evaluation of numerically expensive cost functions. Finding a way to shorten the optimization cycle is highly desirable. Several schemes are available to improve the GA performance, such as: the use of fast full-wave methods, micro-genetic algorithm, which aims to reduce the population size, and parallel GA using parallel computation [1]-[2].

In this paper, the authors describe a hybrid EM-optimization method, which blends an improved version of continuous-GA and a multilayer perceptrons (MLP) model. The method is applied to design spatial mesh filters.

II. CONTINUOUS GENETIC ALGORITHMS

Assuming a GA optimization problem with $Nvar$ input variables and $Npop$ individuals, the population at the k -th iteration is a matrix $\mathbf{P}(k)_{Npop \times Nvar}$ of floating-point elements, denoted by $p_{m,n}^k$, with each row corresponding to an individual (or chromosome). In this way GA chromosome is defined by (1) as a vector with $Nvar$ optimization variables.

$$chromosome(k, m) = [p_{m,1}^k, p_{m,2}^k, \dots, p_{m,Nvar}^k] \quad (1)$$

Based on the cost associated to each chromosome, the population evolves through the generations by the application of standard genetic operators: roulette wheel selection, blending crossover method and real-value mutation [1]-[2].

Inspired in simulating annealing cooling schedules [2], we propose a new mutation operator for continuous-GA as given in (2). It is used to improve the GA convergence at the neighborhood of global minimum of a cost function. When the GA global-cost ($gcost$) decreases or the number of GA iterations increases, the quotient function Q given in (3) decreases the standard deviation of mutation operator (2). The parameter $A = 40$ is a constant standard deviation value and $B = 1E-8$ is a cost value neighbor to the global minimum. The continuous-GA using the real-value mutation definition given in (2) and (3) is denominated improved-GA.

$$p_{m,n}^{k+1} = p_{m,n}^k + randn() \cdot \frac{(p_{max} - p_{min})}{Q(k, gcost(k))} \quad (2)$$

$$Q(k, gcost(k)) = \begin{cases} A, & gcost \geq B \\ A + k \cdot [\log(gcost(k))]^4, & gcost < B \end{cases} \quad (3)$$

III. DESIGN EXAMPLE AND CONCLUSION

The GA optimization was done considering for spatial mesh filter design with a plane periodic array of square metallic patches (freestanding or printed on a single substrate layer), as illustrated in Fig 1(a). The side of square patches is $L = g/2$, where g is the cell size. The filter resonant frequency (f_r) and bandwidth (BW) were evaluated through the equivalent-circuit model [3]. A parametric analysis with Ansoft Designer™ method of moments (MoM) software was done for design region of interest defined by the substrate dielectric constant ($\epsilon_r = 1.0, 3.4, 10.2$) and cell size ($g = 3.75, 6, 10, 15, 20, 25, 30, 40, 70, 100$ mm) variations. The substrate thickness $h = 1.5$ mm was assumed for all dielectric layers. The obtained EM-data from parametric analysis of filters was used for the training of a one hidden layer MLP network model (see Fig. 1(b)). For this purpose, it was utilized the efficient resilient backpropagation algorithm [4].

Fig. 1. (a) Capacitive mesh filter design with a periodic array of square patch-elements; (b) MLP model with 10 hidden neurons

Figure 2(a) shows the simulated results for the resonant frequency obtained through the implemented mesh filter models. Equivalent-circuit model [3] is CPU efficient but reasonable accuracy is only obtained for freestanding case. Numerical MoM model is very accurate but its high CPU requirement turns its use prohibitive for EM-optimization. To overcome these problems a fast and accurate one hidden layer MLP model was developed. Figure 2(b) shows the MLP approach results for the mesh filter bandwidth.

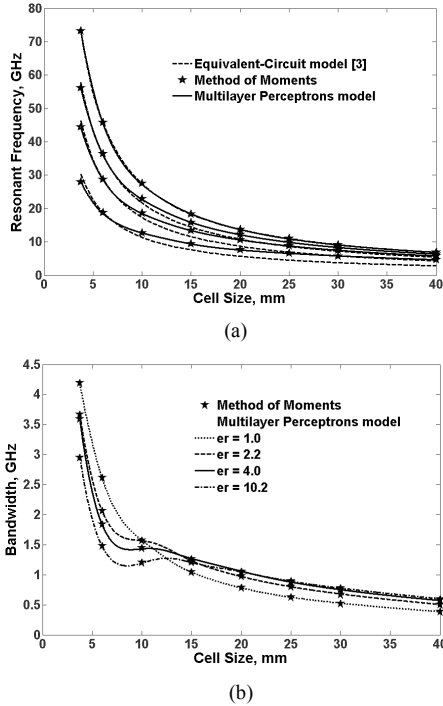

Fig. 2. Capacitive mesh filter modeling: (a) resonant frequency, (b) bandwidth

Given a filter design specification (f , BW), the goal is the minimization of the cost function defined in (4). The functions $f_r(g_m^k, \varepsilon_{r_m}^k)$ and $BW(g_m^k, \varepsilon_{r_m}^k)$ are evaluated using the developed MLP model.

$$\text{cost}(k, m) = \frac{(f - f_r(g_m^k, \varepsilon_{r_m}^k))^2}{f^2} + \frac{(BW - BW(g_m^k, \varepsilon_{r_m}^k))^2}{BW^2} \quad (4)$$

Assuming $f_r = 10$ GHz and $BW = 1.0$ GHz we simulated 500 GA iterations. In Fig. 3(a) is presented the improved-GA path over the contours of cost surface defined in (4) as well the distributions of GA population composed by 100 individuals.

Fig. 3(b) shows the evolving of global-cost for the best individual of GA population. The final global-cost values for improved-GA and continuous-GA were $2.13E-27$ and $1.52E-13$, respectively. The CPU spent-time for GA optimization was ≈ 30 s. The optimized values $g = 20.75$ mm and $\varepsilon_r = 4.404$ were obtained (see final population in Fig. 3(a)). To verify if these results satisfy the filter specifications, the transmission coefficient of optimal mesh filter was simulated with MoM. The obtained results $f_r = 10$ GHz and $BW = 1.03$ GHz are in excellent agreement with desired design values.

Abstract— This paper deals with identification of thermal parameters for transformer's FEM model. The identification technique is based on stochastic optimization algorithm called differential evolution (DE). As the accuracy of the model depends on its parameters, the goal of DE is to identify adequate thermal parameters, in order to achieve best possible agreement between measured and model-calculated values of temperature. The inclusion of identified/optimal thermal parameters into the model, results in good model's accuracy.

I. INTRODUCTION

Operational reliability of electric power system strongly depends on transformers, therefore to predict and to determine thermal phenomena in its compounding parts is an important step in machine designing process. Distribution of thermal field in transformer can be determined by using FEM model [1], [2]. Building of a model requires data of device geometry, sources and boundary conditions. Data of material properties are also required. These are usually obtained from different sources and thus contain some amount of uncertainties. However, this data affects model's accuracy. To achieve model behavior as close to real object, the mentioned data needs to be precisely identified. The novelty of this paper is DE-based technique for identification of model thermal parameters. The goal of DE [3], [4] is to minimize the difference between measured and model-calculated temperature.

II. MODEL OF A POWER TRANSFORMER

Fundamental criterion, which limits the transformers degree of loading and its lifetime, is temperature. Consequentially, the correct determination of temperature distribution in machine design process is important and it can be obtained by using an accurate FEM model. Many physical phenomena are described by similar partial differential equations (PDE). Two examples are equations for magnetic

$$\nabla \cdot (\nu \nabla A) - \sigma(T) \frac{\partial A}{\partial t} = -\sigma(T) V \quad (1)$$

and thermal field

$$\nabla \cdot (k \nabla T) - \rho c \frac{\partial T}{\partial t} + q_t = 0 \quad (2)$$

where ν is the magnetic reluctivity tensor, A the magnetic vector potential, σ the electric conductivity, V the source voltage, T the temperature, ρ the mass density, c the specific heat, k the thermal conductivity and q_t the total losses.

FEM is widely used for solving PDE. In this paper the FEM based programme tool FLUX2D [5] is used for this purpose. For modeling of the thermal processes in transformer, the FEM model that describes coupled electromagnetic and thermal field is used [1], [2]. Coupled electromagnetic-thermal field basically presents two FEM problems (electromagnetic and thermal) and two functions of coupling (losses and temperature dependency of materials).

III. IDENTIFICATION OF THERMAL PARAMETERS BY DE

Modeling process in FLUX2D requires precise data of device geometry, boundary conditions and heat sources, which are quite easy to obtain. On the other hand, required data of material thermal properties and coefficients of convection and radiation are not. As some of these thermal parameters are hard or even impossible to measure, they are usually accessible through catalogues and literature [6]. Consequentially, their accuracy is questionable.

Fig. 1. Schematic presentation of parameters identification process

However, all device data entered in FLUX2D command window is stored in file *f3d_log.spi* (Fig. 1) in command log form. On the basis of this file, the preprocessor *preflu.exe* creates *proj_name.tra* file, which contains all information regarding the model. Calculation parameters such as time step and calculation time are defined in file *proj_name.dif* and used by solver *resgen.exe*. After the calculation completes, the postprocessor *expgen.exe* is employed to display results for various quantities. Desired quantities (in our case temperature) are defined in *expgen.esp* and their calculated values are printed out in file *proj_name.lst*. The important step, after the model simulation completes, is evaluation of the difference between measured and model-calculated values.

Search for optimal thermal parameters is realized by iterative procedure of updating the FEM model with new thermal parameters, calculating the temperature and evaluating

the difference regarding the measured values. New thermal parameters for each update of the *.tra file are generated by DE, which iteratively searches for better solution. Generating the parameters, updating the *.tra file and the automation of the FLUX's calculation process is realized in program tool MATLAB.

Optimal thermal parameters presented in Table I were identified by DE. The goal of the optimization was best possible agreement between measured and calculated temperature. The heating of transformer from cold start-up during 12000 s of operation at nominal load was measured at two locations; one is a specific point of transformer core (point P1) and a second one specific point of winding (point P2). Definition of the objective function q for DE originates from the difference between calculated and measured temperature. Temperature's disagreement can be evaluated by calculating the mean square difference in the given time interval $t \in [t_1, t_2]$

$$q_{P1} = \frac{1}{t_2 - t_1} \int_{t_1}^{t_2} e_{P1}(\tau) d\tau \quad (3)$$

where the difference between measured T_{P1m} and model-calculated temperature T_{P1} in point P1 is defined by $e_{P1}(t) = T_{P1m}(t) - T_{P1}(t)$. The objective function q_{P2} is defined analogically to (3) and it measures the difference between measured and calculated temperature in point P2. Both objective functions are minimized during the optimization procedure and thermal parameters are identified by DE when the objective functions' values become minimal. In order to minimize both objective functions simultaneously, the unified objective function q is introduced by $q = 0.5q_{P1} + 0.5q_{P2}$.

IV. RESULTS

Coupled electromagnetic-thermal field transient calculation results (obtained by using FEM model with identified/optimal parameters) shows good agreement with measured values of temperature, especially in point P1 (Fig. 2). On the other hand, the model containing initial parameters showed obvious disagreement in both points. Such disagreements between measured and model-calculated values have been appearing in early iterations of DE, indicated as higher values of the objective function q as it can be seen in Fig. 3.

Fig. 2. Measured and model-calculated temperatures

The DE algorithm seeks for better solutions throughout the entire optimization by keeping the current best solution until it finds a better one. This can be seen from convergence course

of the optimization process (Fig. 3). Finally, after approximately 80 iterations, DE has found an optimal solution (identified/optimal thermal parameters) where the disagreement q between calculated and measured temperature has become minimal.

Fig. 3. Convergence course of differential evolution

TABLE I
OPTIMIZATION SET VALUES

Physical Quantity	Parameter	Lower value	Upper value	Initial value	Optimal value
Al. Conductivity slope (1/°C)	p_1	-0.0743	-0.0322	-0.0612	-0.0407
Al. Th. Conductivity (W/m °C)	p_2	76	245	204	245
Al. Sp. Heat Capacity slope (1/°C)	p_3	2388	39800	6960	39749

Steel Th. Conductivity (W/m °C)	p_6	12	90	59.1	14.15
Steel Spec. Heat Capacity (J/m ³ °C)	p_7	1.18e6	3.78e6	1.25e6	1.66e6
Air Th. Conductivity (W/m °C)	p_8	0.014	0.05	0.025	0.05
Convection coefficient (W/m ² °C)	p_9	10	100	25	27.86
Radiation Coefficient	p_{10}	0	1	0.28e-7	0.7e-9

V. CONCLUSION

The aim of this work was to identify thermal parameters of the transformer FEM model in order to be able to accurately describe the heating of the transformer and predict the temperature distribution. For this purpose, the optimization method based on DE was employed. The goal of the optimization was best possible agreement between measured and model-calculated temperature values. The results show that a very good agreement is achieved thus proving that the proposed DE-based technique can be used as a tool for thermal parameters identification.

Abstract— This paper presents the multi-objective optimization of an axial flux wind generator of 10kW using NdFeB permanent magnets. The four objectives considered in this work were weight, efficiency, active material cost and volume. The optimization problem was modeled considering seven continuous variables and three discrete ones. The optimization problem was solved using a multi-objective evolutionary algorithm with on-line and off-line populations, with elitism. In each generation, the non-dominated solutions are saved in the off-line population. This generator was designed to match with a three-blade horizontal axis wind turbine characteristics that was planned to operate in the complex terrain wind regime for the countryside of Brazilian land. After founding the non-dominated solutions, the choice of the appropriated one by a decision maker can be made using a decision procedure.

I. INTRODUCTION

The development of renewable energy resources has taken an accelerated pace with the ever increasing concerns on global warming and environmental protection. In the last ten years, the wind power became a reality in terms of its commercial competitiveness, technological maturity and aggressive expanding in power installations all over the world. For wind power systems, the core element is the electrical generator and in this issue several developments has been completed. As in a conventional electric machine design, the efficiency, the weight, the volume and the cost of the electric generator particularly for wind power generation are the major important design figures of merit.

Some works deal with the complicated task of comparison among different topologies of permanent magnet machines, mainly for wind power application. In these studies, the double external rotor and central stator axial flux permanent magnet machines have been appeared as a competitive solution.

The availability of modern high energy density magnet materials, such as sintered NdFeB, has made possible to design special topologies such as toothless stators with air gap windings. They aggregate several unique features such as high efficiency, high power and torque densities, low rotor losses and small magnetic thickness.

The technology of small-sized wind power generators, mainly for isolated applications and grid connected rural systems, represents an adequate challenge, balancing a few number of commercial equipment in the Brazilian market for the expected large latent demand.

Based on the conventional sizing equation and design procedures from former works [1]-[2], this paper presents the multi-objective optimization of a 10kW axial flux Torus generator using NdFeB permanent magnets, considering the variables and bounds shown in Table I. The variables used were the current density on the stator conductor (J_a), linear current density (A_m), peak value of the magnetic flux density on the air gap (B_{mg}), peak value of the magnetic flux density on the stator core (B_{cs}), peak value of the magnetic flux density on the rotor core (B_{cr}), magnetic remanence of the permanent magnet (B_r), inner and outer diameters ratio (K_d), the nominal stator voltage (V), poles number (P) and the number of parallel coils per phase (A_p).

TABLE I

BOUNDS OF THE OPTIMIZATION VARIABLES

Variables	J_a	A_m	B_{mg}	B_{cs}	B_{cr}	B_r	K_d	V	P	A_p

Upper	9	98	0.9	1.9	1.6	1.4	0.7	280	20	20

First, different alternatives of generator design were analyzed, since its rotational speed and power accordance with the wind rotor that defines its gearless nature, up to the electrical compatibility with the power electronics converter that rectify its energy and supply the low short-circuit power rural electric power grid.

The chosen design configuration for this axial flux PM generator was as follows:

- 1) axial-gap type with two external rotors and an internal stator;
- 2) NdFeB permanent magnets with maximum thickness equal to 6mm;
- 3) The outer diameter of the nacelle must not exceed 10% of the diameter of the turbine;
- 4) Maximum stator nominal voltage limited to 400V DC bus of the converter.

Fig. 1 shows the design configuration used.

Fig. 1 Double external rotor and central stator axial flux generator.

Considering four objective functions (weight, efficiency, active material cost and volume), this problem was optimized using a multi-objective evolutionary algorithm [3]. In this optimization, 1001 efficient solutions were generated. The Figs. 2 - 4 show the non-dominated solutions plotted in the objectives spaces.

0.50,0.50,0.00,0.00	100.21	88.31	1466.70	32.30

To choose the better solution according to the decision maker preferences, a fuzzy algorithm [4] was used. The objectives were weighted in different ways to permit a better comprehension of this problem. Tables II - V show these results.

These results show that 20 poles, 272V, with 20 parallel ways per phase is an interesting solution that aggregated good efficiency, light weight, small volume and an acceptable price. This solution shows that the efficiency is about 88.11 %, the weight is only 101.13 Kg and the active material cost is US\$1.270.09 and the volume is lower as 32 dm³. This solution seems to be a good solution if compared with the results published in the literature [5].

Abstract — A new transversal UWB bandpass filter with a reduced size is realized based upon the use of the Genetic Algorithm(GA) optimization. The proposed design is carried out to have the required performance(Insertion loss, return loss, flat group-delay) over the very wide frequency range. Also we can effectively reduce the entire structure by assigning diverse transmission line segments to each of the two transversal signal paths(increased degree of freedom in design). The design results will be presented theoretically and experimentally.

I. INTRODUCTION

The UWB bandpass filters should have the low insertion and return loss over the ultra-wide band 3.1 GHz - 10.6 GHz and higher selectivity[1]. Particularly, the steep skirt around the band edges is needed, avoiding the increased size of the filter. For this, multi-mode coupling design is adopted in size-constraints[2-5], but is followed by cumbersome extra tuning.

The transversal geometry is brought up to have sharper rejection(steeper skirts) with the size limit[6]. However, the previous works of this structure fail in suggesting the size-reduction technique and forming the ultra-wide band. So we need the minimized structure of the transversal filter and enlarged bandwidth just right for the UWB applications.

We now assign diversified impedance steps in the transversal signal paths, which increases the design degree of freedom for a smaller but higher order filter. Many design unknowns are effectively found by the GA optimization work when the ranges of variables are reasonably given. The design is verified by the comparison with the trustworthy simulation and measurement on the fabricated filter.

II. STANDARD TRANSVERSAL FILTER

The sketch of the basic transversal filter geometry is given in Fig. 1. Elaborating on the geometry of interest, it is composed of the transmission line paths connected in parallel. In [6], they assign only one type of transmission line to each of the two paths which has a very limited number of design variables such as one pair of the length and the characteristic impedance of a transmission line.

Fig. 1. Basic configuration of the conventional transversal filter

As is shown clearly in Fig. 1, there are just two pairs of design parameters, say, (Z_A, θ_A) and (Z_B, θ_B) . If we adjust the phase difference between the two paths, transmission zeros can be created which determine the band edges and steepness of the skirt. Here comes a set of formulae that describe the scattering parameters and admittance matrix elements.

$$S_{11} = \frac{(Y_0 - Y_{11})(Y_0 + Y_{22}) - Y_{12}Y_{21}}{(Y_0 + Y_{11})(Y_0 + Y_{22}) - Y_{12}Y_{21}}$$

$$S_{21} = \frac{Y_0 Y_{21}}{(Y_0 + Y_{11})(Y_0 + Y_{22}) - Y_{12}Y_{21}} \quad (1)$$

$$Y_{11} = Y_{22} = \frac{1}{jZ_A \tan \theta_A} + \frac{1}{jZ_B \tan \theta_B}$$

$$Y_{12} = Y_{21} = \frac{j}{Z_A \sin \theta_A} + \frac{j}{Z_B \sin \theta_B}$$

where the characteristic admittance of the port(reference) admittance $Y_0 = 1/Z_0$.

The design is to find (Z_A, θ_A) for path A and (Z_B, θ_B) for path B that make the outputs of the two shunt paths out of phase, namely, 180° 's phase difference at the frequency points as the transmission zeros. Due to the lower design degree of freedom(4 design parameters), the path B can't be shorter than 270° , when path A is as long as 90° . So, in order to reduce the size, what comes next is how we will have a sufficient number of the design parameters to improve the frequency response and miniaturization.

III. PROPOSED TRANSVERSAL FILTER AND DESIGN WITH GA.

Fig. 2. Basic unit of the proposed transversal Bandpass filter

To get over the shortcomings of the standard transversal-type filter, such as the resultant increment in the overall size to comply with the specifications with 4 design parameters and the narrow stopbands, we come up with the segmentation of each of the two paths and the diversification of the segments' impedance and length. The steps between the neighboring segments result in the impedance differences and this, along with the different lengths of segments, will play the key role in reducing the size of the entire structure and enhance the

problem(Path B of Fig. 2 is roughly 3 times less than that of Fig. 1). Now we can divide a horizontal part of the transmission line loop into 3 segments when a vertical part is assumed to have one segment. Then, the loop transmission line has 8 segments and a total of 16 design parameters as the unknowns. Though the symmetry between the input and output ports is assumed, we have 10 unknowns. Inevitably, the nonlinear equations should be solved numerically. This pushes us to think of the GA optimization to identify the desired values of the 10 or more unknowns. Particularly in the GA optimization process, the number of generations is set as 200 and there are 100 individuals that will be selected by regular GA procedure with crossover, mutation and elitism.

(a) Convergence behavior of the unknowns

(b) Convergence of Cost function(average: upper line , fittest : lower line)
Fig 3. Convergence of the physical/electrical variables and the cost function

For the sake convenience, the cost function is defined to have $|S_{21}| < -20\text{dB}$ at ≤ 3.1 GHz and ≥ 10.9 GHz, and $|S_{11}| < -20\text{dB}$ over 3.2 GHz ~ 10.8 GHz.

Fig. 3 presents that the convergence behaviors of the 10 unknowns and cost function. Both figures tell us that over generation number 20, the unknowns begin to approach the optimal design values for the UWB passband formation. Also, the average cost function is oscillatory, but smooth line is that of the fittest in Fig. 3(b). Each of the individuals and the cost functions are going convergent very fast, since the cost function is defined deterministically with the positions of the target transmission zeros and the levels of transmission and reflection coefficients. Fig. 4 shows the desirable way the unknowns in the design have been identified by the GA and they are converted and trimmed to the right physical dimensions. The results convince us of the validity of the design and proposed filter structure.

(a) $|S_{21}|$ and $|S_{11}|$ with the trimming from the unknowns found by the GA(b) Measured $|S_{21}|$ and $|S_{11}|$ compared with the simulation

Fig. 4. S-parameters of the measurement and those of the further tuning starting from the initials obtained by the GA approach

IV. CONCLUSION

A novel transversal-type UWB bandpass filter has been designed on the basis of the Genetic Algorithm Optimization. Its frequency response meets the requirements on the UWB bandpass filtering and has the effect of size-reduction owing to the diversified impedance steps in the divided signal paths. Though the geometry is assumed symmetric with respect to the bi-section line in this paper, but it will be meaningful to deal with the asymmetry leading to the more unknowns in the next step. Detailed implementation procedures including fabrication and measured data will be presented in the final version of this paper, which prove the validity of the proposed design along with the more elaborated figures of the Genetic Algorithm

Abstract—In a demand for continuously shortening engineering cycles and time-to-market windows, precise simulation and problem optimization pose a necessity and a challenge at the same time. Still, accurate problem formulation requires the skills of professionals, for which simulation software serves as a tool in their business, which ought to fit to numerous diverse tasks in a versatile way.

This paper describes the methodology to create such a tool that covers all parts of a multiphysical optimization problem in electrical engineering and its adjoining disciplines as an application of the finite element method.

Making use of modern software engineering principles and well-grounded design, it provides model handling functionality supporting all partitions of prevailing optimization processes.

Index Terms—Object Oriented Programming, Coupled Problems, Optimization.

I. INTRODUCTION

A typical optimization cycle making use of the finite element method (FEM) [1] covers four domains: problem setup, model creation and discretization, solving the equation system, and interpretation of the results to feed the next iteration, if necessary, as shown in Fig. 1.

Well-defined interfaces are mandatory for obtaining best results within such a cycle. Internally, one physic model's calculation relies on the results obtained by another one and vice versa, making accessible data structures mandatory. Externally, interfaces with optimization toolboxes or equation system solvers need to be found. These data structures form the major part of the research reported in this paper.

The central objectives aimed for consist of:

- The facilitation of solving forward problems because of direct - thus fast - data access
- Dynamically adjustable model discretizations in both granularity and geometry
- Option of different models and discretizations for different physics
- Encapsulation of solution data, enabling access control for certain user groups.

As a matter of fact, existing software packages such as EleFAnT [2] impose difficulties on targeting all these objectives equally. In addition, the first and last objective raise a manifest contradiction. To counteract this, methods of object oriented programming (OOP) need to be employed.

II. OBJECT ORIENTED APPROACH

For validating the concept, MATLAB [3] was selected as development environment, while the numerical solutions of the implementation were successfully proven with EleFAnT. The choice came down to MATLAB as it features a number of practical analysis and debugging tools, and starting with version 7.6, native object oriented programming patterns are fully supported.

Compared to procedural programming, the advantage of object orientation for solving FEM optimization problems is obvious. Objects store their own status, so that data can be retrieved any given time. This status can, for example, be the electrical potential of a node object. There is no need to reconstruct the potential from a whole solution matrix, the node of interest is just called for its solution value.

Above that, objects can offer methods to compute some data using sub-objects they instantiate. Thus, the solution value of any given point within a finite element can be calculated using the data provided by the element's nodes.

This leads to consistently defined interfaces. The superclass `FiniteElement`, for example, offers all functionality a finite element has to consist of, regardless of its shape or dimensionality.

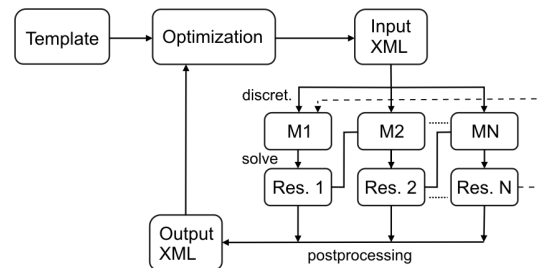

Fig. 1. Optimization Cycle with Data Interfaces

Of course, object oriented programming approaches face their downsides - compared to imperatively coded solutions - when it comes to memory consumption or CPU time usage. Nevertheless, the former fact can be seen to be of minor concern in modern computing surroundings.

Given the respective infrastructure, even the increased CPU usage can be overcome. When, for example, the calculation is

transferred to a clustered computing machine, one can benefit not only from facilitated parallelization of the independent code portions represented by objects, but also from the ability to control the program's flow from independent, relatively cheap machinery.

III. WEAKLY COUPLED OOP FEM EXAMPLE

Hardening of steel components is commonly done using the method of annealing. This often requires controlled heating up of the workpieces to exact temperatures in order to effectuate the desirable material properties.

Therefore, the design of an appropriate heating device would include the determination of the dimensions a heating plate should have, given the fact that the device is supplied with a fixed voltage. The two-dimensional cross-section model of such an appliance is shown in Fig. 2 together with its feed connections shown on either side of the heating plate.

Fig. 2. Current Flow Simulation of Hardening Device

As a result of the current flowing through the heating plate (as depicted in Fig. 2), it will heat up and thus serve as a source for the thermal model simulation. Within this model, the feed connections can be neglected, but as, of course, the workpiece to be hardened has to be taken into account, a problem space discretization entirely different to the current flow model's is the result.

Now, taking advantage of the finite elements being realized as software objects, the input values for source elements of the thermal model can easily be determined for each finite element's integration points. As each FE object of the current flow problem offers its own postprocessing functionality, exact input values - the power dissipation in each integration point as a result of the current density \vec{J} - can be retrieved and fed into the new thermal source elements.

Also, the temperature values in the test points required by the optimization control tool are retrieved in the same manner from the temperature model's FE objects and are then returned to the superordinate control structure for further interpretation.

IV. INTERFACES TO OPTIMIZATION CONTROL STRUCTURES

For interfacing with optimization control structures, XML was chosen as a means of data interchange [4]. XML can easily be created and interpreted, and leaves space for custom extensions. It is therefore widely used for exchanging data in inhomogeneous computing environments.

Leaving further details to the full paper, it is worth being noticed, that the input data specification allows for setting up multiple problem spaces depending on each other to be solved consequently, as shown in the example in III. Different problem spaces can also interdepend on each other, which could further expand the mentioned example by re-feeding the calculated temperature values into the material properties of the current flow problem. In case the change of these properties to be adjusted reaches a percentage lower than a given threshold or stopping condition, the calculation cycle can be halted and the transient state of the whole problem model can be considered stable. The data scheme used for controlling this process is depicted in Fig. 3.

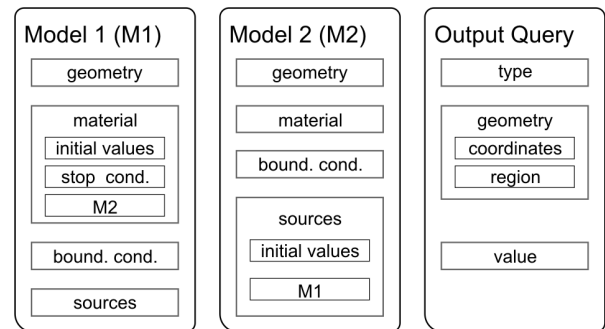

Fig. 3. XML Data Scheme for Controlling Multiple Simulation Models

The results of interest can be queried in a similar manner as well. A part of the input XML string states the properties to be retrieved, i.e. the temperature reached at certain points. The values queried from the finite element objects are then used for populating the appropriate XML entities and passing it back to the control structure.

Also, the program control structure offers tools to users with limited access to perform parameter studies with less degrees of freedom on already created model setups, thus making modelling efforts reusable by others not involved in the optimization process itself but depending on its results.

V. CONCLUSION

It has been shown that object oriented patterns together with careful interface design greatly ease the design process involving optimization in electrical engineering, especially when coupled problems are to be solved.

E-mail: gyimothy@evt.bme.hu

Abstract: An adaptive sampling method is proposed for creating a forward database that can facilitate the inverse problem solution in NDT. The available sensitivity data are utilized for obtaining an optimal sampling with respect to the piecewise linear interpolation applied for data retrieval. The resulting database provides guaranteed quality of approximation using a relatively few number of samples. The efficiency of the method is demonstrated through a test example.

I. INTRODUCTION

The industrial application of nondestructive testing (NDT) requires sufficiently fast operation in addition to reliability. In a modern computer aided, model based defect reconstruction method a discrete inverse problem has to be solved, in which the most time is spent to the numerical computation of the corresponding forward problem. This is because the latter has to be carried out several times in an optimization loop. In order to reduce the reconstruction time, one should use a fast approximator of the forward problem based on its pre-calculated samples.

In preceding papers the authors proposed the interpolation in a so-called *mesh database* for that purpose [1]. In this method a simplex mesh is spanned over the space of defect model parameters, and the solutions of the forward problem for selected defect prototypes are stored in its nodes. The mesh is generated in an adaptive-incremental manner, so that it results in guaranteed interpolation properties with the fewest possible nodes. In the current paper in turn, it is shown how a much more efficient mesh database can be built by utilizing the sensitivity information on the forward problem. Notably, sensitivity data are easy to get analytically in many electromagnetic problems, this is the case in the problem we are considering now [2].

A. The studied example

Let us introduce the proposed approach through the solution of a simple defect reconstruction problem using eddy current testing (ECT). A relatively large non-magnetic conducting plate is supposed to contain a defect (Fig. 1). The plate is tested with a pancake type coil driven by sinusoidal current. The excited eddy current field is perturbed by the defect, thereby changing the impedance of the probe coil. This impedance change is measured at several probe positions above the plate (in this example they form a rectangular grid of $N = 11 \times 41$ points), and called together the impedance signal, Z_i ($i = 1 \dots N$).

The defect is hypothesized as a single void crack opening onto the backside surface of the plate (OD type), having negligible thickness compared to its other dimensions, and a rectangular shape. Assuming that its position and orientation are known, this crack can be characterized by two parameters, the length l and the depth d . The inverse problem targets the estimation of these model parameters by using the measured impedance signal.

B. The forward problem and the sensitivities

The forward problem aims at determining the measurable impedance change at the i -th probe position, $Z_i(l, d)$, for the given crack parameters l and d . This problem can be formulated as an integral equation derived from the so-called thin crack model [3] and, for instance, can be solved numerically using the method of moments [4].

Sensitivity expresses the variation of the ECT signal with respect to the variation of the crack parameters. For the i -th component of the measured data it can be interpreted as a gradient in the parameter space,

$$\nabla Z_i = \left(\frac{\partial Z_i}{\partial l} \quad \frac{\partial Z_i}{\partial d} \right). \quad (1)$$

The sensitivity values for given l and d can be calculated analytically by solving the specified forward problem and its adjoint problem. The numerical realization can be done using the method described in [2].

II. UTILIZATION OF SENSITIVITY DATA

An approximator of the forward problem is said to be of guaranteed quality if the error of approximation, h , is below the prescribed limit, δ , for all conceivable parameter combinations, l and d , that is

$$h(l, d) \equiv \|\mathbf{Z}(l, d) - \bar{\mathbf{Z}}(l, d)\|_2 < \delta \quad \forall l, d \quad (2)$$

where $\mathbf{Z}(l, d) = [Z_i(l, d)]$ is the impedance signal of the crack, and $\bar{\mathbf{Z}}(l, d)$ its approximate. In our method this latter is a piecewise linear (PL) interpolant based on a simplex mesh. The threshold δ is practically identified with the resolution of the real measurement [1].

In order to meet the requirement (2) with our mesh database, a kind of “distance mapping” is carried out in the background during database generation. Each edge of the mesh is associated with a linear spring. The rest length of such an edge-spring is a function of the impedance data stored in the connected nodes. The whole mesh, as a spring system, is relaxed in a hypothetical *control space*. The size and shape of mesh elements in the control space at equilibrium gives instructions on where the database should be refined. For further details the reader is referred to [5].

Figure 1: The studied ECT configuration.

Figure 3. Middle: database structure in the parameter space (d is given in percentage of plate thickness); Left: the structure as seen in the control space (the springs serve for illustration); Right: distribution of the interpolation error $h(l, d)$ over the parameter space (the prescribed limit was 0.08).

Originally, the rest length of spring segments were simply chosen equal to the data distance between the connected nodes [5]. It was demonstrated that with this choice a mesh database showing uniform element density in the control space is optimal with respect to a nearest neighbor (NN) type interpolation. It was also pointed out that this principle can be extended to other interpolation methods, if the rest length is set equal to the interpolation error measured along the given edge.

By using the available sensitivity data we can estimate the average PL interpolation error made along an edge, as illustrated in Fig. 2. First we compute the directional derivatives $\frac{\partial Z_i}{\partial \eta}$ using the gradient in (1), where η is the length parameter along the edge. A higher order approximation, $\hat{Z}_i(\eta)$, of $Z_i(\eta)$ can then be established by using the data $Z_i(0)$, $Z_i(L)$, $\frac{\partial}{\partial \eta} Z_i(0)$ and $\frac{\partial}{\partial \eta} Z_i(L)$, respectively. The average interpolation error for the i -th data component along the k -th edge is defined as

$$h_i^k = \sqrt{\frac{1}{L^k} \int_0^{L^k} |\hat{Z}_i^k(\eta) - \bar{Z}_i^k(\eta)|^2 d\eta^k}. \quad (3)$$

Finally, the rest length of the k -th edge-spring is set equal to the Euclidean norm of the vector $\mathbf{h}^k = (h_1^k, h_2^k, \dots, h_N^k)$.

III. TEST RESULTS

The forward database of the studied problem was generated and optimized for PL interpolation using adaptive mesh generation techniques and spring analogy. The value $\delta = 0.08$ was prescribed as the upper bound of interpolation error (its unit and other details are ignored here). The procedure started with three randomly chosen points. The final database contains 26 nodes. Their distribution in the parameter space is plotted in Fig. 3 (middle).

Figure 2: Estimation of the interpolation error.

The picture of the mesh in the control space can be seen in Fig. 3 (left). Some spring segments as well as a “yardstick” of length δ are drawn for illustration. Since the mesh looks quite homogeneous, with its edges slightly shorter than δ , we expect good interpolation characteristics from the corresponding database.

In order to check this latter, the distribution of the error of linear interpolation was computed at several points in the parameter space and is plotted with grayscale shading in Fig. 3 (right). The picture tells that the interpolation error falls below the prescribed δ value everywhere in the studied parameter domain.

IV. CONCLUSIONS

For comparison we generated a database that is optimal with respect to NN interpolation (not shown here) according to [5] using the same error bound δ . It contains 1463 nodes, which clearly shows the difference in favour of the new method.

Certainly, one could use the available sensitivity data to set up a higher order interpolation over simplices, which would even result in higher accuracy. However, the approximation error was not controlled in that case, and in turn this is the main point in the proposed approach.

The developed method requires that the forward problem behaves “smoothly”. Even if this is the case, the mesh resulting in the parameter space is not necessarily valid. The convergence of the method for other types of problems, e.g. allowing more defect parameters, needs further investigations.

Abstract—In this paper, a multilevel optimization method is proposed for a motor drive system which includes a surface mounted permanent magnet synchronous machine (SPMSM), the converter/inverter, and the control schemes. Firstly, the multilevel optimization is described by using the problem matrix which may be used to allocate the design variables on different levels. The parameters in the problem matrix are deduced by using correlation analysis. Secondly, the architecture and implementation of Multilevel Genetic Algorithm (MLGA) are carried out. As one of the advantages of MLGA, the dynamic adjustment strategy of GA operators is utilized to improve optimal performance. The algorithm is applied to a three-level optimization problem in which the optimization of SPMSM design and the control parameters of drive are considered in different levels. Finally, some results and discussions about the application of the proposed algorithm are presented.

I. INTRODUCTION

Multilevel optimization is an effective method to solve complex optimization problem and it has been reported. Bartheley [1] used problem matrix method to describe the relationship between the objective functions and variables. Q. S. Li, et al. [2] presented Multilevel Genetic Algorithm (MLGA) for the optimization of actively control building under earthquake excitations. Multilevel optimizations are difficult to solve due to the characteristics of nonlinearity, multi-modal functions and mixed discrete variables.

Permanent magnetic synchronous machines (PMSMs) have been an attractive choice for many applications because of its high efficiency and power density. In this paper, MLGA is presented for design optimization of a motor drive system consisting of the drive circuit and an SPMSM controlled by using Field Oriented Control (FOC) to minimize the cost of copper and permanent magnets, and to maximize the efficiency of the motor and the drive system as well as the overshoot and ripples of output torque, speed and d-axis component of current. The finite element analysis (FEA) of the motor is used to calculate the no-load magnetic field, the back-electromagnetic force (back-EMF), the d- and q-axis components of the stator winding inductances.

II. FORMULATION OF MULTILEVEL OPTIMIZATION PROBLEM

In multilevel optimization problems, the relationship between the design variables, constraints and objective functions can be described by a Problem Matrix, as shown in

Fig.1. In Fig. 1, the symbols P_{xx} , i.e. P-values, are the coefficients, which indicate the relative importance between design variables and objective functions, as well as constraints in Correlation Analysis [3]. The larger the P-value is, the less relative importance of the design variable for the objective function is. In this paper, the samples of variables are determined by Design of Experiment (DOE) method. Some commercial statistic software packages, such as Minitab, can provide the module for the relative importance analysis.

Design variables	x_1	x_2	x_3	x_4	\dots	x_m
Objective function	P_{01}	P_{02}	P_{03}	P_{04}	\dots	P_{0m}
Constraint 1	P_{11}	P_{12}	P_{13}	P_{14}	\dots	P_{1m}
Constraint 2	P_{21}	P_{22}	P_{23}	P_{24}	\dots	P_{2m}
\vdots	\vdots	\vdots	\vdots	\vdots	\vdots	\vdots
Constraint n	P_{n1}	P_{n2}	P_{n3}	P_{n4}	\dots	P_{nm}

Fig. 1. Problem matrix

According to P-values in the Problem matrix, the design variables may be arranged on diverse levels. For one objective function, the variables possess similar P-values will be managed on the same level.

III. MULTILEVEL GENETIC ALGORITHM

The architecture of MLGA is shown in Fig. 2. In MLGA the design optimization variables are classified and allocated to different levels according to the relative importance among the variables and objective functions, constraints, as well as the practical engineering weight and optimization sequence. The variables on different levels are encoded independently. Each level may have multiple populations and each of them can adopt different dynamic genetic operators and parameters. Furthermore, the relationship between sub-problems in multilevel problems can be handled by MLGA. The details about Genetic Algorithm (GA) operators, implementation process of MLGA will be presented in the full paper.

IV. APPLICATION OF MULTILEVEL OPTIMIZATION USING MLGA

An SPMSM controlled by FOC, rated at 950W output power, 2000 r/min speed and 128V line-to-line voltage, is used to verify the MLGA for multilevel optimization. The multilevel structure of optimization is shown in Fig. 3.

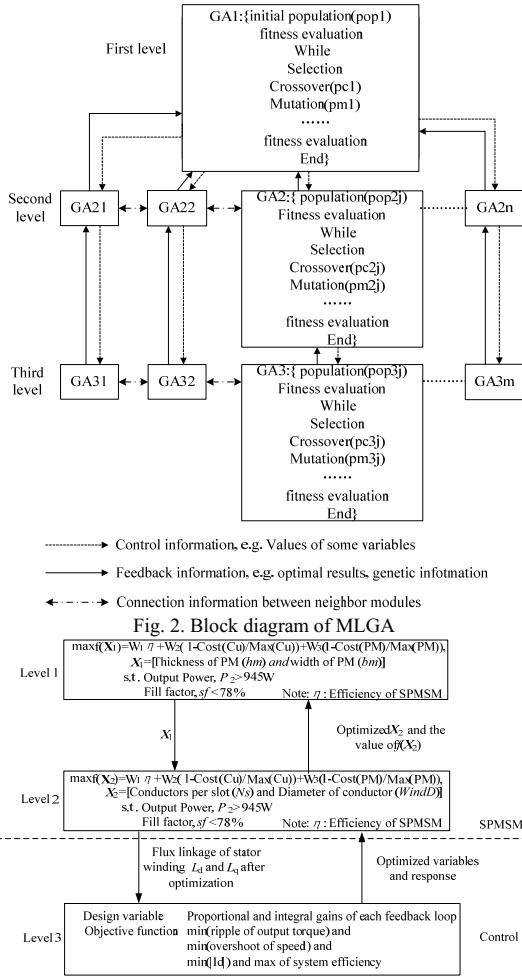

Fig. 3. Three-level structure of optimization

The design variables and objective functions defined on each level based on correlation analysis will be presented in the full paper.

On each level, if the fitness maintains in a defined interval during several consecutive generations, the mutation operator P_{mu} is automatically adjusted according to (1)

$$P_{mu} = \begin{cases} P_m & , n_{unchange} = 0 \\ \frac{n_{unchange}}{\maxgeneration} \omega & , n_{unchange} > 0 \end{cases} \quad (1)$$

where P_{mu} is dynamic mutation value, P_m is initial mutation value, $n_{unchange}$ is the number of unchanged consecutive generations of population fitness, ω is the regulator and \maxgeneration is the terminating iteration.

The design variables, optimal results and comparison of MLGA and traditional GA on Level 1 and 2 are listed in TABLE I.

The proportional and integral gains calculated on the third level are listed in Table. 2. Fig. 4 illustrates the speed of SPMSM before and after PI controller parameters optimization. The transient d-axis component of current,

torque and system efficiency will be analyzed and discussed in full paper.

TABLE I
OPTIMAL RESULTS FOR SPMSM IN LEVEL 1 AND 2

Variables and performances	Original design	Multilevel GA	Traditional GA
Thickness of PM, h_m / cm	0.18	0.23	0.21
Width of PM, b_m / cm	3.14	3.03	3.03

V. CONCLUSION

According to the features and decision-making sequences, many real-world optimization problems in the engineering systems could be solved in multilevel procedures. This paper proposes an MLGA algorithm for SPMSM drive system to achieve complex multi-objective functions. The Correlation analysis is applied to construct the three-level structure and dynamic mutation operators on each level may dependently improve the convergence of the MLGA. It can be seen that the performances of both SPMSM and its controller can be optimized by using MLGA.

Abstract — The applications of the level set function for images segmentation of the teeth was presented in this paper. There was used the idea of the level set method and variational formulation for geometric active contours. This formulation of the level set method consists of an internal energy term that penalizes the deviation of the level set function and an external energy term that drives the motion of the zero level set toward the desired image features. The proposed algorithm has been applied to real pictures with promising results in the roentgen images segmentation.

I. INTRODUCTION

This paper presents the applications of the level set function for images segmentation of the teeth. The level set idea, devised in Osher and Sethian [4], is known to be a powerful and versatile tool to model evolution of interfaces. Variational formulation for geometric active contours that forces the level set function to be close to a signed distance function [3]. This formulation of the level set method consists of an internal energy term that penalizes the deviation of the level set function and an external energy term that drives the motion of the zero level set toward the desired image features.

II. LEVEL SET METHOD

The level set idea, devised in Osher and Sethian [4], is known to be a powerful and versatile tool to model evolution of interfaces. The original idea behind the level set method was a simple one. Given an interface Γ in \mathbb{R}^n of dimension one, bounding an open region Ω . It was analyzed and computed its subsequent motion under a velocity field \vec{v} . This velocity can depend on position, time, the geometry of the interface (e.g. its normal or its mean curvature) and the external physical conditions. The idea is merely to define a smooth function $\phi(x, t)$, that represents the interface as the set where $\phi(x, t) = 0$. The motion is analyzed by the convection the ϕ values (levels) with the velocity field. The Hamilton-Jacobi equation of the form [2], [5], [6], [7]

$$\frac{\partial \phi}{\partial t} + \vec{v} \cdot \nabla \phi = 0 \quad (1)$$

When flat or steep regions complicate the determination of the contour, reinitialization is necessary. The reinitialization procedure is based by replacing by another function that has

the same zero level set but behaves better. This is based on following partial differential equation:

$$\frac{\partial}{\partial t} \phi + S(\phi)(\nabla \phi - 1) = 0 \quad (2)$$

Figure 1 presents the images segmentation by using the level set method with reinitialization.

Fig. 1. Image reconstruction – the level set method with reinitialization

III. VARIATIONAL LEVEL SET METHOD

This formulation of the variational level set method consists of an internal energy term that penalizes the deviation of the level set function and an external energy term that drives the motion of the zero level set toward the desired image features. Variational formulation for geometric active contours that forces the level set function to be close to a signed distance function, and therefore completely eliminates the need of the costly reinitialization procedure. The resulting evolution of the level set function is the gradient flow that minimizes the overall energy functional [3]:

$$P(\phi) = \int_{\Omega} \frac{1}{2} (|\nabla \phi| - 1)^2 dx dy \quad (3)$$

An external energy for a function $\phi(x, y)$ is defined as below:

$$E(\phi) = \mu P(\phi) + E_m(\phi) \quad (4)$$

$P(\phi)$ – internal energy,

$E_m(\phi)$ – external energy.

The process for minimization of the functional E is the following:

$$\frac{\partial \phi}{\partial t} = \mu \left[\Delta \phi - \operatorname{div} \left(\frac{\nabla \phi}{|\nabla \phi|} \right) \right] + \lambda \delta(\phi) \operatorname{div} \left(g \frac{\nabla \phi}{|\nabla \phi|} \right) + \omega g \delta(\phi) \quad (5)$$

For more than two phases was introduced the multiple level sets idea by Vese and Chan [1]. The algorithm set formulation and algorithm for the general Mumford-Shah minimization problem in image processing, to compute piecewise-smooth optimal approximations of a given image. The problem can be easily generalized to the case where the domain contains more than two materials.

Then material c is representing following:

$$c = c_1 H(\phi) + c_2 (1 - H(\phi)) \quad (6)$$

where H is the Heaviside function

IV. IMAGE SEGMENTATION

Figure 2 presents the roentgen images segmentation in the following iterative process. The algorithm of the image reconstruction consists variational level set method and the Mumford-Shah function.

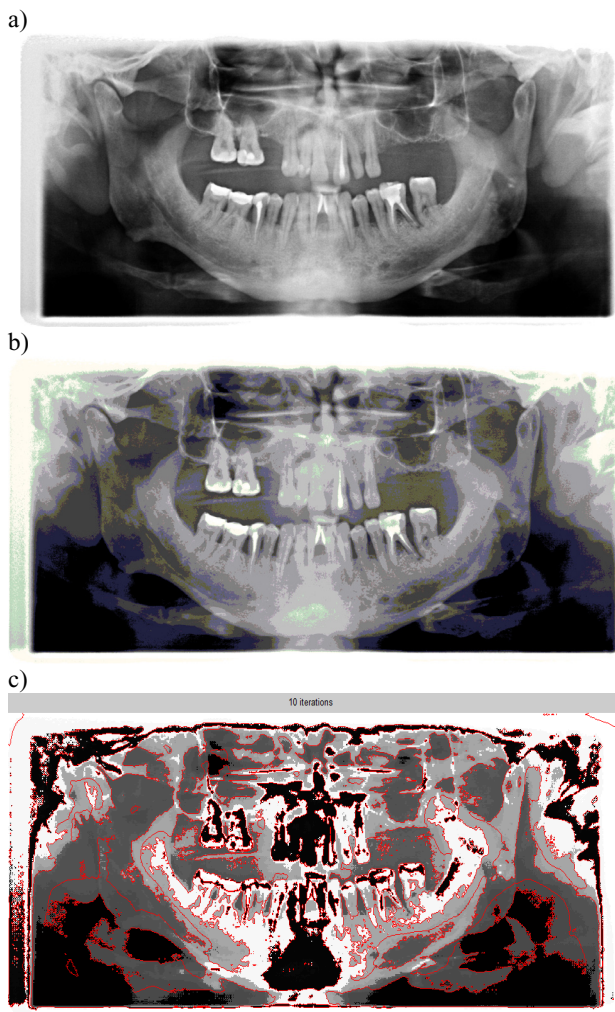

Fig. 2. Image reconstruction: a) the original image , b) the image 256 colors , c) reconstruction after the 10 iterations, d) reconstruction after the 50 iterations, e) reconstruction after the 500 iterations

V. CONCLUSION

The applications of the level set function for images segmentation in the stomatology was presented in this paper. The level set idea is known to be a powerful and versatile tool to model evolution of interfaces. Variational formulation for geometric active contours that forces the level set function to be close to a signed distance function, and therefore completely eliminates the need of the costly reinitialization procedure. The proposed algorithm has been used to real pictures with promising results in the roentgen (teeth) images segmentation.

Numerical tool for the design of magnetic sensors based on GMI effect

Léna Abi Rached, Francisco Alves, Yann Le Bihan

lena.abirached@lgep.supelec.fr

Abstract — In this paper, we present a numerical procedure for calculating the impedance of a three-layered sandwich, consisting of two metallic ferromagnetic layers separated by a non-magnetic conductive layer, serving to optimize the performances (impedance variation) of these three-layered giant magneto-impedance (GMI) sensors. It consists in the calculation of impedance using finite elements method (FEM). The effective permeability μ_{eff} is obtained from experimental data of the resistive and inductive parts of the impedance. This numerical tool, compared to analytical approaches is more realistic and allows taking into account the leakage flux when the sensor is submitted to high fields.

I. MOTIVATION

Sandwiched GMI sensors are mainly formed of three insulated foils $\text{Fe}_{75}\text{Si}_{15}\text{B}_6\text{Cu}_1\text{Nb}_3/\text{Cu}/\text{Fe}_{75}\text{Si}_{15}\text{B}_6\text{Cu}_1\text{Nb}_3$ [1] or $\text{CoFeSiB}/\text{Cu}/\text{CoFeSiB}$ [2] (Fig.1). In this work, we develop an electromagnetic simulation tool to design sandwiched structures (see Fig.2) in order to optimize geometrical parameters such as width, length and thickness of each layer. Structures, analyzed with different dimensions, are tested to improve the response of the GMI sensor.

Fig. 1 : Sandwiched structure with Finemet® and copper foils (thicknesses 20 μm)

Fig. 2 : GMI 2D model, due to the symmetry of the sensor only half part is meshed

The impedance for the GMI structures is calculated and analyzed as a function of the physical parameters of the device and frequency. This tool should reduce costs and manufacturing time for the micro-sensors fabrication using micro-technology facilities.

From another side, “closed” structure with the magnetic film closing at the edges along the width, and an “open” structure without flux closures are simulated. The “closed” structure is more efficient magnetically and presents a highly inductive response to much higher frequencies than the

“open” structure. The results obtained are practically applicable to the design of GMI magnetic sensors.

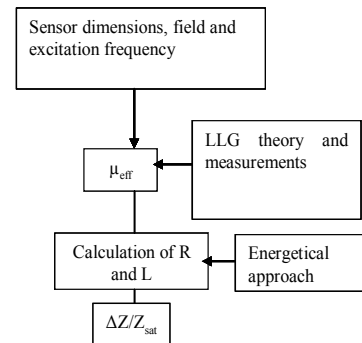

Fig. 3: Flow chart of the design procedure

II. MODEL IMPLEMENTATION

Fig. 3 presents the flow chart of the design procedure. The modeling of GMI sensors allows evaluating and improving of their performances without the need to multiply the realization of costly prototypes. A fine modeling of GMI sensors require the use of numerical modeling methods. Among them, the finite element method (FEM) is particularly adapted since it allows considering structures of arbitrary geometry and taking into account of anisotropic or nonlinear behavioral laws. The FEM is based on a weak variational formulation of the problem. The solution of this formulation is done on a discretized space obtained by meshing the study domain with elements. The fields to be calculated are obtained by a linear combination of simple functions (shape functions) deduced from the size and shape of the elements. These functions are generally defined at the nodes of the elements and are expressed as a linear combination of polynomial functions. The solving of the algebraic system provides an approximate solution of the problem. For the modeling of the GMI sensor, a magneto-dynamic formulation was used taking into account the eddy currents and neglecting the displacement currents. It is based on the calculation of the magnetic vector potential and of the electric scalar potential at the nodes of the meshing with a current as source. Taking into account the high length of a GMI sensor compared to its depth and width, a bidimensional representation of it was adopted. A cross-section of the sensor is then considered and meshed with surfacic elements (triangular in our case since it allows meshing arbitrary shaped areas). After solving of the system, the electric and magnetic fields are deduced from the potentials. These fields allow computing the power losses and

the magnetic energy which provides the sensor impedance real and imaginary parts, respectively.

III. RESULTS

The impedance values of the sandwiched structures with different geometrical dimensions are computed using the finite element method (FEM). The giant magneto-impedance (GMI) is calculated from the difference of the impedance values obtained with high and low permeability (at field saturation) of the magnetic material.

$$\left(\frac{\Delta Z}{Z}\right)_{sat} = 100 \times \frac{|Z_{Hext}| - |Z_{Hsat}|}{|Z_{Hsat}|}$$

Fig.4 shows the experimental results of impedance versus field carried out at 150 kHz. In our samples, the inductive part of the impedance is much higher than the resistive one. The impedance per meter at zero-field is 9Ω/m. For an applicative point of view, we can remark that this sensor requires a bias field if we need to maximize sensitivity of the sensor to AC fields.

Fig. 4 : Experimental curves Z(H) for an excitation current at 150 kHz

Fig.5 represents simulation (FEM) results by varying the permeability value of the magnetic foil. We observe that the variation of the impedance as function of the permeability fits the experimental curve at 9Ω/m for $\mu_{eff}=4000$. This method only gives values of impedance at zero and saturation fields. In the full paper, we present an implementation of Landau-Lifshitz-Gilbert equation (to estimate μ_{eff}) in the design procedure (Fig.3) in order to determine the MI ratio whatever the magnitude of the external magnetic field is.

We have optimized geometrical dimensions of a sandwiched GMI micro-sensor with the aim to obtain maximum effect at the smallest frequencies. As an example, in Fig.6, a 2D-FEM simulation highlights the frequency behavior of the magnetic/copper width ratio on the MI effect and Fig. 7 presents impedance ratio versus magnetic/Cu width ratios, showing the material width have a determinant effect on the sensor performances at a certain level.

Fig. 5 : Calculated real (Re) and imaginary (Xe) parts of impedance Ze versus relative permeability of the magnetic foils at 150 kHz

Fig. 6 : Comparison between measurements and FEM simulations on the frequency behavior of MI effect.

Fig. 7 : Impedance ratio versus magnetic/Cu width ratios. Ferromagnetic and Cu thicknesses are respectively 2μm and 4μm (1:2:1 configuration). Cu width is 100μm. Frequency of excitation current is 150 kHz.

The results depend considerably on shape factors, demonstrating that edge effects are decisive for the GMI performance.

IV. CONCLUSION

The conclusions of this study are of great importance for the successful design of miniaturized GMI devices. The consideration of the influence of the geometry on the GMI helps identify the discrepancies between theory and experiments. Besides we demonstrate that the geometry of the sample must be carefully chosen to improve device performances, especially the length of the sensor had to be taken into account by 3D FEM simulations, in progress.

Abstract— The Jiles-Atherton (J-A) model is widely used to the modeling of the nonlinear characteristics of magnetic materials. It can include the effects of stress, temperature and external field frequency and is given in the form of a set of non-linear and first-order ordinary differential equations. This paper presents a harmony search (HS) optimization method based on Cauchy distribution (CHS) to the parameter identification of the J-A model of hysteresis is proposed. The performance of the HS and the proposed CHS optimization approach are evaluated and compared with result of hysteresis modeling, which is included in the dynamic model of a single-phase transformer, of recent literature.

Index Terms— magnetic hysteresis, modeling, Jiles-Atherton model, optimization, harmony search, transformer.

I. INTRODUCTION

Hysteresis are encountered in a wide range of physical systems and devices, such as magnetic materials, piezoelectric and piezoceramic actuators, shape memory alloys, electronic relay circuits, among others. Hysteresis is a complex process. Only complicated models describe this phenomenon with satisfying accuracy.

The description of magnetization processes in soft magnetic materials proposed by Jiles and Atherton [1] still remains one of the most widely used ones and has been the subject of considerable interest in the scientific community due to its physical backgrounds and the possibility to include the effects of stress, temperature and external field frequency. It is given in the form of a set of non-linear and first-order ordinary differential equations. Such model typically contains a set of parameters referred to herein as “model parameters” or “material parameters,” that need to be extracted from experimental data.

The paper presents an attempt to estimate the parameters of Jiles and Atherton (J-A) model description of magnetization process using an improved harmony search (HS) optimization method using Cauchy operator (CHS). The proposed CHS method was validated into dynamical model of a single-phase transformer. In this context, the data of single-phase transformer used in validation was also employed in [2].

II. DYNAMIC MODEL OF A TRANSFORMER AND J-A HYSTERESIS MODEL

By using simplifications presented in [2] and knowing transformer geometry, a single-phase transformer model obtains the following form

$$u_1 = i_1 R_1 + L_{\sigma 1} \frac{di_1}{dt} + N_1 A \frac{dB}{dH} \left(\frac{N_1}{l} \frac{di_1}{dt} + \frac{N_2}{l} \frac{di_2}{dt} \right) \quad (1)$$

$$u_2 = i_2 R_2 + L_{\sigma 2} \frac{di_2}{dt} + N_2 A \frac{dB}{dH} \left(\frac{N_1}{l} \frac{di_1}{dt} + \frac{N_2}{l} \frac{di_2}{dt} \right) \quad (2)$$

where u_1 , u_2 , and i_1 , i_2 are the primary and secondary voltages and currents, respectively; R_1 and R_2 are the primary and secondary resistances, $L_{\sigma 1}$ and $L_{\sigma 2}$ are the primary and secondary leakage inductances, N_1 and N_2 are the primary and secondary number of turns, A is the average area of the transformer iron core, l is the mean path length of the magnetic flux, H is the magnetic field, and B is magnetic flux densities.

In Eqs. (3) and (4), term dB/dH can now be determined using the J-A hysteresis model. The original J-A hysteresis model with magnetic field as an independent variable, delivered from [3], [4] is given by [2]

$$\frac{dM}{dH} = \frac{(1-c) \frac{dM_{irr}}{dH_c} + c \frac{dM_{an}}{dH_e}}{1 - \alpha c \frac{dM_{an}}{dH_e} - \alpha(1-c) \frac{dM_{irr}}{dH_c}} \quad (3)$$

$$\frac{dM_{an}}{dH_e} = \frac{M_s}{a} \left[1 - \coth^2 \left(\frac{H_e}{a} \right) + \left(\frac{a}{H_e} \right)^2 \right] \quad (4)$$

$$\frac{dM_{irr}}{dH_e} = \frac{\gamma(M_{an} - M_{irr})}{k\delta} \quad (5)$$

$$\delta = \begin{cases} +1, & dH/dt \geq 0 \\ -1, & dH/dt < 0 \end{cases} \quad (6)$$

$$\gamma = \begin{cases} 1, & (M_{an} - M_{irr})dH_e \geq 0 \\ 0, & (M_{an} - M_{irr})dH_e < 0 \end{cases} \quad (7)$$

$$\frac{dB}{dH} = \mu_0 \left(1 + \frac{dM}{dH} \right) \quad (8)$$

where M_{an} and M_{irr} are the anhysteretic and irreversible magnetizations, respectively; μ_0 is the permeability of vacuum, and dH_e is denoted as $dH_e = dH + \alpha \cdot dM$. The parameters of the original J-A hysteresis model that must be identified are: the anhysteretic behavior a , the main field parameter α , the saturation magnetization M_s , the parameter which is proportional to the hysteresis loop width and domain flexing constant c , and the pinning parameter k .

III. FUNDAMENTALS OF HARMONY SEARCH

The HS algorithm proposed by [5] is a metaheuristic optimization algorithm based on the musical process of searching for a perfect state of harmony, such as jazz improvisation. In this improvisation process, members of the musical group try to find the best harmony as determined by an aesthetic standard, just as the optimization algorithm tries to find the global optimum as determined by the objective function. The notes and the pitches getting played by the individual instruments determine the aesthetic quality, just as the objective function value is determined by the values assigned to design variables.

The optimization procedure of the HS algorithm consists of steps 1-5, as follows:

1. Define the optimization problem and HS algorithm parameters.
2. Initialize the harmony memory.
3. Improvise a new harmony from the harmony memory.
4. Update the harmony memory.
5. Repeat Steps 3 and 4 until the termination criterion is satisfied.

In the proposed CHS approach, an operator based on Cauchy distribution is introduced in step 3 of classical HS to escape from local optima.

IV. OPTIMIZATION RESULTS

The objective function to be minimized using HS and CHS is given by

$$F = \sqrt{\frac{\sum_{i=1}^N (B_{i\text{meas}} - B_{i\text{model}})^2}{N}} \quad (9)$$

where $B_{i\text{meas}}$ is the measured magnetic flux density, $B_{i\text{model}}$ is the calculated magnetic flux density from the model, and N is the number of points of measured magnetic flux density. For the measurement purpose, the transformer was supplied with sinusoidal voltage whilst the primary voltage and current were being measured. The hysteresis loop with magnetization curve was then determined from known geometry of the iron core and measured data [2].

Parameters identified using HS and CHS for the J-A model are presented in Table I. In terms of mean and minimum F values in 30 runs (adopted 60,000 evaluations of objective function in each run), results shown in Table I indicate that CHS can tackle the J-A modelling more efficiently than the classical HS. Fig. 1 presents a comparison of measured and calculated hysteresis loop using the best results obtained by

CHS. Table II present the best results using CHS and the result using differential evolution (DE) given in [2]. Based on results of Table II, the DE and CHS presented similar performance in terms of F values.

TABLE I
BEST RESULTS OF F (30 RUNS) FOR THE J-A MODEL

Optimization Techniques	Objective Function F in 30 Runs			
	Maximum (Worst)	Mean	Minimum (Best)	Std. Dev.
HS	0.03894	0.03316	0.03155	0.00230
CHS	0.03474	0.03257	0.03154	0.00104

Fig. 1. Comparison of measured and calculated B - H hysteresis loop.

TABLE II
PARAMETERS OBTAINED BY BEST RESULTS

Parameter	DE [2]	CHS
a (A/m)	226.25	223.27
α	$0.502 \cdot 10^{-3}$	$0.497 \cdot 10^{-3}$
M_s (A/m)	$1.335 \cdot 10^6$	$1.331 \cdot 10^6$
c	0.724	0.721
k (A/m)	300.05	295.49
F	0.03154	0.03154

V. CONCLUSION

Hysteresis is a complex phenomenon, which is important both from theoretical and practical points of view. A relevant approach to describe hysteresis can be found in the J-A model. In this paper a novel approach to estimation of J-A model parameters has been presented. The proposed CHS approach was successful to estimate the J-A model parameters.

Automatic Design of Insulation Structure of Power Transformer Based on Sensitivity Analysis

Liu Yang, Cui Xiang

School of electrical and electronic engineering, North China Electric Power University
Box 10, 619 Yonghua North Street, Baoding city, Hebei province, 071003, P.R. China
E-mail: hdwllly@163.com

Abstract—Based on the finite element method, a new algorithm for evaluating the sensitivity of electric field intensity to geometric parameters is presented in this paper. By means of this algorithm, the sensitivity can be evaluated as like the nodal potential solution. Adopting Hermite polynomial instead of Taylor polynomial greatly decreased the order of the high-order cross sensitivity. Numerical results show that this algorithm is very effective and can be used in the automatic design of the insulation structure in power transformer.

I. INTRODUCTION

In the automatic design of electromagnetic apparatus, the optimization technique based on the derivatives of objective function, i.e. sensitivity, is often selected as a numerical tool. It is key to evaluate the partial derivatives of objective function with respect to the geometric parameters in this technique. Dr. J. L. Coulomb proposed a Taylor polynomial approximation of objective function and an algorithm based on Jacob's matrix [1]. In general Taylor polynomial order is relatively high, and the stability of objective function is low. It takes up too much memory of computer and the allowable variation of the designed parameters is limited.

In this paper, the multi-dimensional Hermite polynomial and a new algorithm of computing the sensitivity which has nothing to do with Jacob's matrix is presented.

II. HERMITE POLYNOMIAL

The 2D Hermit polynomial $f_h(p,q)$ can be expressed as follows:

$$\begin{aligned} f_h(p,q) = & f_{ij}\alpha_{ij} + f_{i+1,j}\alpha_{i+1,j} + f_{i,j+1}\alpha_{i,j+1} \\ & + f_{i+1,j+1}\alpha_{i+1,j+1} + f'_{i,j(p)}\beta_{i,j} + f'_{i+1,j(p)}\beta_{i+1,j} \\ & + f'_{i,j+1(p)}\beta_{i,j+1} + f'_{i+1,j+1(p)}\beta_{i+1,j+1} + f'_{i,j(q)}\gamma_{i,j} \\ & + f'_{i+1,j(q)}\gamma_{i+1,j} + f'_{i,j+1(q)}\gamma_{i,j+1} + f'_{i+1,j+1(q)}\gamma_{i+1,j+1} \\ & + f''_{i,j(pq)}\eta_{i,j} + f''_{i+1,j(pq)}\eta_{i+1,j} + f''_{i,j+1(pq)}\eta_{i,j+1} \\ & + f''_{i+1,j+1(pq)}\eta_{i+1,j+1} \end{aligned} \quad (1)$$

where $f_{i,j}, f_{i+1,j}, f_{i,j+1}, f_{i+1,j+1}$ are the function values of the four corners of each division, $f'_{i,j}, f'_{i+1,j}, f'_{i,j+1}$ and $f'_{i+1,j+1}$ are one order partial derivatives, $f''_{i,j}, f''_{i+1,j}, f''_{i,j+1}$ and $f''_{i+1,j+1}$ are two order cross partial derivatives and $\alpha_{ij}(p,q), \beta_{ij}(p,q), \gamma_{ij}(p,q), \eta_{ij}(p,q)$ are division fundamental functions of the sixth power. The results in [2] show this technique is effective.

III. COMPUTATION OF SENSITIVITY

For electrostatic field problem, the finite element equation is:

$$K \varphi = 0 \quad (2)$$

where φ is nodal potential, K is stiffness matrix. If three-node triangular element is used, K can be calculated by

$$K_{ij}^e = \varepsilon \iint_{\Delta_e} \nabla N_i^e \cdot \nabla N_j^e dx dy \quad (3)$$

$$N_i^e = \frac{1}{2\Delta_e} (a_i + b_i x + c_i y) \quad (4)$$

where N_i^e is the function in the e -th triangular element, where Δ_e, a_i, b_i, c_i are functions depended on the nodal coordinates.

A. One Parameter Problem

Let p be a geometric parameter, then $\partial K_{ij}^e / \partial p$ may be calculated as follows:

$$\begin{aligned} \frac{\partial K_{ij}^e}{\partial p} = & \frac{\partial K_{ij}^e}{\partial \Delta_e} \sum_{k=1}^3 \left(\frac{\partial \Delta_e}{\partial x_k} \frac{\partial x_k}{\partial p} + \frac{\partial \Delta_e}{\partial y_k} \frac{\partial y_k}{\partial p} \right) + \frac{\partial K_{ij}^e}{\partial b_i} \sum_{k=1}^3 \left(\frac{\partial b_i}{\partial y_k} \frac{\partial y_k}{\partial p} \right) \\ & + \frac{\partial K_{ij}^e}{\partial b_j} \sum_{k=1}^3 \left(\frac{\partial b_j}{\partial y_k} \frac{\partial y_k}{\partial p} \right) + \frac{\partial K_{ij}^e}{\partial c_i} \sum_{k=1}^3 \left(\frac{\partial c_i}{\partial x_k} \frac{\partial x_k}{\partial p} \right) + \frac{\partial K_{ij}^e}{\partial c_j} \sum_{k=1}^3 \left(\frac{\partial c_j}{\partial x_k} \frac{\partial x_k}{\partial p} \right) \end{aligned} \quad (5)$$

Suppose E^e is the electric field intensity in the e -th element

$$E^e = \sqrt{(E_x^e)^2 + (E_y^e)^2} \quad (6)$$

$$\text{Then} \quad \frac{\partial E^e}{\partial p} = \frac{1}{E^e} \left(E_x^e \frac{\partial E_x^e}{\partial p} + E_y^e \frac{\partial E_y^e}{\partial p} \right) \quad (7)$$

The terms in (7) can be calculated by following way

$$\frac{\partial E_x^e}{\partial p} = -\frac{E_x^e}{\Delta_e} \frac{\partial \Delta_e}{\partial p} - \frac{1}{2\Delta_e} \sum_{i=1}^3 \left(\varphi_i \frac{\partial b_i}{\partial p} + b_i \frac{\partial \varphi_i}{\partial p} \right) \quad (8)$$

$$\frac{\partial E_y^e}{\partial p} = -\frac{E_y^e}{\Delta_e} \frac{\partial \Delta_e}{\partial p} - \frac{1}{2\Delta_e} \sum_{i=1}^3 \left(\varphi_i \frac{\partial c_i}{\partial p} + c_i \frac{\partial \varphi_i}{\partial p} \right) \quad (9)$$

The column matrix in (8) and (9) may be solved from (2)

$$\frac{\partial \varphi}{\partial p} = -K^{-1} \frac{\partial K}{\partial p} \varphi \quad (10)$$

Optimization

B. Two Parameters Problem

Now suppose that p and q are two geometric parameters. Then we can derive (7) respect to the parameter q , and find the new formula of the derivatives of E^e :

$$\begin{aligned} \frac{\partial^2 E^e}{\partial p \partial q} = & -\frac{1}{E^e} \frac{\partial E^e}{\partial p} \frac{\partial E^e}{\partial q} + \frac{1}{E^e} \frac{\partial E_x^e}{\partial p} \frac{\partial E_x^e}{\partial q} + \frac{E_x^e}{E^e} \frac{\partial^2 E_x^e}{\partial p \partial q} \\ & + \frac{1}{E^e} \frac{\partial E_y^e}{\partial p} \frac{\partial E_y^e}{\partial q} + \frac{E_y^e}{E^e} \frac{\partial^2 E_y^e}{\partial p \partial q} \end{aligned} \quad (11)$$

where $\frac{\partial^2 E_x^e}{\partial p \partial q}$ and $\frac{\partial^2 E_y^e}{\partial p \partial q}$ can be calculated from (8) and (9):

$$\begin{aligned} \frac{\partial^2 E_x^e}{\partial p \partial q} = & -\frac{1}{\Delta_e} \frac{\partial \Delta_e}{\partial p} \frac{\partial E_x^e}{\partial q} + \frac{E_x^e}{\Delta_e} \frac{\partial \Delta_e}{\partial p} \frac{\partial \Delta_e}{\partial q} - \frac{E_x^e}{\Delta_e} \frac{\partial^2 \Delta_e}{\partial p \partial q} \\ & + \frac{1}{2\Delta_e^2} \frac{\partial \Delta_e}{\partial q} \sum_{i=1}^3 (\varphi_i \frac{\partial b_i}{\partial p} + b_i \frac{\partial \varphi_i}{\partial p}) - \frac{1}{2\Delta_e} \\ & \sum_{i=1}^3 (\frac{\partial b_i}{\partial p} \frac{\partial \varphi_i}{\partial q} + \varphi_i \frac{\partial^2 b_i}{\partial p \partial q} + \frac{\partial \varphi_i}{\partial p} \frac{\partial b_i}{\partial q} + b_i \frac{\partial^2 \varphi_i}{\partial p \partial q}) \end{aligned} \quad (12)$$

$$\begin{aligned} \frac{\partial^2 E_y^e}{\partial p \partial q} = & -\frac{1}{\Delta_e} \frac{\partial \Delta_e}{\partial p} \frac{\partial E_y^e}{\partial q} + \frac{E_y^e}{\Delta_e} \frac{\partial \Delta_e}{\partial p} \frac{\partial \Delta_e}{\partial q} - \frac{E_y^e}{\Delta_e} \frac{\partial^2 \Delta_e}{\partial p \partial q} \\ & + \frac{1}{2\Delta_e^2} \frac{\partial \Delta_e}{\partial q} \sum_{i=1}^3 (\varphi_i \frac{\partial c_i}{\partial p} + c_i \frac{\partial \varphi_i}{\partial p}) - \frac{1}{2\Delta_e} \\ & \sum_{i=1}^3 (\frac{\partial c_i}{\partial p} \frac{\partial \varphi_i}{\partial q} + \varphi_i \frac{\partial^2 c_i}{\partial p \partial q} + \frac{\partial \varphi_i}{\partial p} \frac{\partial c_i}{\partial q} + c_i \frac{\partial^2 \varphi_i}{\partial p \partial q}) \end{aligned} \quad (13)$$

The column matrix $\frac{\partial^2 \varphi}{\partial p \partial q}$ in (12) and (13) may be solved from (10) as follows:

$$\frac{\partial^2 \varphi}{\partial p \partial q} = -K^{-1} \left(\frac{\partial K}{\partial p} \frac{\partial \varphi}{\partial q} + \frac{\partial^2 K}{\partial p \partial q} \varphi + \frac{\partial K}{\partial q} \frac{\partial \varphi}{\partial p} \right) \quad (14)$$

IV. NUMERICAL VERIFICATION

For showing the application of above algorithm, we analysis the field a coaxial cable with inner radius $R_1=1\text{cm}$, outer radius $R_2=5\text{cm}$, applying 100V between conductors. The sensitivity of electric field intensity to R_1 and R_2 at five specified points is evaluated. Numerical results and analytic values are shown in Table I. These results show that the new algorithm in this paper is very effective.

TABLE I. COMPUTATIONAL RESULTS OF SENSITIVITIES

Specified points		X=0.86 Y=4.56	X=2.94 Y=0.96	X=1.66 Y=1.69	X=0.85 Y=1.66
E	Values(V/cm)	48.09	32.22	19.77	13.00
	Error(%)	-3.49	2.65	0.29	-1.12
$\frac{\partial E}{\partial R_1}$	Values(V/cm ²)	30.53	19.88	12.20	8.03
	Error(%)	-1.39	1.94	-0.43	-1.82
$\frac{\partial E}{\partial R_2}$	Values(V/cm ²)	-5.98	-4.01	-2.46	-1.59
	Error(%)	-3.47	2.67	0.34	-2.59
$\frac{\partial^2 E}{\partial R_1 \partial R_2}$	Values(V/cm ³)	-7.47	-4.97	-3.03	-1.98
	Error(%)	-2.87	2.55	-0.44	-2.72

Fig. 1 is a simplified model in the lower part of the insulation structure of a 500kV power transformer. Let the maximum of the electric field intensity on the outer surface of the insulation layer of the electrostatic ring be the objective function $f(x)$. Suppose that R_1 and B be two geomrteic parameters.

In this design, the objective function is defined by

$$f(B, R_1) = (E - E_0)^2 \quad (15)$$

where E is the maximum of electric field intensity on the outer surface of the insulation layer of the electrostatic ring and E_0 is the specified design electric field intensity. Now, we hope to obtain a design so that $E_0=5.60\text{kV/mm}$ when $500/\sqrt{3}\text{ kV}$ is applied between the high-voltage winding and the low-voltage winding. Applying above procedure of automatic design based on the genetic algorithm to the design, through computation of 6 generations and 37 seconds *cpu* time, we can obtain a desired design with $E=5.60\text{kV/mm}$ in which $B=83.0\text{mm}$, $R_1=10.7\text{mm}$. In order to check verification of the design, we also use the finite element method to calculate the maximum of electric field intensity that is 5.64kV/mm . The relative error is 0.71% between the electric field intensities calculated by the finite element method and by the sub-region Hermite polynomials. Therefore, above procedure of automatic design is very effective.

Fig. 2. Insulation structure of a 500kV transformer.

V. CONCLUSION

This optimization method has adopted Hermite polynomials in stead of Tolor polynomial, which has greatly decreased the order of the high cross sensitivity. The computation of sensitivity discussed in this paper is based on the finite element method. Numerical results show that this algorithm is very effective.

Abstract — The effectiveness of a case-based reasoning system for the preliminary design of electromagnetic (EM) devices is heavily dependent on a highly competent case base to allow fast exploration of the design space and make high-quality decisions. However, sufficient good cases are difficult to obtain from industrial examples. In this paper, the construction of a competent case base for EM devices based on a refined combined competence model is described. This case base involves functional, geometrical and material information for EM devices.

I. INTRODUCTION

The optimization of an electromagnetic device or system, such as an electrical machine, needs a starting point in the design space for the search. There are two approaches to this task. The first is known as “sizing” and relies on simple (and often inaccurate) magnetic circuit models. The second is an approach used by experienced designers and is based on previous solutions. While the former approach has been used in computer based systems, the latter paradigm is somewhat more difficult to implement as it requires a significant amount of data mining and classification. The approach which embodies this is known as “Case-Based Reasoning” (CBR) [1]. The problem to be considered is that of a search space with a very large number of dimensions (design parameters) and performance requirements (which may be multi-objective). This results in an extremely complex Response Surface which is difficult, if not impossible, to model. The approach proposed using CBR provides a methodology for exploring the design space based on previous design information, i.e. the performance results of tested designs. While, in the conventional industrial approach, these designs in the database would normally be those which have been built and tested, the existence of advanced analysis tools and a virtual laboratory provides an opportunity to generate a synthetic database which could include both “good” and “bad” designs and can complement those actually constructed. Two previous papers have described the construction of an effective case base library, its role in the design process and the theoretical fundamentals of competence for a case-base[2],[3], and it is the intention of this paper to further explore an approach to classifying the cases in terms of their “competence”, or their usefulness in representing the design space, and thus to refine the original combined competence model given in [3]. To do this, it is necessary to develop a methodology for determining “competence”.

II. A REFINED COMBINED COMPETENCE MODEL

The refined combined competence model presented here is evolved from the previous work to include the calculation of

the the coverage-range of low-quality as well as high-quality cases. The concept of how well a particular example can be generalized to represent the surrounding design space is embodied in a “combined competence” model which is formally described with the following concepts and formulae. First, this model adopts the definitions of coverage, reachability, and the four classes of cases in any case base as described in Smyth and McKenna’s competence model [4]; then it illustrates how to compute the case base competence in two situations. The first relates to a uniform distribution of cases; and the second to a nonuniform distribution. Finally, it calculates the cover-range of competent cases [4].

Given a case-base $C = \{c_1, \dots, c_n\}$, for $c \in C$, $\text{Adaptable}(c, b)$ is an adaptation process which transforms a case retrieved (c) into a solution appropriate for the presented problem (b).

The following definitions are then made:

$\text{Coverage}(c) = \{c_i \in C : \text{Adaptable}(c, c_i)\}$

$\text{Reachable}(c) = \{c_i \in C : \text{Adaptable}(c_i, c)\}$

Note that these are conditions which should hold for any optimization algorithm.

Then we can define the following:

- Pivotal Case: $\text{Reachable}(c) - \{c\} = \emptyset$

- Auxiliary Case: $\exists c_i \in \text{Reachable}(c) - \{c\}$:

$\text{Coverage}(c) \subsetneq \text{Coverage}(c_i)$

- Spanning Case: $\neg \text{Pivotal}(c) \wedge \text{Coverage}(c) \cap \bigcup_{c_i \in \text{Reachable}(c) - \{c\}} \text{Coverage}(c_i) \neq \emptyset$

- Support case: $\exists c_i \in \text{Reachable}(c) - \{c\}$:

$\text{Coverage}(c_i) \subset \text{Coverage}(c)$

- A competence of a group of cases (G): is defined as the group coverage of G in the following (were, $\text{SM}(a, b)$ is a function used to calculate the similarity between two cases):

$$\text{Casedensity}(c, G) = \frac{\sum_{c_i \in G - \{c\}} \text{SM}(c, c_i)}{|G| - 1} \quad (1)$$

$$\text{Groupdensity}(G) = \frac{\sum_{c \in G} \text{Casedensity}(c, G)}{|G|} \quad (2)$$

$$\text{Group coverage}(G) = 1 + |G|(1 - \text{Groupdensity}(G)) \quad (3)$$

- Case Base Competence: is defined as follows:

$$\text{Situation}_1 = \sum_{G_i \in G} \text{GroupCoverage}(G_i) \quad (4)$$

$$\text{Overlap coverage} = \sum_{c_i \in C^*} \text{Coverage}(c_i) \cap \text{Coverage}(CB - C^*) \quad (5)$$

$$\text{Situation}_2 = \text{Situation}_1 - \text{Overlap coverage} \quad (6)$$

- Competence group cover-range (CGCR): is defined as the maximum weighted distance between any pair of cases (c_p, c_q) in a competence group.

$$CGCR(G_i) = \max d^{(w)}(c_p, c_q) \quad (7)$$

- Flag case cover-range (FCCR): is defined as the minimum weighted distance between a pivotal case and a competence group.

$$FCCR(c_p^*) = \min d^{(w)}(c_p^*, c_q) \quad (8)$$

Fig. 1. EM device cases in a multi-dimensional design space

$C^* = \{c_1^*, \dots, c_n^*\}$ is the pivotal case collection of a case-base. Here the case-base is classified into two situations, in situation 1, it consists of disjoint subsets: $\{G_1, \dots, G_n\}$; in situation 2, there exist pivotal cases (Fig. 1).

III. THE USE OF COMPETENCE IN PRODUCING A DESIGN PROTOTYPE

Each of the competence groups found by the process developed above provides a search group for matching a set of design specifications. If the specifications exactly match those of the competence group then a prototype can be developed from the group with a high confidence level that it is a good starting point. However, as the search moves away from the group, the confidence in a prototype developed from the group reduces. At some point, a prototype might be developed by combining features from two different competence groups. For example, a stator from one group might be combined with a rotor from another. In addition, some examples in the database might indicate areas of the search space, for the given specifications, which will not produce satisfactory solutions. These are areas to be avoided and can have negative inputs to the construction of a prototype.

IV. A COMPETENT CASE BASE FOR INDUCTION MOTORS

According to the refined combined competence model above, a competent case base for induction motors is designed as a structured database with entities and relationships tying together building blocks to form designs. This case base presents rich information to describe an induction motor, such as the steady state equivalent circuit, geometry, material, coil windings and performance analysis results, and it also includes the four classes of cases (pivotal, auxiliary, spanning and support). Simulation can be used to complement and extend the cases available from industrial designs with new examples within the design space. However, even then, the number of points in the design space that can be created is

relatively small compared to the size of the space. In addition, since all the devices represent points in the design response surface, both good and bad examples (in terms of design requirements) may be included. Such a database has been constructed and consists of a set of induction motors with varying performance characteristics and a variety of physical structures. These devices form the data set for the competence algorithm. Fig. 2 shows a slice through the multi-dimensional design space for the full load power against the machine outer diameter and efficiency. As can be seen, these cases are clustered into groups which can be identified by the competence algorithm.

Fig. 2. An illustrating induction motor case base

This case base has been built with the help of MotorSolve provided by Infolytica Corporation [5].

V. CONCLUSION

A refined combined competence model has been developed and applied to a database of induction motor designs. Using the information generated, it is possible to generate a potential candidate for a prototype device which can be used as the starting point for an optimization process. In effect, the case-based system provides an efficient and fast method for exploring the potential design space allowing the optimizer to concentrate on the exploitation phase. The full paper will provide details of the case-base, the algorithms involved in competence determination and an example of their use.

Slot Shape Optimization for Permanent Magnet Synchronous Machines by Evolution Strategy and Time-Stepped Finite Element Analysis

Yang Zhan and Andrew M. Knight

Department of Electrical and Computer Engineering, University of Alberta
Edmonton, Alberta, T6G 2V4, Canada
knight@ece.ualberta.ca

Abstract— This paper presents the application of (1+4) and (1,4) evolution strategies to minimize the losses in a permanent magnet synchronous machine designed for operation in a flywheel energy storage system. The optimization strategies are used to adjust the stator slot shape to reduce the open circuit iron loss and magnet eddy-current loss calculated using time-stepped finite element analysis. At each generation of the optimization, the fitness of each candidate is evaluated in parallel. The performances of the (1+4) and (1,4) algorithm are compared, and an optimal slot shape design is presented.

I. INTRODUCTION

Permanent magnet synchronous machines (PMSM) is an attractive candidate for use with flywheel energy storage systems as they have high power density, high efficiency and are relatively simple to control. Even though PMSM are typically considered to be high efficiency machines, particular attention should be made to losses in a machines designed for use in with a flywheel. Total loss should be as low as possible, in order to maximize round-trip energy efficiency. High frequency eddy current losses in the magnets should be minimized, as the rotor of the system is typically evacuated, eliminating conductive and convective heat transfer from the rotor.

Adjustment of the stator slot shape is an economical approach to contribute towards loss reduction after an initial design using low-loss materials has been carried out. In the process of design optimization, machine losses are evaluated for each design, and an optimization algorithm is required to seek the optimal design according to certain criteria. The slot shape design optimization for loss reduction has been investigated in a number of papers, e.g. [1], [2]. However, losses due to flux density space harmonics contribute significantly to both magnet and iron losses in a high speed machine. The time-stepped finite element analysis (FEA) may fully model the effect of rotor motion on the electromagnetic harmonics, therefore its use with an optimization algorithm is considered in this paper.

Regarding the optimization algorithm, there are a wide variety of options on deterministic or probabilistic search and optimization techniques. As a probabilistic technique based on adaption and evolution, evolution strategy (ES) has been successfully applied to some attempts at machine design optimization [3], [4], [5]. In this paper, within each ES iteration, time-stepped FEA is implemented in parallel to evaluate the machine losses of each candidate.

The flywheel application in flywheel system places a number of requirements on the PMSM design and drive system. As the flywheel may be frequently accelerated or decelerated, the PMSM is required to be operated at a wide range of high speeds, and the field weakening control is required at these high speeds. Initial design of the PMSM is carried out using an analytical lumped-parameter prediction, then verified by magnetostatic FEA. Once these parameters are determined, operation under load is simulated using time-stepped FEA to obtain full evaluations of iron loss, magnet eddy-current loss, efficiency, power factor, etc. The initial design uses a rotor with surface mounted magnets (SPM) and two-layer fractional-slot short-pitched distributed windings. Details about the initial design & operational requirements can be found in [6].

II. SLOT SHAPE VARIABLES AND COST FUNCTION

The stator slot shape is described using 6 objective variables shown in Fig.1. The adjustment of these variables is constrained to ensure that total slot area (A) is above a minimum value determined by the slot current density. Additional constraints include d - and q - axis inductances (L_d , L_q) and permanent magnet flux linkage (λ_m). The optimal slot shape should maintain the design values of inductance and flux linkage to ensure that field weakening control may be applied efficiently. As this PMSM adopts a SPM design with the equal L_d and L_q , their constraints are similar. The constraints on L_d , L_q and λ_m are determined with quantitative analysis based on the d - q axis equations and the field weakening conditions. The constraints on the objective variables and other relevant parameters are shown in Table II.

Fig. 1. Slot shape variables

The cost function to be minimized is constructed by superimposing the penalty functions on the total machine loss:

$$C = W + P_1(A) + P_2(L_d) + P_3(\lambda_m) \quad (1)$$

W is the total machine Watts loss. The penalty functions P_1 , P_2 and P_3 may add positive numbers to the cost function when the constrained parameters violate the constraints. To determine the penalty factors in the penalty functions for L_d

and λ_m , one needs to evaluate the effect of L_d and λ_m variations on the machine performances using the d-q axis equations.

TABLE I
VARIABLE AND PARAMETER CONSTRAINTS

	δ (mm)	d_1 (mm)	d_2 (mm)	w_1 (mm)	w_2 (mm)	b (mm)	A (mm ²)	L_d, L_q (mH)	λ_m (Wb)
Lower	1.90	0.30	1.00	2.00	4.00	70.00	206.4	0.275	0.085
Upper	4.00	3.00	5.00	8.00	20.00	105.00	--	0.418	0.108

As the flywheel PMSM would rarely operate at steady speeds, it is impractical to minimize the machine losses under a range of varying load conditions. The variation of machine loss brought by the slot shape adjustment can be evaluated with the simulations on the open circuit operations. The PMSM losses at open circuit comprise the iron loss and the magnet eddy-current loss. The latter can be calculated by time-stepped eddy-current FEA, while the former can be evaluated by substituting the flux densities obtained by time-stepped FEA into the classical equations [7].

III. OPTIMIZATION BY EVOLUTION STRATEGY

ES seeks the optimum by simulating the biological evolution. There are two categories of ES algorithm: (μ, λ) -ES and $(\mu+\lambda)$ -ES. $(\mu+\lambda)$ -ES differs from (μ, λ) -ES in the stage of selection. $(\mu+\lambda)$ -ES selects the best μ as the parents for the next generation from the combination of μ parents and λ children. The (1+1)-ES [3], [5] and the (1,5)-ES [4] algorithms have been applied to PMSM and induction motor design.

In this paper both the (1+4)-ES and the (1,4)-ES are applied to the slot shape design optimization for minimization of the open circuit losses at the speed of 28,000 rpm. Parallelized (1+4)-ES and (1,4)-ES algorithms are efficiently carried out on a quad-core computer. Both strategies start from the same initial slot design, with the progress of the cost function plotted in Fig. 2. It is clear that the (1,4)-ES converges to a smaller cost function value than the (1+4)-ES, which is trapped into a local minimum. This phenomenon can be explained by comparing the manner of selection of the two algorithms. In the (1+4)-ES any child inferior to its parent will not survive for the next generation, therefore this algorithm may escape from a local optimum only if it reproduces by chance a mutant which is out of the close neighborhood of the local optimum and superior to its parent. With the (1,4)-ES a child inferior to its parent still has the opportunity to survive for more than one generation, and may eventually help the algorithm converge to the global optimum.

Tables II and III summarize the initial slot design and the optimal results obtained by the (1,4)-ES. The optimal design reduces the total machine loss by 12.7%. Fig. 3 shows the loss density distribution of the initial and optimal designs. The optimization gives a shorter and narrower slot shape design with a smooth tip-tooth transition. This optimal design reduces the fluctuation of air gap flux density and brings a notable improvement that the magnet eddy-current loss is reduced by 57.6%. This may greatly reduce the risk of overheating and demagnetizing the permanent magnet.

TABLE II INITIAL AND OPTIMAL DIMENSIONS

	δ (mm)	d_1 (mm)	d_2 (mm)	w_1 (mm)	w_2 (mm)	b (mm)	A (mm ²)	L_d, L_q (mH)	λ_m (Wb)
Initial	2.44	2.00	2.49	6.20	12.00	90.58	248.05	0.310	0.102
Optimal	1.94	0.90	3.97	4.88	11.93	87.89	206.40	0.319	0.103

Fig. 2. Cost function values of parents

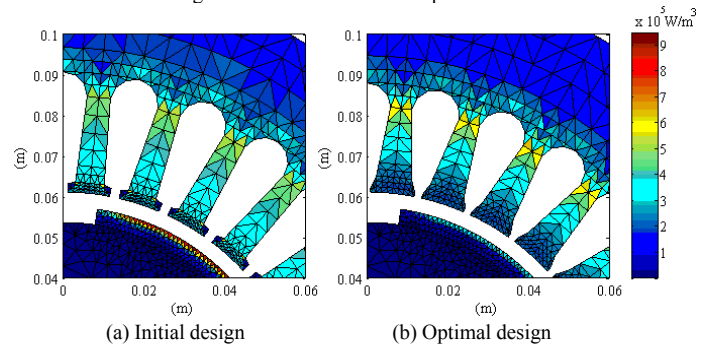

Fig. 3. Loss density distribution

TABLE III INITIAL AND PREDICTED LOSSES

	Total (W)	Iron(W)	Magnet (W)
Initial	756.86	707.49	49.37
Optimal	660.55	639.64	20.91

IV. CONCLUSIONS

Parallelized (1+4)-ES and (1,4)-ES are utilized with Time stepped FEA to improve the stator slot design of a flywheel PMSM to minimize open circuit losses. The parallel approach significantly reduces the time required to evaluate the fitness of the children, and is practical to implement on a quad-core computer. The (1,4)-ES result is superior to the (1+4)-ES and significantly reduces the total machine loss and the magnet eddy-current loss.

Abstract—The following digest gives a short overview about the analytical modeling of a electrical linear generator in combination with numerical optimization and modeling methods. The final paper will be more detailed and contains results. The digest gives an overview about the general project steps. The complete mechatronic system is described by basic differential equations. Those are combined with analytical terms which describe the linear machine. Several complexity levels are shown and will be compared with the results of an FE model in the final paper.

I. INTRODUCTION

Engineers developing electrical machines at university normally optimize of such machines for special purposes. Therefore only single aspects like efficiency or room of the machine shall be optimal. The system in which the machine is mounted, is usually neglected in those projects.

In this case however a specific combined heat and power system (see fig. 1) shall be optimized. It exists of a pneumatic pressure excited alternating piston that is stiff coupled to a linear permanent magnetic excited synchronous machine (LPMSM). The complete system should produce about 3-6kW electric power.

Our task is the design of the linear machine under specific limitations like maximum speed, acceleration, minimal weight and low complexity. Other work deals with the design and modeling of linear induction machines[4]. Especially for space use or elevator systems one can find well designed machines [2]. But to achieve high power density a tubular LPMSM shall be applied within the system. The best configuration is a tubular polysolenoid type (e.g.[1]).

In our project we use a new "multidisciplinary" approach to optimize the machine. The system is reduce to it's basic

parameters like pressure, dimensions, weight or forces. Then a numerical simulation with differential equations and optimization algorithms is used to find best parameter sets. The feedback of the linear machine is refined more and more with each phase of the project. The design and optimization process combines analytic methods, finite element methods and numerical optimization what is a new approach in developing electrical machines.

II. OPTIMIZATION AND DESIGN PROCESS

Fig. 2 gives a general overview about the complete process we are using to design a machine which fits the system-requirements. As we know the topology we start directly on the system level. To do a quick an accurate system optimization those parameters have to be detected against which the system behaves sensitive. For those different known optimization methods like genetic algorithms and particle swarm algorithms are used to find the best parameter configuration of the complete system which fits the requirements best in terms of the criteria. Those are minimal weight, small room, best dynamics and best efficiency. The first iterations use simple analytical methods to get feedback of the linear machine. The feedback has been detected to be mainly the movers mass, the linear force and the maximum speed of the system. The methods are refined with each step. After we have a good quality profile we start with a further level within wich we design the principal dimensions of the machine and use analytical methods again for the feedback. On the last level

Fig. 1. Principal view of the system

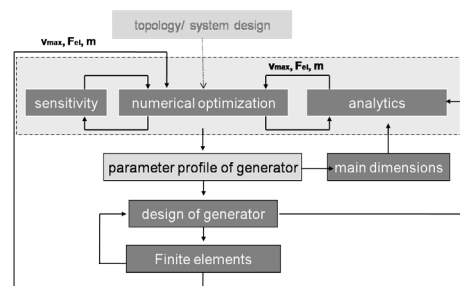

Fig. 2. Optimization and design process.

an exact analytical model is implemented and FE methods are added. On this level we do several iterations to find a complete machine design which interacts with the complete mechatronic system in such a way, that the configuration is optimal to fit the requirements.

III. ANALYTICAL SIMULATION MODEL

The coupled analytical simulation and optimization of the mechatronic system is done with Simulink. For this purpose we describe the whole system with differential equations based on equilibrium of forces (see eq. (1)).

$$F_{piston} - F_r - F_{el} - m \cdot \ddot{s} = 0 \quad (1)$$

To find out sensitivities of the system a continuous analytical description would be necessary. But the electromagnetic force of the generator and the pneumatic force of the piston are both nonlinear, not discrete and depend on different variables (see fig. 3). Especially the speed, which is a result of the system simulation, provides problems. Therefore the system is analyzed in discrete intervals, where such variables don't have a knick or a saltus. For particular sensitive parameters like those which influence the force of the piston and those which influence the force of the generator the optimization is done several times while the feedback of the generator is considered. This feedback is a big challenge of this work. As it is not reasonable to do a complete design process of the machine each step we have to use approximations based on the desired force-speed characteristics. Therefore the mass of the generator is calculated based on the load factor, a maximum air gap flux density and a maximum current distribution. The speed, acceleration and the maximum pressure of the system are used as boundaries.

$$P_{el} \rightarrow C_{load} \rightarrow \hat{B}_{delta} \approx 0,8 T, \hat{a} \approx 230 \frac{kA}{m} \quad (2)$$

$$\tau = \hat{B}_{delta} \cdot \hat{a} \rightarrow A_{Gen,surf} \rightarrow m_{Gen}(l_{ax}, r_{tube}) \quad (3)$$

After completing this phase a profile of the system is available which contains the optimal parameters and main dimensions to fit the requirements.

IV. EXACT ANALYTICAL MACHINE MODEL

In the next step the analytical model of the generator is refined and a detailed design process is set up. We run through this phase several times and add features to the analytics each time. The aim is to find out, which level of detail has to be modeled to achieve high quality results for the system profile. For the machine a classical approach is chosen. The force-generating terms are described by a fourier transformation

Fig. 3. Pneumatic force on piston depending on the axial position and force of linear machine depending on the speed.

of the exciting stator currents and a replacement flux of the permanent magnets. Then the force is calculated and the inductances of the machine. The complete design process is aided by a Matlab script what helps to find valid configurations of the geometry and the windings fast.

The results of this phase are more detailed information of the coupling between generator and system. This information is gained by an overlaid optimization process which tries to find best configurations. In the final paper there will be room for more detailed information about limitations and reductions which have to be made to make the optimization converge within reasonable time.

V. FE FEEDBACK

The last step is an overlay with Finite Elements. This is more or less a verification of the results from above. With the parameters we get from the FE we want to do further work to refine the analytical modeling and gain best quality results within shortest time. It exists an easy 2D model which directly gets it's information from the optimizer and is used to verify the dynamic behavior. A second 3D model is only used to detect losses. Especially losses within the machine are a big challenge and will be added in later work to the analytics.

VI. CONCLUSION

Within this short digest, we are not able to show results. This digest gives an overview over the complete project and it's several steps which have to be done. All in all we can say, that with modern optimization algorithms it is possible to gain fast and reliable parameters profiles of complete mechatronic systems. The best way is to be reduce systems to minimal models first and add complexity in several steps. Then in early states now configurations can be checked under consideration of main design rules. When the system is fixed, the design process it self for the single components can start. The time-costly FE process is placed at the end as verification. This is a now approach for time effective development of electrical drives.

Abstract — The optimization method using the ON/OFF sensitivity analysis has an advantage that an epoch-making construction of magnetic circuit may be obtained. Therefore, it is attractive for designers of magnetic devices. We have already developed the ON/OFF method for the optimization of a static magnetic field problem, and the effectiveness is verified by applying it to the optimization of magnetic recording heads. In this paper, the ON/OFF sensitivity method is extended to the optimization of the eddy current problem using the adjoint variable. The newly developed ON/OFF method is applied to the determination of the optimal topology of the yoke of the billet heater for rolling wire rod. As a result, the optimal shape of yoke, which we could not imagine beforehand can be obtained. It is shown that the local heating of the yoke was reduced without decreasing the heating efficiency.

I. INTRODUCTION

If a topology optimization method which can determine the optimal topology by distributing materials in a design domain is used, there is a possibility that a new magnetic circuit can be discovered, because it is not necessary to set design variables in advance[1-4]. The application of the ON/OFF method to the 3-D static magnetic field problem, such as magnetic recording head[1] has already been reported. The topology optimization of a simple linear eddy current problem is reported[1,2]. But, the topology optimization method which is applicable to the 3-D eddy current problem of actual magnetic device is not yet developed. Although a technique for calculating the design sensitivity by representing it by a finite difference equation is proposed[8], a long CPU time is necessary because an adjoint variable method[2] was not utilized.

In this paper, the ON/OFF method is extended to the optimization of the 3-D eddy current problem by combining the ON/OFF method with the step-by-step method and the adjoint variable method. The ON/OFF method is applied to the optimization of the laminated yoke of a billet heater for rolling wire rod. The laminated yoke is installed in the outside of the coil as the return path of flux which flows in the billet. There is a problem that the heating efficiency of the billet decreases by the eddy current loss generated in the laminated yoke. Then, a 3-D optimal topology of the laminated yoke of the model of an actual billet heater which avoids this problem is obtained using the newly developed ON/OFF optimization

method.

II. ON/OFF METHOD FOR EDDY CURRENT PROBLEM USING ADJOINT VARIABLE

The region (design domain) of which the shape (topology) is determined is subdivided into many design cells (finite elements). The material distribution is updated so that the desired result can be obtained, which allows each design cell to have only one state, that of a void (this state is called as “OFF”) or a solid (“ON”). We call this algorithm as an “ON/OFF method”. To determine the material distribution by judging ON or OFF, the sensitivity dW/dp (p : design variable (conductivity or reluctivity), W : objective function) of each cell is evaluated.

The adjoint variable method[2] is applied for calculating the sensitivity analysis method. If the objective function W is the function of A' (time differential of vector potential $\partial A'/\partial t$) and design variable p , the derivative of W with respect to p is given as:

$$\frac{dW}{dp} = \left. \frac{\partial W}{\partial p} \right|_{A'=const} + \left. \frac{\partial W}{\partial A'} \right|_{p=const} \frac{\partial A'}{\partial p} \quad (1)$$

III. OPTIMIZATION OF LAMINATED YOKE OF BILLET HEATER

Fig. 1 shows the analyzed model of the billet heater. This is a 1/8 model. Although the original billet heater has four yokes around the coil, it is assumed that there are only two yokes in order to reduce the number of elements. Material constants are shown in Table I. Since the yoke is laminated, the conductivity in the x direction of the yoke is set to zero. The relative magnetic permeability was set as 1000, and the linear analysis is carried out. The current of the coil is set as 50000AT (700Hz). The conductivity of the billet at 1200 °C is used. The copper shield was installed on both sides of yoke in order to reduce the perpendicular flux which invades into a side surface of the yoke.

The objective function is defined as follows in order to maximize the eddy current loss in the billet (this is equal to minimize W_1), and minimize the eddy current loss W_2 in the laminated yoke:

6. Optimization

Fig. 1. Model of billet heater.

Fig. 2. Optimal shape of laminated yoke.

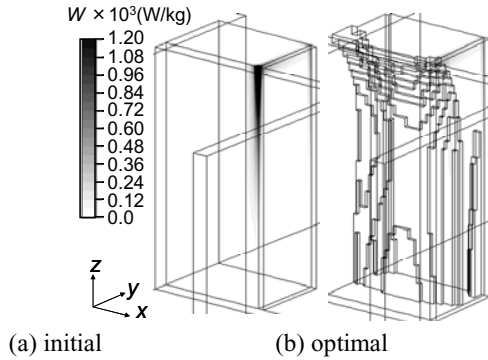

Fig. 3. Eddy current loss in yoke.

$$W = k_1 \cdot W_1 + k_2 \cdot W_2 \quad (17)$$

$$W_1 = \sum_{ie} V^{(ie)} \left\{ \frac{(J_{ex}^{(ie)})^2}{\sigma_x} + \frac{(J_{ey}^{(ie)})^2}{\sigma_y} + \frac{(J_{ez}^{(ie)})^2}{\sigma_z} \right\}^{-1} \quad (18)$$

$$W_2 = \sum_{ie} V^{(ie)} \left\{ \frac{(J_{ey}^{(ie)})^2}{\sigma_y} + \frac{(J_{ez}^{(ie)})^2}{\sigma_z} \right\} \quad (19)$$

$$k_1 = 1, \quad k_2 = \frac{W_1}{W_2} \quad (20)$$

where, ie is the element number in the target region. The target region is the billet in the case of W_1 , and is the yoke in

the case of W_2 . J_{ex} , J_{ey} and J_{ez} are the x -, y - and z -components of the eddy current vector, σ_x , σ_y and σ_z are the conductivities, V is the volume of the element. k_1 and k_2 are the weighting factors. They were calculated using the previous values of W_1 and W_2 in order to arrange the amplitudes of first and second terms of Eq. (5) as nearly the same values. In the optimal design, the conductivity σ is chosen as the design variable p .

The optimized shape using the ON/OFF method is shown in Fig. 2. The yoke became thin toward the center. The flux flows into the wide entrance of yoke. Fig. shows the eddy current loss distribution in the yoke. The concentration of the eddy current loss in the yoke edge is reduced by optimizing the yoke. Since the volume of a yoke is decreased compared with the initial shape, the eddy current loss in the yoke is also decreased. Table I shows the eddy current losses at each part. W_{eyoke} , $W_{eshield}$ and $W_{ebillet}$ are the eddy current loss in the yoke, shield and billet in the 1/8 region. W_{eyoke} and $W_{eshield}$ are reduced (-52% and -15%) by the optimization, but $W_{ebillet}$ is almost the same (-2.5%).

TABLE I
EDDY CURRENT LOSSES (1/8 REGION)

	initial	optimal
W_{eyoke} (W)	11.9	5.7
$W_{eshield}$ (W)	165.7	141.1
$W_{ebillet}$ (W)	25797	25146

IV. CONCLUSION

The ON/OFF method for topology optimization is extended to the linear eddy current problem by combining the ON/OFF method with the step-by-step method. The newly developed ON/OFF method is applied to the optimization of the model of actual billet heater. As a result of optimization of the laminated yoke of billet heater, the local overheating of the yoke was decreased without reducing the heating efficiency. The speed up of calculation, the nonlinear analysis etc. are the future subjects.

Abstract—Recently, there are several attempts to extend the Differential Evolution (DE) to solve multiobjective problems. In this paper, an enhanced multiobjective version with external archive to store nondominated solutions of the DE method (EMODE) is proposed. The validity of the given algorithm is tested to solve the TEAM workshop benchmark problem 25. Optimization results on TEAM problem 25 indicate that EMODE outperforms the classical multiobjective differential evolution algorithm in the global search ability.

Index Terms—multiobjective optimization, differential evolution, electromagnetic optimization.

I. INTRODUCTION

Many electromagnetic devices optimization problems can be treated as optimizations with multiple objectives and sometimes more than one decision-maker is involved in selecting an appropriate solution.

Among various evolutionary algorithms, such as evolutionary programming, evolution strategy, and genetic algorithms, differential evolution (DE), which characterized by the different mutation operator and competition strategy from the other classical evolutionary algorithms, has shown great promise in many numerical benchmark problems [1]-[2].

To improve the global optimization property of DE, a novel enhanced multiobjective DE (EMODE) algorithm, which uses an updating strategy, is proposed in this paper. In this work, EMODE was evaluated for the TEAM workshop benchmark problem 25. The proposed EMODE is compared to the classical MODE proposed in [2] and outperform it, thus demonstrating its potential.

II. MULTIOBJECTIVE DIFFERENTIAL EVOLUTION

DE is a stochastic population-based optimization approach [1-2] for global optimization over continuous search spaces. It initializes the population randomly by uniform distribution over search space and maintains a population with NP individuals in each generation. A new vector is generated, by adding a weighted difference between two random vectors, to a third vector. This operation is called mutation. The mutated vector is then mixed with the components of another predetermined vector and this operation is called crossover. If the generated vector by crossover (the offspring) has a lower objective function value than the predetermined vector, than it replaces the vector, and this operation is called selection. The above evolution process is repeated until some termination conditions are met.

Recent studies have shown that in general, the most effective DE strategies are DE/rand/1/bin and DE/best/2/bin. The variant implemented in this paper was the DE/rand/1/bin. The following is the outline of the MODE inspired in the algorithm proposed on [1].

- i) Initialize a population of individuals (solution vectors) $x(t)$, $i=1, \dots, n$, with random values generated according to a uniform probability distribution in the n dimensional problem space. Set the generation counter, $t=0$;
- ii) Evaluate the population of individuals (potential solutions of optimization problem) using an objective function, F .
- iii) Generate a new population using mutation operation where each new vector (child) is created, according to

$$z_i(t+1) = x_{i,r_1}(t) + f_m \cdot [x_{i,r_2}(t) - x_{i,r_3}(t)] \quad (1)$$

- iv) Following the mutation operation, crossover is applied in the population. For each mutant vector, $z_i(t+1)$, an index $rnbr(i) \in \{1, 2, \dots, NP\}$, where NP is the population size, is randomly chosen using uniform distribution, and a trial vector, $u_i(t+1) = [u_{i_1}(t+1), u_{i_2}(t+1), \dots, u_{i_n}(t+1)]^T$, is created:

$$u_{i_j}(t+1) = \begin{cases} z_{i_j}(t+1), & \text{if } (randb(j) \leq CR) \text{ or } (j = rnbr(i)), \\ x_{i_j}(t), & \text{if } (randb(j) > CR) \text{ or } (j \neq rnbr(i)) \end{cases} \quad (2)$$

To decide whether or not the vector $u_i(t+1)$ should be a member of the population comprising the next generation, it is compared to the corresponding vector $x_i(t)$. In this context, if F is the objective function under minimization, then

$$x_i(t+1) = \begin{cases} u_i(t+1), & \text{if } F(x_i(t+1)) < F(x_i(t)), \\ x_i(t), & \text{otherwise} \end{cases} \quad (3)$$

- v) Select a new parent solution between parent and child vectors based on nondominated solution criterion. More details are presented in [1];
- vi) Update the external archive. If the archive size A_s exceeds the maximum size, it selected the less crowded solutions based on crowding distance to keep the archive size at N_{max} .
- vii) Increment the generation count, $t = t + 1$;
- viii) Loop to step (iii) until a stopping criterion is met, usually a maximum number of iterations (generations), t_{max} .

In the above equations, $i=1, 2, \dots, NP$ is the individual's index of population; $j=1, 2, \dots, n$ is the parameter index; t is the time (generation); $x_i(t) = [x_{i_1}(t), x_{i_2}(t), \dots, x_{i_n}(t)]^T$ stands for the position of the i -th individual of population of NP real-

A Populational Particle Collision Algorithm Applied to Electromagnetic Optimization

Abstract— Recently, a new class of stochastic optimization algorithms called Particle Collision Algorithm (PCA) has been proposed. PCA is loosely inspired by the physics of particle interactions in a nuclear reactor, particularly scattering and absorption. This paper introduces the basics of PCA, proposes a modified version of the PCA approach and tests its efficiency on Loney’s solenoid benchmark problem.

Index Terms— Loney’s solenoid design, electromagnetic optimization, particle collision algorithm.

I. INTRODUCTION

Electromagnetic optimization problems often exhibit multiple optima in the feasible domain and therefore stochastic optimization methods are commonly used, mainly due to their ability to avoid being trapped in local optima of the objective function. A typical example of the rough objective function surface typical of many electromagnetic problems is shown by Loney’s solenoid problem [1]-[6].

This paper proposes a modified version of a recently proposed stochastic optimization algorithm called Particle Collision Algorithm (PCA) [7]-[11] to solve Loney’s solenoid problem.

PCA is loosely inspired by the physics of the interaction of nuclear particles inside nuclear reactors, mainly scattering, in which an incident particle is scattered by a target nucleus, and absorption, in which the incident particle absorbed by the target nucleus.

II. FUNDAMENTALS OF PCA

PCA is a Metropolis-based algorithm that was introduced as an alternative to the classical Simulated Annealing (SA) algorithm. In PCA a “particle” that reaches a promising area of the search space is “absorbed”, while one that hits a low-fitness region is “scattered”. Like SA, also PCA is a Metropolis algorithm, i.e. a solution worse than the current best one may be accepted with a certain probability (Metropolis criterion) which decreases during iteration.

The starting point of the algorithm to be presented in this paper is called populational PCA or PPCA [10]-[11], and its pseudo code is shown in Figure 1. In contrast with the basic PCA in which only one solution evolves in time, in PPCA a population of candidate solutions evolve in parallel.

```

For  $i = 1$  to  $Pop\_Size$ 
  - Generate an initial solution  $Old\_Config[i]$ 

For  $n = 0$  to  $N_{iter}$ 
  For  $i = 1$  to  $Pop\_Size$ 
    - Call the Perturbation function
    - If  $F(New\_Config[i]) < F(Old\_Config[i])$ 
       $Old\_Config[i] := New\_Config[i]$ 
      Call the Exploration function
    Else
      Call the Scattering function
  End For
  - Call  $New\_Pop$  function
End For

Perturbation function
- For  $i = 0$  to (Dimension-1)
   $Upper := Superior\ Limit\ [i]$ 
   $Lower := Inferior\ Limit\ [i]$ 
   $Rnd = Random(0,1)$ 
   $New\_Conf[i] := Old\_Conf[i] + ((Upper - Old\_Conf[i])*Rnd) - ((Old\_Conf[i] - Lower)*(1-Rnd))$  (1)
  If  $(New\_Config[i] > Upper\ or\ New\_Config[i] < Lower)$ 
     $New\_Config[i] := Upper\ or\ Lower$ 

Exploration function
For  $n = 0$  to # of iterations
  - Generate a small stochastic perturbation of the solution
  - If  $F(New\_Config[i]) < F(Old\_Config[i])$ 
     $Old\_Config := New\_Config$ 

Scattering function
-  $p_{scattering} = F(New\_Config[i]) / best\ F$ 
- If  $p_{scattering} < random(0, 1)$ 
   $Old\_Config[i] := random\ solution$ 
Else
  Call Exploration function

New_Pop function
- Cross two random individuals from population
- Rank parents and siblings in descending fitness order
- Pick the first  $Pop\_Size$  ranked individuals
  
```

Figure 1. Pseudo-code of the classical populational PCA algorithm.

cm and $l=1.0871$ cm with $F(s,l)=2.03920 \cdot 10^{-8}$.

A. Modified populational PCA (MPPCA) approach

In PPCA the mechanism through which new population members are generated is embodied in the Perturbation function. Here we propose a Modified PPCA (MPPCA) in which the uniform distribution in range $[0,1]$ is substituted by a truncated Cauchy distribution. Furthermore, the Perturbation function is modified by substituting Eq. 1 of Fig. 1 by:

$$\begin{aligned} \text{New_Config}[i] := & \text{Old_Config}[i] + ((\text{Upper} - \\ & \text{Old_Config}[i]) * \text{Rand} * U) - \\ & ((\text{Old_Config}[i] - \text{Lower}) * (1 - \text{Rand}) * P), \end{aligned} \quad (2)$$

where U and P are variables with value 0 or 1 with 50% of probability for each.

III. LONEY'S SOLENOID DESIGN

Appropriately stated, Loney's solenoid design problem consists in determining the position and size of two correcting coils in order to generate a uniform magnetic flux density B within a given interval on the axis of a main solenoid.

The upper half plane of the axial cross-section of the system is presented in Figure 1. The interval of the axis, where the magnetic flux density B_0 must be as uniform as possible is $(-z_0, z_0)$. The current density J_0 in the coils is assumed to be constant [6]. The separation s and the length l of the correcting coils are to be determined while all other dimensions are given. Both s and l are bounded in $[0,0.2]$ according to the problem definition and optimized by MPPCA.

Figure 1. Axial cross-section of Loney's solenoid (upper half-plane).

In particular, three different basins of attraction of local minima can be recognized in the domain of F with values of $F > 4 \cdot 10^{-8}$ (high level region), $3 \cdot 10^{-8} < F < 4 \cdot 10^{-8}$ (low level region), and $F < 3 \cdot 10^{-8}$ (very low level region - global minimum region) [4].

In this work, the parameters of PPCA and MPPCA are set as follows: the population size is 30 and the stopping criterion was 200 iterations, in other words, both PCA approaches performed 6,000 objective function evaluations in each run.

In order to eliminate stochastic discrepancy, in each case study 30 independent runs were made for each of the optimization methods.

The classical PPCA found the best design with $s=13.5994$ cm and $l=4.0420$ cm with $F(s,l)=2.4338 \cdot 10^{-8}$, and the proposed MPPCA obtained the best design in 30 runs with $s=10.7332$

TABLE I

SIMULATION RESULTS OF F IN 30 RUNS

Optimization Method	$F(s, l) \cdot 10^{-8}$			
	Maximum (Worst)	Mean	Minimum (Best)	Std. Dev.
Populational PCA	21.5249	8.1522	3.4251	5.1175
MPPCA	13.4685	5.8887	2.3920	2.5359

IV. CONCLUSIONS

The effectiveness of MCCPA with respect to PCA has been shown on Loney's solenoid design problem. In the extended paper the algorithm will be commented in greater depth, further modifications to it will be analyzed and the algorithm will be compared with other stochastic optimization methods.

Abstract— The propagation characteristics of the fundamental mode of annular ring microstrip antennas (ARMSA) on double-layered ferrite substrates are discussed. A full-wave analysis is formulated based on the spectral domain technique in conjunction with Galerkin approach. It takes into account the effects of the applied dc magnetic bias field in the behavior of these structures. Numerical results of resonant frequencies and radiation patterns are found as functions of some geometrical and ferrite parameters.

I. INTRODUCTION

The ever increasing demand on wireless communication systems requires the development of lightweight, low-profile, low-cost and flush-mounted antennas. Microstrip patch antennas offer these useful features and are ideally suited for applications requiring compactness and integration with monolithic microwave integrated circuits (MMICs) [1]-[4].

One of the advantages of using ARMSA is that it offers smaller size and larger bandwidth when compared to other conventional microstrip antennas, for a given frequency. The small size is an important requirement for portable communication equipment, such as global positioning satellite (GPS) receivers and several mobile communication applications. If a magnetized ferrite is used as a substrate instead of an isotropic dielectric, an additional degree of freedom to the design of the antenna is provided due to the permeability characteristic of the ferrite. Also, the high permittivity of the ferrimagnetic material leads to a reduction in the antenna dimensions allowing miniaturization.

In most cases, the analysis of the ARMSA on ferrite has been performed using approximate methods [1]. However, accurate results can be obtained adopting a full-wave approach in conjunction with the method of moments [4].

This paper presents an analysis of ARMSA printed on a double-layered substrate that is constituted by an isotropic and a ferrite layers. Suspended antennas and antennas on a single isotropic layer can be analyzed as particular cases. The analysis uses the full-wave formulation by means of the Hertz vector potentials method in the Hankel transform domain. The dyadic Green function and Galerkin's method are used to determine the resonant frequencies and radiation patterns.

II. THEORY

A cross section view of the ARMSA is shown in Fig. 1. Region 3 has thickness d_3 and is filled up with a dielectric, whose permittivity is ϵ_3 . The ferrite layer (region 2) has thickness d_2 , scalar permittivity ϵ_2 , and tensor permeability $\vec{\mu}$. For a ferrite magnetized in the z direction, $\vec{\mu}$ is given by [2]:

$$\vec{\mu} = \begin{bmatrix} \mu & 0 & j\kappa \\ 0 & \mu & 0 \\ -j\kappa & 0 & \mu_0 \end{bmatrix} \quad (1)$$

where the components μ and k are dependent on the operating frequency ω , the saturation magnetization of the ferrite $4\pi M_s$, and the applied dc magnetic-field H_0 . The region 1 has permittivity ϵ_0 and permeability μ_0 denoting the free-space.

Fig. 1. Annular ring microstrip patch antenna on ferrite substrate.

The electric and magnetic Hertz potential vectors, $(\vec{\pi}_e)$ and $(\vec{\pi}_h)$, respectively, are defined along the z -direction, according to the orientation of the applied magnetic bias field, and can be written in terms of cylindrical functions [3].

In the spectral domain, the electric and magnetic fields are expressed in terms of the $E_{\pm} = E_{\rho} \pm jE_{\phi}$, as follows:

$$E_{\pm i} = e^{jn\phi} \int_0^{\infty} \alpha \left[\omega \mu_0 \mu_{ri} \tilde{\pi}_{hi} \mp \frac{1}{\mu_{ri}} \frac{\partial^2 \tilde{\pi}_{ei}}{\partial z^2} \right] J_{n\pm 1}(\alpha \rho) \alpha d\alpha \quad (4)$$

Similarly, for the magnetic field, we can write that:

$$H_{\pm i} = e^{jn\phi} \int_0^{\infty} -\alpha \left[\omega \epsilon_0 \epsilon_{ri} \frac{1}{\mu_{ri}} \tilde{\pi}_{ei} \pm \omega \epsilon_0 \epsilon_{ri} \frac{k_{ri}}{\mu_{ri}^2} \tilde{\pi}_{hi} \pm \frac{\partial^2 \tilde{\pi}_{hi}}{\partial z^2} \right] J_{n\pm 1}(\alpha \rho) \alpha d\alpha \quad (5)$$

On the conducting patch plane, $z = d_{23}$ (Fig. 1), by imposing the boundary conditions, the transformed electric field components are written as functions of the transformed

current density components allowing the determination of the impedance matrix, in the Hankel domain, as follows [3]-[4]:

$$\begin{bmatrix} \tilde{E}_x \\ \tilde{E}_z \end{bmatrix} = \begin{bmatrix} \tilde{Z}_{11} & \tilde{Z}_{12} \\ \tilde{Z}_{21} & \tilde{Z}_{22} \end{bmatrix} \begin{bmatrix} \tilde{J}_x \\ \tilde{J}_z \end{bmatrix}, \quad (6)$$

Parseval's theorem and Galerkin's method are used to obtain the determinantal equation that enables the numerical calculation of the resonant frequencies.

III. RESULTS AND DISCUSSIONS

Numerical results are presented for the ARMSA depicted in Fig. 1. The ring patch has inner radius r_1 and outer radius r_2 . The dc magnetic bias field H_0 is applied along z direction.

The curves obtained for ARMSA printed on a double-layered substrate are shown in Fig. 2 and Fig. 3. It is observed in Fig. 2 that the resonant frequency increases with the dielectric thickness (d_3). The influence of the magnetic-bias field H_0 is also verified. Radiation pattern for E_θ field is shown in Fig. 3. The patch is supported by a double layered substrate. The dc magnetic bias field is $H_0 = 1500$ Oe. The isotropic layer has permittivity $\epsilon_{r3} = 2.32$. It is considered three different values for d_3 thickness. It is observed that the directivity increases with the isotropic layer thickness.

Fig. 4 depicts the influence of the air gap thickness on the resonant frequency of ARMSA, against H_0 . The air gap is varied from 0.7 mm to 2 mm. It is found that the resonant frequency of the suspended ARMSA can be tuned by adjusting the air gap width. Observe also the effect of a varying dc bias field on the resonant frequency and a magnetic tuning possibility.

Fig. 2. Resonant frequency as a function of the dielectric thickness.

Fig. 3. Radiation pattern (E_θ) as a function of three different values of the dielectric ($\epsilon_{r3} = 2.32$) thickness: --- $d_3 = 0.20$ mm, -- $d_3 = 0.45$ mm, and — $d_3 = 3$ mm. Ferrite substrate: $H_0 = 1500$ Oe.

Fig. 4. Resonant frequency as a function of the air gap thickness.

Fig. 5 shows the behavior of the resonant frequency as a function of the ratio r_2/r_1 ($r_1 = 0.35$ cm), for different values of H_0 . Note that the resonant frequency of the antenna shifts to a higher frequency and the results approach those for the isotropic case as the dc magnetic field strength increases. For a particular value of H_0 , the resonant frequency increases when the annular ring dimensions are decreased.

Fig. 5. Resonant frequency as a function of the ratio r_2/r_1 .

IV. CONCLUSION

This paper has described an analysis of the behavior of the ARMSA supported by ferrite material. Ferrite-resonator antennas exhibit greater agility in controlling their radiation characteristics by the application of a dc magnetic bias field.

tmatsuo@kuee.kyoto-u.ac.jp

Abstract — The CFL conditions for finite integration methods using parallelogram and parallelepiped elements are derived. Piecewise uniform elements allow time-step that is $\sqrt{3}$ times as large as that for linearly interpolated elements.

I. INTRODUCTION

Finite integration (FI) methods [1]-[4] enable the use of nonorthogonal grids in electromagnetic-wave analysis. Several methods to construct permittivity and reluctivity matrices have been proposed [3]-[5] because they greatly affect the efficiency and accuracy of FI methods. The efficiency depends on the computational cost of permittivity matrix inversion and on the Courant-Friedrichs-Lewy (CFL) condition, which gives the maximum time-step for stable computation. Previous works have derived the CFL conditions for nonorthogonal grids [6]-[9]. However, the CFL criterions are not explicitly deduced from the permittivity and reluctivity matrices. This article derives CFL conditions for FI methods using parallelogram and parallelepiped grids.

II. CFL CONDITION

The time-stepping of the FI method is written as

$$\mathbf{e}^{k+1} = \mathbf{e}^k + \Delta t \boldsymbol{\varepsilon}^{-1} \mathbf{C}^T \mathbf{v} \mathbf{b}^{k+1/2}, \quad \mathbf{b}^{k+3/2} = \mathbf{b}^{k+1/2} - \Delta t \mathbf{C} \mathbf{e}^{k+1} \quad (1)$$

where \mathbf{e} denotes the vector of line integrals of the electric field along the edges of primal grid, \mathbf{b} is the vector of magnetic fluxes across the faces of primal grid, \mathbf{C} is the curl matrix for primal grid, $\boldsymbol{\varepsilon}$ is the (global) permittivity matrix, and \mathbf{v} is the (global) reluctivity matrix.

The CFL condition is given as [8]

$$\Delta t \leq 2 / \gamma_{\max}^{1/2} \quad (2)$$

where γ_{\max} is the maximum eigenvalue of $\boldsymbol{\Gamma}$ given by

$$\boldsymbol{\Gamma} = \mathbf{C} \boldsymbol{\varepsilon}^{-1} \mathbf{C}^T \mathbf{v}. \quad (3)$$

III. CFL CONDITIONS FOR PARALLELOGRAM ELEMENTS

Fig. 1(a) shows a parallelogram element used for FI analysis of TE wave, where \mathbf{l}_1 and \mathbf{l}_2 are two edges of primal grid. (Whitney-like) Linearly interpolated basis functions for parallelogram edge element are given as

$$\begin{aligned} \mathbf{w}_1(\mathbf{r}) &= (1-t)\mathbf{f}_1/S, & \mathbf{w}_2(\mathbf{r}) &= (1-s)\mathbf{f}_2/S, \\ \mathbf{w}_3(\mathbf{r}) &= t\mathbf{f}_1/S, & \mathbf{w}_4(\mathbf{r}) &= s\mathbf{f}_2/S \end{aligned} \quad (4)$$

where $\mathbf{r} = s\mathbf{l}_1 + t\mathbf{l}_2$, $\mathbf{f}_1 = \mathbf{l}_2 \times \mathbf{e}_z$, $\mathbf{f}_2 = \mathbf{e}_z \times \mathbf{l}_1$, $S = |\mathbf{l}_1 \times \mathbf{l}_2|$, and \mathbf{e}_z is the unit vector along the z -direction. Piecewise uniform basis functions [4] are given as

$$\begin{aligned} \mathbf{w}_1(\mathbf{r}) &= U(1/2-t)\mathbf{f}_1/S, & \mathbf{w}_2(\mathbf{r}) &= U(1/2-s)\mathbf{f}_2/S, \\ \mathbf{w}_3(\mathbf{r}) &= U(t-1/2)\mathbf{f}_1/S, & \mathbf{w}_4(\mathbf{r}) &= U(s-1/2)\mathbf{f}_2/S \end{aligned} \quad (5)$$

Fig. 1. Parallelogram element

Fig. 2. Eigenmodes corresponding to $\boldsymbol{\varepsilon}$: (a) \mathbf{e}_1 , and (b) \mathbf{e}_2

where $U(x) = 0$ ($x < 0$), $1/2$ ($x = 0$), and 1 ($x > 0$).

Local permittivity matrix $\boldsymbol{\varepsilon}_L = \{\varepsilon_{Lij}\}$, $\varepsilon_{Lij} = \varepsilon \int \mathbf{w}_i \cdot \mathbf{w}_j dS$ for the linearly interpolated basis functions is written as

$$\boldsymbol{\varepsilon}_L = \frac{\varepsilon S}{12} \begin{pmatrix} 4\mathbf{w}_1 \cdot \mathbf{w}_1 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 2\mathbf{w}_1 \cdot \mathbf{w}_1 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 \\ 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 4\mathbf{w}_2 \cdot \mathbf{w}_2 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 2\mathbf{w}_2 \cdot \mathbf{w}_2 \\ 2\mathbf{w}_1 \cdot \mathbf{w}_1 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 4\mathbf{w}_1 \cdot \mathbf{w}_1 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 \\ 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 2\mathbf{w}_2 \cdot \mathbf{w}_2 & 3\mathbf{w}_1 \cdot \mathbf{w}_2 & 4\mathbf{w}_2 \cdot \mathbf{w}_2 \end{pmatrix}. \quad (6)$$

It has eigenvalues $\lambda_1 = \varepsilon S \mathbf{w}_1 \cdot \mathbf{w}_1 / 6 = \varepsilon l_2^2 / 6S$ and $\lambda_2 = \varepsilon S \mathbf{w}_2 \cdot \mathbf{w}_2 / 6 = \varepsilon l_1^2 / 6S$ for eigenvectors $\mathbf{e}_{L1} = (1, 0, -1, 0)$ and $\mathbf{e}_{L2} = (0, 1, 0, -1)$, respectively. The piecewise uniform basis functions give $\boldsymbol{\varepsilon}_L$ eigenvalues $3\lambda_1$ and $3\lambda_2$ for eigenvectors \mathbf{e}_{L1} and \mathbf{e}_{L2} .

The global permittivity matrix $\boldsymbol{\varepsilon}$ is constructed by assembling $\boldsymbol{\varepsilon}_L$. For simplicity, a regular parallelogram grid as depicted in Fig. 1(b) is used with periodic boundary conditions for eigenvalue analysis. The permittivity ε and permeability μ are assumed to be uniform. The linearly interpolated basis functions give $\boldsymbol{\varepsilon}$ eigenvalues $2\lambda_1$ and $2\lambda_2$ for eigenvectors $\mathbf{e}_1 = (1, 0, -1, 0, \dots)^T$ and $\mathbf{e}_2 = (0, 1, 0, -1, \dots)^T$, respectively (see Fig. 2) whereas the piecewise uniform basis functions give $\boldsymbol{\varepsilon}$ eigenvalues $6\lambda_1$ and $6\lambda_2$.

On the other hand, the reluctivity matrix \mathbf{v} is given as

$$\mathbf{v} = 1/\mu S \mathbf{1} \quad (7)$$

where $\mathbf{1}$ is the unit matrix.

According to the eigenvalues and eigenvectors above, matrix $\boldsymbol{\Gamma}$ has the maximum eigenvalue $\gamma_{\max} = 12c^2 (1/l_1^2 + 1/l_2^2)$ or $4c^2 (1/l_1^2 + 1/l_2^2)$ for the linearly interpolated basis functions or the piecewise uniform basis functions, respectively, which has an eigenvector $(1, -1, \dots)^T$. Consequently the CFL conditions is written as

$$\Delta t \leq \alpha / c (1/l_1^2 + 1/l_2^2)^{1/2} \quad (8)$$

where α is $1/\sqrt{3}$ for the linearly interpolated functions and is 1 for the piecewise uniform functions.

IV. CFL CONDITIONS FOR PARALLELEPIPED ELEMENTS

Fig. 3(a) shows a parallelepiped element used for FI analysis, where \mathbf{l}_1 , \mathbf{l}_2 , and \mathbf{l}_3 are three edges of primal grid. Linearly interpolated basis functions for parallelepiped edge element are given at position $\mathbf{r} = s\mathbf{l}_1 + t\mathbf{l}_2 + u\mathbf{l}_3$ as

$$\begin{aligned} \mathbf{w}_1 &= (1-t)(1-u)\mathbf{f}_1/V, & \mathbf{w}_2 &= (1-u)(1-s)\mathbf{f}_2/V, & \mathbf{w}_3 &= (1-s)(1-t)\mathbf{f}_3/V, \\ \mathbf{w}_4 &= t(1-u)\mathbf{f}_1/V, & \mathbf{w}_5 &= u(1-s)\mathbf{f}_2/V, & \mathbf{w}_6 &= s(1-t)\mathbf{f}_3/V, \\ \mathbf{w}_7 &= (1-t)u\mathbf{f}_1/V, & \mathbf{w}_8 &= (1-u)s\mathbf{f}_2/V, & \mathbf{w}_9 &= (1-s)t\mathbf{f}_3/V, \\ \mathbf{w}_{10} &= tu\mathbf{f}_1/V, & \mathbf{w}_{11} &= us\mathbf{f}_2/V, & \mathbf{w}_{12} &= st\mathbf{f}_3/V \end{aligned} \quad (9)$$

where $\mathbf{f}_1 = \mathbf{l}_2 \times \mathbf{l}_3$, $\mathbf{f}_2 = \mathbf{l}_3 \times \mathbf{l}_1$, $\mathbf{f}_3 = \mathbf{l}_1 \times \mathbf{l}_2$, and $V = (\mathbf{l}_1 \times \mathbf{l}_2) \cdot \mathbf{l}_3$. Piecewise uniform basis functions [4] are similarly defined.

The local permittivity matrix $\boldsymbol{\varepsilon}_L$ is given by $\varepsilon_{L,ij} = \int \mathbf{w}_i \cdot \mathbf{w}_j dV$. It has eigenvalues $\lambda_1 = \varepsilon S_{23}^2/36V$, $\lambda_2 = \varepsilon S_{31}^2/36V$, and $\lambda_3 = \varepsilon S_{12}^2/36V$ corresponding to eigenvectors $(1, 0, 0, -1, 0, 0, -1, 0, 0, 1, 0, 0)^T$, $(0, 1, 0, 0, -1, 0, 0, -1, 0, 0, 1, 0)^T$, and $(0, 0, 1, 0, 0, -1, 0, 0, -1, 0, 0, 1)^T$, respectively, for the linearly interpolated basis functions, where $S_{ij} = |\mathbf{l}_i \times \mathbf{l}_j|$. The piecewise uniform basis functions give $\boldsymbol{\varepsilon}_L$ eigenvalues $9\lambda_1$, $9\lambda_2$, and $9\lambda_3$.

The global permittivity matrix $\boldsymbol{\varepsilon}$ is constructed on regular parallelepiped grid with periodic boundary conditions as in Fig. 3(b). Corresponding to $\boldsymbol{\varepsilon}_L$, the matrix $\boldsymbol{\varepsilon}$ has eigenvalues $4\lambda_1$, $4\lambda_2$, and $4\lambda_3$ with eigenvectors $(1, 0, 0, -1, 0, 0, \dots)^T$, $(0, 1, 0, 0, -1, 0, \dots)^T$, and $(0, 0, 1, 0, 0, -1, \dots)^T$, respectively, for the linearly interpolated basis functions. The piecewise uniform basis functions give $\boldsymbol{\varepsilon}$ eigenvalues, $36\lambda_1$, $36\lambda_2$, and $36\lambda_3$.

Linearly interpolated basis functions for parallelepiped face element are given as

$$\begin{aligned} \mathbf{w}_1^f &= (1-s)\mathbf{g}_1/V^2, & \mathbf{w}_2^f &= (1-t)\mathbf{g}_2/V^2, & \mathbf{w}_3^f &= (1-u)\mathbf{g}_3/V^2, \\ \mathbf{w}_4^f &= s\mathbf{g}_1/V^2, & \mathbf{w}_5^f &= t\mathbf{g}_2/V^2, & \mathbf{w}_6^f &= u\mathbf{g}_3/V^2 \end{aligned} \quad (10)$$

where $\mathbf{g}_1 = \mathbf{f}_2 \times \mathbf{f}_3$, $\mathbf{g}_2 = \mathbf{f}_3 \times \mathbf{f}_1$, $\mathbf{g}_3 = \mathbf{f}_1 \times \mathbf{f}_2$. The corresponding local reluctivity matrix \mathbf{v}_L is given by $v_{L,ij} = 1/\mu \int \mathbf{w}_i^f \cdot \mathbf{w}_j^f dV$ as

$$\mathbf{v}_L = \frac{V}{12\mu} \begin{pmatrix} 4\mathbf{w}_1^f \cdot \mathbf{w}_1^f & 3\mathbf{w}_1^f \cdot \mathbf{w}_2^f & 3\mathbf{w}_1^f \cdot \mathbf{w}_3^f & 2\mathbf{w}_1^f \cdot \mathbf{w}_4^f & 3\mathbf{w}_1^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_1^f \cdot \mathbf{w}_6^f \\ 3\mathbf{w}_1^f \cdot \mathbf{w}_2^f & 4\mathbf{w}_2^f \cdot \mathbf{w}_2^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_3^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_4^f & 2\mathbf{w}_2^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_6^f \\ 3\mathbf{w}_1^f \cdot \mathbf{w}_3^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_3^f & 4\mathbf{w}_3^f \cdot \mathbf{w}_3^f & 3\mathbf{w}_3^f \cdot \mathbf{w}_4^f & 3\mathbf{w}_3^f \cdot \mathbf{w}_5^f & 2\mathbf{w}_3^f \cdot \mathbf{w}_6^f \\ 2\mathbf{w}_1^f \cdot \mathbf{w}_4^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_4^f & 3\mathbf{w}_3^f \cdot \mathbf{w}_4^f & 4\mathbf{w}_4^f \cdot \mathbf{w}_4^f & 3\mathbf{w}_4^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_4^f \cdot \mathbf{w}_6^f \\ 3\mathbf{w}_1^f \cdot \mathbf{w}_5^f & 2\mathbf{w}_2^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_3^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_4^f \cdot \mathbf{w}_5^f & 4\mathbf{w}_5^f \cdot \mathbf{w}_5^f & 3\mathbf{w}_5^f \cdot \mathbf{w}_6^f \\ 3\mathbf{w}_1^f \cdot \mathbf{w}_6^f & 3\mathbf{w}_2^f \cdot \mathbf{w}_6^f & 2\mathbf{w}_3^f \cdot \mathbf{w}_6^f & 3\mathbf{w}_4^f \cdot \mathbf{w}_6^f & 3\mathbf{w}_5^f \cdot \mathbf{w}_6^f & 4\mathbf{w}_6^f \cdot \mathbf{w}_6^f \end{pmatrix} \quad (11)$$

It has eigenvalues $\kappa_1 = l_1^2/6\mu V$, $\kappa_2 = l_2^2/6\mu V$, and $\kappa_3 = l_3^2/6\mu V$ with eigenvectors $(1, 0, 0, -1, 0, 0)^T$, $(0, 1, 0, 0, -1, 0)^T$, and $(0, 0, 1, 0, 0, -1)^T$, respectively, for the linearly interpolated basis functions (see Fig. 4). The piecewise uniform basis functions give \mathbf{v}_L eigenvalues $3\kappa_1$, $3\kappa_2$, and $3\kappa_3$.

Corresponding to \mathbf{v}_L , the global permittivity matrix \mathbf{v} has eigenvalues $2\kappa_1$, $2\kappa_2$, and $2\kappa_3$ with eigenvectors $\mathbf{e}_1^f = (1, 0, 0, -1, 0, 0, \dots)^T$, $\mathbf{e}_2^f = (0, 1, 0, 0, -1, 0, \dots)^T$, and $\mathbf{e}_3^f = (0, 0, 1, 0, 0, -1, \dots)^T$, respectively, for the linearly interpolated basis functions. The piecewise uniform basis functions give \mathbf{v} eigenvalues $6\kappa_1$, $6\kappa_2$, and $6\kappa_3$.

According to the eigenvalues and eigenvectors above, the maximum eigenvalue γ_{\max} of $\boldsymbol{\Gamma}$ is given by.

$$\gamma_{\max} = p_1 + (p_1^2 - 4p_0)^{1/2} \quad (12)$$

$$\begin{aligned} p_1 &= \{ (\kappa_2 + \kappa_3)/\lambda_1 + (\kappa_3 + \kappa_1)/\lambda_2 + (\kappa_1 + \kappa_2)/\lambda_3 \} / 3\alpha^2, \\ p_0 &= (1/\lambda_1\lambda_2 + 1/\lambda_2\lambda_3 + 1/\lambda_3\lambda_1)(\kappa_2\kappa_3 + \kappa_3\kappa_1 + \kappa_1\kappa_2) / 9\alpha^4 \end{aligned} \quad (13)$$

The coefficient α is $1/\sqrt{3}$ for the linearly interpolated basis functions and is 1 for the piecewise uniform basis functions. The corresponding eigenvector is a linear combination of \mathbf{e}_1^f , \mathbf{e}_2^f , and \mathbf{e}_3^f .

When $S_{23} = l_2 l_3$ and $S_{31} = l_3 l_1$, the CFL condition becomes

$$\Delta t \leq \alpha / c \{ (1/l_1^2 + 1/l_2^2) / \sin^2 \theta_{12} + 1/l_3^2 \}^{1/2} \quad (14)$$

where θ_{12} is the angle between \mathbf{l}_1 and \mathbf{l}_2 . Eq. (14) for the piecewise uniform functions ($\alpha=1$) agrees with the CFL condition for the conventional FDTD method ($\sin \theta_{12} = 1$).

Fig. 3. Parallelepiped element

Fig. 4. Eigenmodes corresponding to \mathbf{v} : (a) \mathbf{e}_1^f , (b) \mathbf{e}_2^f , and (c) \mathbf{e}_3^f

V. CONCLUDING REMARKS

A piecewise uniform parallelogram or parallelepiped element allows a time-step that is $\sqrt{3}$ times as large as that for a linearly interpolated element. Detailed discussions and numerical verification will be presented in the extended paper.

Abstract — In this paper a genetic algorithm is used to obtain an equation for path loss in an urban environment. The model was developed from measurements at 947 MHz, in Munich, Germany, and validated with data from measurements in Ottawa, Canada, at 910 MHz.

I. INTRODUCTION

The calculation of the transmitted power attenuation as it propagates through space (path loss) is a fundamental component in the design of wireless communication systems. The electromagnetic wave between the transmitter and receiver propagates through different paths, from direct line of sight (LOS) to a situation where the environment is obstructed by buildings, trees etc [1].

Several propagation models are available to calculate the fluctuations in the signal intensity in urban environment. Due to the nonlinear and complex characteristics of propagation in these environments, some researchers suggest the use of artificial intelligence techniques to predict the path loss [2]-[3]. In this work, a new hybrid model is presented, which combines measures with genetic algorithm to obtain an equation that considers various characteristics of the propagation environment.

II. THE PROPOSED MODEL

The log-distance path loss model, used for the mean path loss is given by the equation:

$$L_B(\text{dB}) = L_B(d_0) + 10n \log_{10} \left(\frac{d}{d_0} \right) \quad (1)$$

where n is the path loss exponent which indicates the rate at which the path loss increases with the distance d ; and d_0 is the reference distance, normally 1 km when large coverage cellular systems are used or 1 m to 100 m in microcellular systems. In (1), $L_B(d_0)$ is the mean path loss at reference distance d_0 , calculated using some model or through field measurements [1]. In this model, n is defined in a subjective manner, being dependent on the propagation environment. For example, $n = 2$ for free space; $2.7 \leq n \leq 3.5$ for urban area cellular radio; and $4 \leq n \leq 6$ when the path is obstructed by buildings. Even for a particular kind of environment, there is a range of values to be chosen. In order to quantify the different characteristics of the propagation environment, the following equation is proposed to calculate the mean path loss, which has the advantage of quantifying the environment, removing the subjective nature in the choice of n in (1):

$$L_B(\text{dB}) = A - 20 \log_{10}(h_T) - 20 \log_{10}(h_R) \\ + B f(C + D m_a) + E g(F + G b_n) \\ + [H + I h(J + K m_a) + L i(M + N b_n)] \log_{10} \left(\frac{d}{d_0} \right) \quad (2)$$

where h_T and h_R are the height of transmitter and receiver antennas, respectively; m_a and b_n varies with the receiver position and the propagation environment between the transmitter and receiver.

The parameter m_a is defined in the $[0, 1]$ interval and quantifies the building occupation in an area within a sector of 30° from the transmitter towards the receiver. Its value is obtained by simple average of the percentage of area covered by buildings for distances equal to $d/3$, $2d/3$ and d . Thus, a higher correlation between m_a and the path loss is obtained. The value of b_n is the number of buildings that block the direct line of sight between transmitter and receiver.

The constants A, B, C, D, \dots, N and the functions $f()$, $g()$, $h()$ and $i()$ were determined by a genetic algorithm, a tool that provides a simple way to test various functions and constants without using brute force technique. For the genetic algorithm input, measurements provided by Mannesmann Mobilfunk covering an area of $2.4 \text{ km} \times 3.4 \text{ km}$ in Munich, Germany were used [4]. The database contains building data in vector format, the height of each building, and measures of path loss to around 2300 points on 3 different routes. The measurements were performed at 947 MHz and the heights of transmitting and receiving antennas were 13 m and 1.5 m respectively. Measured values are available for distance between approximately 100 m and 2 km. This database was separated into two sets of measures: one for training and another for testing. The set used for training was formed from 44 measurements selected to represent different values for the triple (m_a, b_n, d) .

In this genetic algorithm, each chromosome represents the constants A to N and the functions $f()$, $g()$, $h()$ and $i()$ shown in (2). Each constant was coded with a 15-bit binary string: 1 bit for the signal, 7 for the fractional part, and 7 for the integer part. The functions were coded in a 3-bit binary string.

For each of the 44 samples of the test database, the path loss is determined using (2) and the constants and functions given by the chromosome decoding. The mean square error between the measurements and the predicted path loss

determines the chromosome fitness. The higher the error, the lower the fitness and vice versa.

Using this methodology, the following equation was obtained for the path loss:

$$L_B(\text{dB}) = 107.3 - 20\log_{10}(h_T) - 20\log_{10}(h_R) + 60m_a + 12.17\log_{10}(0.21 + 0.05b_n) + (53.46 - 50.24m_a + 0.37b_n)\log_{10}\left(\frac{d}{100}\right) \quad (3)$$

III. RESULTS AND CONCLUSION

Figure 1 shows the comparison between measured path loss and the predicted one by the proposed model and the COST 231-Walfish-Ikegame (COST-WI [5]) through the three routes considered. The first order statistics for this cases is presented in Table I. Figure 2 shows the path loss measured, predicted using the proposed model and the COST-WI to data available in [6]. Table II summarizes the first order statistics for this case. As can be seen, the proposed model describes with good accuracy the measured path loss.

The proposed model was developed and tested near 900 MHz for distances between 100 m and 2 km. The results show that the method has remained consistent when the propagation environment is changed. Equivalent models can be built for different frequencies bands, from measurements and (2).

The great advantage of the proposed model is the possibility of obtaining the parameters directly related to the propagation environment using the genetic algorithm. To do this, it is necessary to have measurements in some part of the area of interest. This allows the model to become flexible and easily adaptable to the region of under analysis.

TABLE I
FIRST ORDER STATISTIC FOR MUNICH DATABASE

Model		Route 0	Route 1	Route 2
COST-WI	Mean error (dB)	10.9	14.5	15.5
	Standard deviation (dB)	7.6	6.9	8.7

Abstract — It is well known that refractive indexes of materials used for fabricating optical fibers are affected by variations of temperature. In this way, it can be expected a dependence on the temperature for several parameters related with optical fibers and devices based on them. The understanding of this dependence can lead to the design of temperature sensors or athermal devices through the maximization or the compensation of these effects, respectively. In this work we proposed and analyzed the coupling characteristics for a directional coupler based on two ultralow dispersion fibers separated by a small distance for power monitoring purposes. An efficient vectorial finite element method has been used for this purpose.

Keywords — Numerical Techniques, Directional Coupler, Temperature.

I. INTRODUCTION

Optical fibers have several characteristics which permit their use as an excellent transmission medium for short and large distances. The chromatic dispersion is one of the most important parameters and should be carefully analyzed during their design. There are several profiles, including some based on photonic crystals with very low chromatic dispersion for several wavelengths [1-3]. On the other hand, they are also used to design devices to split the power in two or more ports by using directional couplers. In this work, a novel optical fiber [1], See Fig. 1a, where an air hole has been introduced at the core center, has been used to design a directional coupler and their coupling characteristics as well as its temperature dependence has been analyzed by using the beam propagation method based on the frequency domain finite element [4]. The directional coupler is composed by two of these fibers disposed in parallel, See Fig. 1b.

The Sellmeier equation used for the refractive index of fused silica (SiO_2), including the temperature, is:

$$n^2 = A + B / (1 - C / \lambda^2) + D / (1 - E / \lambda^2) \quad (1)$$

where A , B , C and D are the first order temperature Sellmeier coefficients and E is a constant, the values used were taken

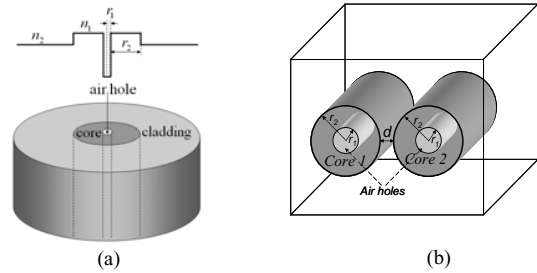

Fig. 1. (a) Refractive index profile of the step index holey fiber and (b) proposed directional coupler.

from [5]: $A = 1,31552 + 6,90754 \times 10^{-6} T$; $B = 78,8404 + 2,35835 \times 10^{-5} T$; $C = 110,199 + 5,84758 \times 10^{-7} T$; $D = 0,91316 + 5,48368 \times 10^{-7} T$ and $E = 100$. Here, T represents the temperature in $^{\circ}\text{C}$ and λ is the wavelength. These coefficients can be used for $26^{\circ}\text{C} < T < 100^{\circ}\text{C}$ and $\lambda > 1.1 \mu\text{m}$.

The refractive index of an optical fiber $n(r, \lambda)$ can be written as $n(r, \lambda) = \eta(r) n_s(\lambda)$, where $n_s(\lambda)$ is the refractive index of fused silica and $\eta(r)$ is the normalized refractive index which only depends on the radial coordinate [3].

II. FINITE ELEMENT FORMULATION

The FEM is widely used for the analysis of photonic devices [1-4], [6-7]. Their accuracy for wave propagation is shown in [4] and [7].

The chromatic dispersion (CD) is a key parameter related to the widening of optical pulses and signal degradation with the propagated distance. In this way, the directional coupler used here was implemented by placing two ultralow dispersion fibers in parallel. The main application of this directional coupler is the power monitoring by tapping a fraction of the transmitted power.

To analyze the coupling characteristics, we start from the vectorial Helmholtz equations in 2D, with perfectly matched layers (PMLs) to avoid reflections from the computational domain,

$$\nabla \times \left(\bar{\bar{k}} \nabla \times \bar{\bar{H}} \right) - k_0^2 \bar{\bar{H}} = 0 \quad (2)$$

where $\bar{\bar{k}} = 1/\bar{\bar{\epsilon}}$ and $\bar{\bar{\epsilon}}$ represent the relative permittivity tensor, respectively. Considering a dielectric material with transversal anisotropy and defining \hat{u}_x , \hat{u}_y e \hat{u}_z associated with the directions x , y e z respectively, $\bar{\bar{\epsilon}}$ can be written as

$\bar{\varepsilon} = \varepsilon_{xx}\hat{u}_x\hat{u}_x + \varepsilon_{xy}\hat{u}_x\hat{u}_y + \varepsilon_{yx}\hat{u}_y\hat{u}_x + \varepsilon_{yy}\hat{u}_y\hat{u}_y + \varepsilon_{zz}\hat{u}_z\hat{u}_z$. After some manipulating algebra and considering an slow variation for the fields and the medium in the propagation direction, z , [4], equation (2) can be rewritten as:

$$\bar{k}_a \frac{\partial^2 \bar{h}_T}{\partial z^2} - 2\gamma \bar{k}_a - \bar{k}_b \nabla_T (\nabla_T \cdot \bar{h}_T) - \nabla_T \times k_{zz} \nabla_T \times \bar{h}_T + (\bar{k}_c + \gamma^2 \bar{k}_a) \bar{h}_T = 0 \quad (3)$$

where \bar{k}_a , \bar{k}_b and \bar{k}_c represent transversal tensors given in [4]. Applying the finite element method for the transversal direction, we obtain,

$$[M] \frac{\partial^2 \{\bar{h}_T\}}{\partial z^2} - 2\gamma [M] \frac{\partial \{\bar{h}_T\}}{\partial z} + ([K] + \gamma^2 [M]) \{\bar{h}_T\} = \{0\} \quad (4)$$

where $\{\bar{h}_T\}$ represents a vector with the unknown fields hxj and hyj , $\{0\}$ is a null vector and $[M]$ e $[K]$ are the global matrices defined in [4]. Using the Padé approximation (1,1) [4], in (3), results in:

$$[\tilde{M}] \frac{d \{\bar{h}_T\}}{dz} + [K] \{\bar{h}_T\} = \{0\} \quad (5)$$

where, $[\tilde{M}] = [M] - \frac{1}{4\gamma^2} ([K] + \gamma^2 [M])$. Finally the finite difference

method is applied in the propagation direction, obtaining a matrix equation,

$$([\tilde{M}(z)] + \theta \Delta z [K(z)]) \{\bar{h}_T(z + \Delta z)\} = ([\tilde{M}(z)] - (1 - \theta) \Delta z [K(z)]) \{\bar{h}_T(z)\} \quad (6)$$

where Δz is the step size along z and θ ($0 \leq \theta \leq 1$) is used to control the stability ($0.5 \leq \theta \leq 1$). For $\theta = 0.5$ we obtain the Crank Nicholson scheme.

The effective index is updated during each propagation step to maintain the accuracy according to [4],

$$n_{eff}^2(z) = \text{Re} \left[\frac{\{\bar{h}_T(z)\}^\dagger [K(z)] \{\bar{h}_T(z)\}}{k_0^2 \{\bar{h}_T(z)\}^\dagger [M(z)] \{\bar{h}_T(z)\}} \right] \quad (7)$$

where \dagger represents the transpose conjugated complex.

III. NUMERICAL RESULTS

We considered two identical optical fibers with parameters: $\eta_1 = 1.05214$, $\eta_2 = 1.0$, $r_1 = 0.2 \mu\text{m}$ and $r_2 = 1.8 \mu\text{m}$ and separated by a distance $d = 0.5 \mu\text{m}$. See Fig. 1b. The coupling characteristics at several operating wavelengths and temperatures were thoroughly analyzed. The ratio of transferred power can be controlled by changing the core separation and the length of the coupler.

The computational domain was $9 \mu\text{m}$ (x direction) and $9 \mu\text{m}$ (y direction) discretized by 12,000 quadratic elements with a propagation step size $\Delta z = 0.1 \mu\text{m}$. The left fiber was

excited with the E_{11}^x mode, which (n_{eff}) is obtained from the relation β/K_0 , through the modal analysis [6]. The Fraction of power as a function of the distance is shown in Fig. 2, for $\lambda = 1.53 \mu\text{m}$. The coupling length obtained by the Vectorial Beam Propagation Method (VBPM) is in good agreement whit the one obtained by the modal analysis by using the beating length definition [7]. The maximum transfer of energy for $T = 28^\circ\text{C}$ happens at $z = 444.5 \mu\text{m}$, and for $T = 300^\circ\text{C}$ it happens at $z = 446 \mu\text{m}$. We have then a small variation of $1.5 \mu\text{m}$ for the coupling length at the above mentioned temperatures. The explanation for small coupling length variations can be explained by the fact that the coupling length of this directional coupler is very short.

Fig. 2. Fraction of normalized power as a function of the distance in (a) core 2 of Fig 1b (maximum) and (b) core 1 of Fig 1b (minimum).

IV. CONCLUSIONS

In this work, the vectorial frequency domain finite element method has been used to analyze efficiently the temperature dependence of the coupling length of directional couplers. We can observe a small dependence of the coupling length on the temperature. Several other geometries are under analysis and will be presented at the time of the conference.

Abstract - The two-dimensional parabolic equation is extensively used to make predictions for the radio wave propagation in the troposphere. However, the effects associated with the lateral variations of a realistic ground are completely ignored by two-dimensional models. In this paper, these effects are considered, extending the two-dimensional parabolic equation for three dimensions. The vector fields are represented in terms of two Hertz potentials. So, depolarization of the fields is automatically included in the formulation. The impedance boundary condition of the ground is applied after a transformation of variables. The problem solution through the finite difference method leads to a sparse system of linear equations more general, which will be solved by an interactive method.

I. INTRODUCTION

Radio signals propagating in the VHF and UHF bands can be strongly attenuated by the effects of irregular terrain. Attenuation in excess to that due to free space is normally estimated using one of many classical (Bullington, Epstein-Peterson and Deygout) or ITU-R models (Recommendations ITU-R P.526 and ITU-R P.1812) [1]. These models are semi-empirical extensions of the basic theoretical model of diffraction by a knife-edge obstacle and have been continually improved by work performed over decades. Computationally-intensive models based on parabolic differential equations, integral equations or ray tracing have also been developed with prediction purposes [1]. In the process, attempts have been made to approximate available experimental data as closely as possible. Although the agreement between predictions and measurements are steadily improving, errors are still high.

All the above are two-dimensional models that assume lateral uniformity of the terrain. This approximation neglects energy propagating outside the vertical plane containing the transmitting and receiving antennas, which may be a reasonable assumption for some environments. However, in the presence of steep terrain, lateral diffraction and scattering may have a significant impact on propagation.

To include the effects of the lateral terrain variations and to investigate the possibility of obtaining better agreement between predictions and measurements, a three-dimensional formulation of the parabolic approximation to the Helmholtz equation will be presented. There are relatively few similar formulations available in the literature [2]-[5], which will

not be discussed here. However, it should be mentioned that they incorporate one or more features which may limit their usefulness for the present application.

The present formulation assumes a two-dimensional irregular terrain on top of the spherical Earth. It is developed with basis on spherical coordinates, which easily accommodates the spreading of the transmitting antenna beam with azimuth. Atmospheric effects are represented by a height-dependent index of refraction. The vector electromagnetic field is expressed in terms of the vertically-oriented electric and magnetic Hertz potentials, each satisfying the scalar Helmholtz equation. This representation automatically guarantees divergent-free electric and magnetic fields at all points of space. The two Hertz potentials, and consequently also the electromagnetic field components, are coupled by the surface of the irregular terrain through the vector impedance boundary condition. So, depolarization is included in the present formulation.

A simple mapping is applied to the region of interest to transform the irregular terrain into a spherical surface. As a consequence of this mapping, the resulting Helmholtz equation and its parabolic approximation include additional variable coefficients, and the components of transformed impedance boundary condition assume more complex forms. On the other hand, the components of the new boundary condition are enforced on a simple spherical surface. The computational domain is truncated by forcing absorbing conditions at the upper and the two lateral boundaries of the region of interest. The absorbing boundary conditions are designed to smoothly weaken the field outside the propagation domain and to avoid spurious reflections originating from the artificial limits imposed to the computational domain.

The parabolic equation and the appropriate boundary conditions define an initial value problem that can be solved using a numerical scheme that progresses along the axial direction. That is, the known field values on a surface transverse to the axial direction are used to determine those on a surface one step further away from the source. For the initial condition, an aperture source distribution is specified to create a Gaussian beam in the far field region.

Model predictions are compared with height-function measurements of field strength performed using an OFCOM (Swiss Federal Office of Communications) vehicle,

equipped with a height-adjustable telescopic mast (up to 11 m in height) that support a Yagi antenna, being able to automatically measure the field strength versus height or azimuth. The measurement data were processed and the final results were calculated, plotted and made available for further studies such as the present one.

II. FORMULATION

Assuming the harmonic dependence with time $e^{-i\omega t}$, source-free media, and assuming that the index of refraction of the atmosphere varies only in the radial direction, the Maxwell equations are manipulated to express the vector electric and magnetic fields in terms of scalar vertically-oriented electric and magnetic Hertz potentials

$$\vec{E} = \frac{1}{n^2} \nabla \times \nabla \times (\Pi^e \hat{r}) + \frac{1}{n^2} i\omega \mu_0 \nabla \times (\Pi^m \hat{r}) \quad (1)$$

$$\vec{H} = \frac{k^2}{i\omega \mu_0} \nabla \times (\Pi^e \hat{r}) + \nabla \times \left[\frac{1}{n^2} \nabla \times (\Pi^m \hat{r}) \right] \quad (2)$$

In the above equations, k is wave number, μ_0 is the permeability of vacuum, n is index of refraction, \hat{r} is the radial unit vector, and the Hertz potentials $\Pi^{e,m}$ satisfy the scalar Helmholtz equation

$$\nabla^2 \Pi^{e,m} + k^2 n^2 \Pi^{e,m} = 0 \quad (3)$$

Next, the complex amplitude $u(r, \theta, \varphi)$ is defined in spherical coordinates by

$$\Pi^{e,m}(r, \theta, \varphi) = \frac{e^{ika\theta}}{r\sqrt{\sin\theta}} u^{e,m}(r, \theta, \varphi) \quad (4)$$

where a is Earth's radius, and the terrain height function $h(\theta, \varphi)$ is taken into account through the mapping

$$\Theta = \theta \quad (5a)$$

$$\Phi = \varphi \quad (5b)$$

$$z = r - a - h(\theta, \varphi) \Rightarrow r = z + a + h(\Theta, \Phi) \quad (5c)$$

$$u^{e,m}(r, \theta, \varphi) = v^{e,m}(z, \Theta, \Phi) \quad (5d)$$

Substituting equations (4) and (5) into equation (3) and introducing the parabolic approximation

$$\left| \frac{\partial^2 v^{e,m}}{\partial \Theta^2} \right| \ll 2ka \left| \frac{\partial v^{e,m}}{\partial \Theta} \right| \quad (6)$$

the modified Helmholtz equation is reduced to

$$\begin{aligned} \frac{\partial v^{e,m}}{\partial \Theta} = & -\frac{r^2}{2ika} \left\{ \left[1 + \left(\frac{1}{r} \frac{\partial h}{\partial \Theta} \right)^2 + \left(\frac{1}{r \sin \Theta} \frac{\partial h}{\partial \Phi} \right)^2 \right] \frac{\partial^2 v^{e,m}}{\partial z^2} - \right. \\ & - \frac{2}{r^2} \left(\frac{\partial h}{\partial \Theta} \frac{\partial^2 v^{e,m}}{\partial z \partial \Theta} + \frac{1}{\sin^2 \Theta} \frac{\partial h}{\partial \Phi} \frac{\partial^2 v^{e,m}}{\partial z \partial \Phi} - \frac{1}{2 \sin^2 \Theta} \frac{\partial^2 v^{e,m}}{\partial \Phi^2} \right) - \\ & - \left(\frac{2ika}{r^2} \frac{\partial h}{\partial \Theta} + \frac{1}{r^2} \frac{\partial^2 h}{\partial \Theta^2} + \frac{1}{r^2 \sin^2 \Theta} \frac{\partial^2 h}{\partial \Phi^2} \right) \frac{\partial v^{e,m}}{\partial z} + \\ & \left. + \left[k^2 \left(n^2 - \frac{a^2}{r^2} \right) + \frac{1}{4r^2} + \frac{1}{4r^2 \sin^2 \Theta} \right] v^{e,m} \right\} \quad (7) \end{aligned}$$

Coupling between the complex amplitude functions v^e and v^m is introduced by the impedance boundary condition [6]

$$\hat{n}_t \times \vec{E} = Z_1 \hat{n}_t \times (\hat{n}_t \times \vec{H}) \quad (8)$$

In equation (8), \hat{n}_t is the unit vector normal to the irregular terrain. Substituting expressions (1), (2), and (3) to (5) into equation (8), each of the three components of the transformed impedance boundary condition is expressed in the general form

$$\begin{aligned} & a_{zz}^e \frac{\partial^2 v^e}{\partial z^2} + a_{z\Theta}^e \frac{\partial^2 v^e}{\partial z \partial \Theta} + a_{z\Phi}^e \frac{\partial^2 v^e}{\partial z \partial \Phi} + a_z^e \frac{\partial v^e}{\partial z} + \\ & + a_{\Theta}^e \frac{\partial v^e}{\partial \Theta} + a_{\Phi}^e \frac{\partial v^e}{\partial \Phi} + a_0^e v^e = \\ = & a_{zz}^m \frac{\partial^2 v^m}{\partial z^2} + a_{z\Theta}^m \frac{\partial^2 v^m}{\partial z \partial \Theta} + a_{z\Phi}^m \frac{\partial^2 v^m}{\partial z \partial \Phi} + a_z^m \frac{\partial v^m}{\partial z} + \\ & + a_{\Theta}^m \frac{\partial v^m}{\partial \Theta} + a_{\Phi}^m \frac{\partial v^m}{\partial \Phi} + a_0^m v^m \quad (9) \end{aligned}$$

The coefficients $a_{ij}^{e,m}$ are specific for each component and depend on partial derivatives of the terrain function $h(\theta, \varphi)$. It is usual to approximate the derivatives with respect to Θ by the expression resulting from the parabolic equation (7). The above three components of the impedance boundary condition are linearly dependent and only two of them are applied at the smoothed boundary $z = 0$ resulting from transformation (5).

The finite difference version of the above equations resulting from the Crank-Nicolson scheme is arranged in the form of a diagonal system of equations. The equations corresponding to points entirely located in the atmosphere display nine coefficients symmetrically arranged around the main diagonal. On the other hand, equations corresponding to points located on the ground display fourteen coefficients asymmetrically arranged around the main diagonal. In each step of the progress along the axial direction defined by the transmitter and receiver, the coefficients are recalculated and the sparse system of linear equations is solved with the help of the PARDISO parallel direct sparse solver, available through the Intel Math Kernel Library. This easy-to-use software solves large sparse symmetric and asymmetric linear systems of equations on shared memory multiprocessors, supporting a wide range of sparse matrix types.

Abstract — A new, fast and effective method for the determination of locations and current intensities of electromagnetic sources located in an infinite medium is presented. The method is based on the analytical continuation of the total electric field vector measured on a line of finite length. The problem is then reduced to the solution of a non-linear equation which is solved iteratively through linearization in the Newton sense. Numerical evaluations show that the method yields quite accurate results for both the source locations and intensities.

I. INTRODUCTION

Inverse source problems whose aim is to determine the locations and current intensities of electromagnetic sources are of interest due to their potential applications in the areas of non-destructive testing, mobile communications, security, fault diagnosis of electrical machines etc. During the last decade several research activities have been carried out in this direction. Most of methods are developed for sources located inside a spherical domain and spherical harmonic expansions are widely used in the solution process [1-3]. On the other hand, in the real applications such as mobile communications, it is very difficult to perform the measurements on a spherical surface. Instead planar or linear measurement configurations would be preferable. For that reason, methods based on such measurements possibilities should be developed.

The aim of this paper is to give a new, fast and effective algorithm for the determination of both locations and current intensities of current filaments from the electric field vector values obtained through the measurements which are performed on a certain line segment. The method is based on the analytical continuation of the measured total field to the region where the sources are located. The analytical continuation is achieved in terms of the plane wave spectral representation of the total electric field vector. The problem is then reduced to the solution of an operator equation which is linear with respect to intensities and non-linear with respect to locations. The operator equation is solved iteratively via linearization in the Newton sense [4]. The initial estimates for the locations are obtained by plotting the reconstructed total field in the whole space. The method is tested by considering some illustrative examples and it has been shown that it yields quite accurate reconstructions for both intensities and locations.

II. GENERAL FORMULATION OF THE INVERSE SOURCE PROBLEM

We consider the configuration in Fig.1 where n filamentary sources with current intensities (I_1, I_2, \dots, I_n) and locations (r_1, r_2, \dots, r_n) are located in a non-magnetic medium of infinite extend having wavenumber k . The inverse source problem considered here is to reconstruct the current intensities (I_1, I_2, \dots, I_n) and source points (r_1, r_2, \dots, r_n) from the measurement of the total electric field vector on the line $x_2 = \gamma$, say Γ . Note that the measurements can be performed by a receiving antenna R_x moving on the line Γ (See Fig. 1).

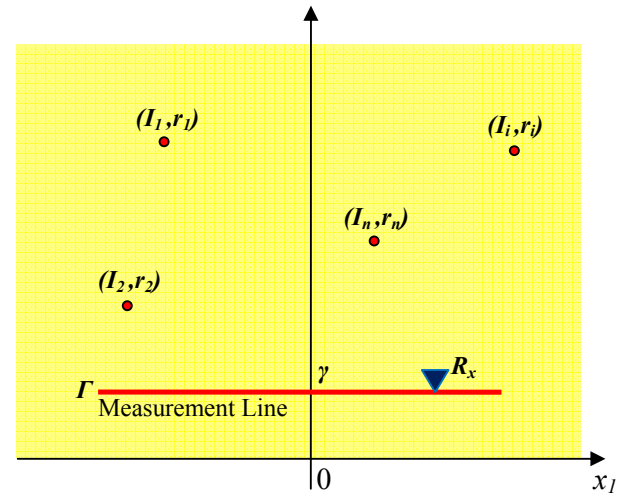

Fig. 1. n filamentary line sources located in a non-magnetic lossless medium and the measurement configuration

In the following, for the sake of simplicity, the analysis will be given by considering $2D$ case where the problem can be formulated as a scalar one in terms of total electric field function $u(x)$. Here $x = (x_1, x_2)$ denotes the position vector in R^2 . Through the measured total field, say $u_m(x)$, the total field in the region above the measurement line can be expressed as a combination of plane waves in the spectral domain, namely;

$$u(x) = \frac{1}{2\pi} \int_{-k}^{+k} \check{u}_m(\alpha) e^{-i\sqrt{k^2 - \alpha^2}(x_2 - \gamma) + i\alpha x_1} d\alpha \quad (1)$$

where $\check{u}_m(\alpha)$ denotes the Fourier transform of the measured total field with respect to x_1 . Note that the plane wave spectral representation in (1) contains only the propagating modes. Equation (1) is nothing but the analytical continuation of the measured data to the region $x_2 > \gamma$ where the sources are located. $u(x)$ is a regular function of x except the source points (r_1, r_2, \dots, r_n) . Thus, basically, one can get the source locations by simply plotting the field $u(x)$ and observing the points where the field is discontinuous. Such an approach gives an approximate source locations which can be used as an initial estimate for the iterative procedure described below.

By considering the explicit expressions of the fields created by individual sources, the problem is then reduced to solution of a functional equation of the form

$$\mathbf{F}(I_1, I_2, \dots, I_n; r_1, r_2, \dots, r_n; \alpha) = \check{u}_m(\alpha) e^{i\sqrt{k^2 - \alpha^2} \gamma}. \quad (2)$$

\mathbf{F} is a known operator which is linear with respect to intensities (I_1, I_2, \dots, I_n) and non-linear with respect to source locations (r_1, r_2, \dots, r_n) . Equation (2) is solved iteratively by linearizing simultaneously with respect to the intensities and the locations. More precisely, given (c_1, c_2, \dots, c_n) for the intensities and (s_1, s_2, \dots, s_n) for the locations, we determine the updates $(c_1 + \mu_1, c_2 + \mu_2, \dots, c_n + \mu_n)$ and $(s_1 + \sigma_1, s_2 + \sigma_2, \dots, s_n + \sigma_n)$ from the linearized equation

$$\begin{aligned} & \mathbf{F}(c_1 + \mu_1^j, \dots, c_n + \mu_n^j; s_1 + \sigma_1^j, \dots, s_n + \sigma_n^j; \alpha) + \\ & \mathbf{F}'(c_1 + \mu_1^j, \dots, c_n + \mu_n^j; s_1 + \sigma_1^j, \dots, s_n + \sigma_n^j; \alpha) \cdot \delta\sigma \\ & = \check{u}_m(\alpha) e^{i\sqrt{k^2 - \alpha^2} \gamma}. \end{aligned} \quad (3)$$

Here \mathbf{F}' denotes the gradient of \mathbf{F} with respect to source locations, j is the iteration number while $\delta\sigma = (\sigma_1, \dots, \sigma_n)$. The equation (3) needs to be solved in a least square sense after collocating it at a sufficient number of collocation points $\alpha_j \in (-k, k)$, $j = 1, \dots, M$. For stability, a penalty term on the unknown locations and intensities has to be added, that is, Tikhonov regularization has to be employed to the solution of (3).

III. NUMERICAL RESULTS

The method described above is tested by considering some illustrative examples. Here we present the results of one of them. Three line sources with current intensities $I_1=1$, $I_2=3$, $I_3=7$ and source locations $r_1=(0,-1.5)$, $r_2=(-1,0)$ and $r_3=(0.5,1.5)$, respectively, are considered. The operating frequency of the sources are 3GHz. The measurements are

performed on the line $x_1 \in (-1.5, 1.5)$, $x_2 = -3$, at 40 points. Note that all the distances are given in meters.

Fig. 1. Two dimensional plot of the reconstructed total field

Fig 2. shows the two dimensional variation of the reconstructed total in the domain $x_1 \in (-4, 4)$, $x_2 \in (-4, 4)$. Obviously, the total field has discontinuities at the source locations. By choosing the points where the field has maximum values as the initial estimate for the source locations and solving the equation (3) iteratively, we get the values of the intensities and source location as given in Table 1. The results are obtained for 11 iterations. The reconstructed intensities and the locations are quite accurate.

TABLE I
Reconstructed current intensities and source locations

Source Number	Intensity (Ampere)	Location (Meters)
I	0.99978	(0.00021, -1.49993)
II	3.01003	(-1.00171, 0.00211)

Improved FE-mesh truncation by surface operator implementation to speed up antenna design

W. Renhart, C. Magele, C. Tuerk

Abstract—Several possibilities to truncate the domain of an unbounded electromagnetic wave problem exist. The ambition of this contribution lies in the improvement of the conditions to be specified along the truncation boundaries in case no scatterer being present. Thereby, the more common case of the outgoing wave to propagate no longer perpendicular to the truncation boundary will be treated. Tracking this idea, an additional surface operator to the widely used surface impedance boundary condition (SIBC) will be built into a finite element formulation. Speed up benefit and accuracy will be evaluated on an asymmetric RFID tag antenna.

I. INTRODUCTION

The variant kinds of mesh truncation when using finite elements always represent a compromise between sufficient accuracy and smallest possible computation effort. The use of absorbing boundaries (ABC) has been improved seriously by some iterative procedures, as reported eg. in [1] and [2]. Multiple calculations of the same problem boost the effort and extend the computation time. The application of perfectly matched layers (PMLs), as suggested eg. in [3], suffers from a condition number degraded set of equations system to be solved. Hence the convergence while applying a solving procedure becomes worse.

The design of antenna geometries belongs to a type of electromagnetic wave problems where scatterer have not to be considered (Fig. 1). Along the truncation bound-

Fig. 1. Basic arrangement, antenna in point of origin, domain truncated by boundary Γ_{tr} .

aries (Γ_{tr}) the propagation direction then is determined by the location of radiating antenna and the truncation surface, only. The knowledge of the incident angle of the outgoing wave all-over Γ_{tr} enables the design of more pre-

cise conditions between the tangential field vectors \vec{E}_t and \vec{H}_t on it.

II. BOUNDARY CONDITIONS FOR THE MESH TRUNCATION

In finding improved boundary conditions for the truncation surface Γ_{tr} we begin with the Maxwell equations

$$\nabla \times \vec{E} = -j\omega\mu\vec{H}, \quad \nabla \times \vec{H} = j\omega\epsilon\vec{E}. \quad (1)$$

Therein, the field vectors \vec{E} and \vec{H} as well as the ∇ operator can be split into a normal and two orthogonal tangential components. The normal component will be described by n and the tangential vector by t . It follows:

$$\vec{E} = \vec{E}_t + \vec{n} E_n, \quad \vec{H} = \vec{H}_t + \vec{n} H_n, \quad \nabla = \nabla_t + \frac{\partial}{\partial n} \vec{n}. \quad (2)$$

With this relations the normal components of the fields, E_n and H_n can be eliminated in (1) to attain

$$\frac{\partial(\vec{n} \times \vec{E}_t)}{\partial n} = -j\omega\mu\vec{H}_t - \frac{1}{j\omega\epsilon}\nabla_t \times (\nabla_t \times \vec{H}_t) \quad (3)$$

$$\frac{\partial(\vec{n} \times \vec{H}_t)}{\partial n} = j\omega\epsilon\vec{E}_t + \frac{1}{j\omega\mu}\nabla_t \times (\nabla_t \times \vec{E}_t). \quad (4)$$

These equations are commonly valid, consequently on the truncation surface, too. On Γ_{tr} we have the situation as

Fig. 2. Incident wave at a point on Γ_{tr} .

shown in Fig. 2. The incident wave is represented by the wave vector \vec{k} , which has been decomposed by the normal vector $\vec{\beta}$ and the tangential vector \vec{k}_t . It follows:

$$\vec{k} = \vec{k}_t + \vec{\beta}, \quad \beta = \pm\sqrt{k^2 - k_t^2}, \quad k = \omega\sqrt{\mu\epsilon}. \quad (5)$$

To get rid of the derivatives $\frac{\partial}{\partial n}$ in (3) and (4), the integration along z for the negative z -half space must be performed. To do so, we can evaluate the field decay in negative z -direction, perpendicular to Γ_{tr} easily by

$$\int_{-\infty}^0 \vec{H}_{t_0} e^{j\beta z} dz = \frac{1}{j\beta} \vec{H}_{t_0}, \quad \int_{-\infty}^0 \vec{E}_{t_0} e^{j\beta z} dz = \frac{1}{j\beta} \vec{E}_{t_0}. \quad (6)$$

\vec{H}_{t_0} and \vec{E}_{t_0} represent the field vectors at $z = 0$. Together with (5) the relations (3) and (4) change to

$$\vec{n} \times \vec{E}_{t_0} = \frac{-\omega\mu\vec{H}_{t_0}}{\sqrt{k^2 - k_t^2}} + \frac{\nabla_t \times (\nabla_t \times \vec{H}_{t_0})}{\omega\epsilon\sqrt{k^2 - k_t^2}} \quad (7)$$

$$\vec{n} \times \vec{H}_{t_0} = \frac{\omega\epsilon\vec{E}_{t_0}}{\sqrt{k^2 - k_t^2}} - \frac{\nabla_t \times (\nabla_t \times \vec{E}_{t_0})}{\omega\mu\sqrt{k^2 - k_t^2}}. \quad (8)$$

These relations between the tangential components of \vec{E}_{t_0} and \vec{H}_{t_0} now can be used to model the higher order boundary conditions on Γ_{tr} .

Transverse components of the outgoing wave may be transformed into the Fourier domain ($e^{-j\vec{k}_t \cdot \vec{r}}$ -terms), only to see, that its tangential derivation can be expressed as $\nabla_t = -j\vec{k}_t$.

An increased incident angle results always in a larger wave vector \vec{k}_t and obviously the curl curl-terms in (7) and (8) become more and more relevance to achieve accurate boundary conditions. If the wave propagates perpendicularly to Γ_{tr} , \vec{k}_t vanishes and the curl curl-terms become zero. The first order SIBCs remain, only.

When applying the Galerkin method to the well known \vec{A} , v or \vec{T} , Φ -formulations [4], the $\vec{n} \times \vec{H}_t$ or the $\vec{n} \times \vec{E}_t$ terms occur, hence (7) or (8) directly can be implemented.

In order to show the performance, we implemented (8) into the \vec{A} , v -formulation. For the weak form of the vectorial equation follows

$$\begin{aligned} & - \int_{\Omega} \nabla \times \vec{N}_i \cdot \frac{1}{\mu} \nabla \times \vec{A} d\Omega + \int_{\Gamma_H} \vec{N}_i \cdot \underbrace{\left(\vec{n} \times \left(\frac{1}{\mu} \nabla \times \vec{A} \right) \right)}_{\vec{n} \times \vec{H}} d\Gamma \\ & + \int_{\Omega} \vec{N}_i \cdot (\sigma + j\omega\epsilon) j\omega (\vec{A} + \nabla v) d\Omega = 0. \end{aligned} \quad (9)$$

In (9) the underbraced term directly may be substituted by (8) and the field \vec{E}_t has to be expressed by the potentials to $\vec{E}_t = -j\omega(\vec{A}_t + \nabla_t v)$.

III. NUMERICAL INVESTIGATION

A symmetric T-folded RFID tag antenna has been evaluated. Its geometry has been chosen from [5] and is shown in Fig. 3. Therein L_1 , L_2 and L_3 indicate the design parameters, either to match the antenna impedance with the transponder chip or to tune the resonant frequency. Consecutively the computational effort for the

Fig. 3. Symmetric T-folded dipole antenna.

use of standard PMLs and for the proposed boundary conditions has been compared. For our first computations the costs are summarized in Table I. When applying the

TABLE I. COMPUTATIONAL EFFORT

method	DOF	iterations	time [s]
PMLs	64120	10340	1275
proposed BCs	38377	2170	432

proposed boundary conditions no PML-region has to be modeled, so that the DOF changes. Hence the comparison of the values given above limps a bit. Nevertheless, the time score points to get the results faster. No investigations in the influence of the subdivision along Γ_{tr} to the accuracy of the solutions obtained have been done up to now. They are matter of the running activities.

IV. CONCLUSION

For the type of wave propagation problems without containing scattering objects improved mesh truncation conditions have been proposed. Advantage has been taken from the fact, that along the truncation boundaries the incident angle of the outgoing wave is known. Thus improved absorbing conditions containing surface operators can be implemented in an integral term over the truncation boundary. Compared to the PML mesh truncation a smaller domain has to be computed and a well better conditioned equations system must be solved.

Abstract — This paper presents a near field analysis by method of moments for optical scattering by metal nanoparticles with complex shape illuminated by a plane wave. For testing the developed algorithm, we compare our numerical calculations with the exact Mie scattering theory. The Lorentz-Drude model with one interband term is used to describe complex permittivity of the gold sphere in optical frequencies. The obtained numerical results are the spectral response, resonances, and the regions where the near field is enhanced.

I. INTRODUCTION

The electromagnetic scattering of the metals in optical frequencies possess special characteristics. In these frequencies, there are electron oscillations on the metal, called plasmons with distinct resonant frequencies, which produce strongly enhanced near fields at the surface's metal. The analysis of this effect can be realized with the Lorentz-Drude model of the complex dielectric constant. This study of the electromagnetic optical response of metals nanostructures is known as *plasmonics* or *nanoplasmonics* [1]-[2].

An application of the plasmonics is the design of nanoantennas [3]-[11], which are metal nanostructures used to confine and enhance optical electromagnetic fields. An optical monopole antenna is presented in [4]. In [5]-[7], Bowtie optical antennas are analyzed. Dipoles nanoantennas are presented in [8]-[9], and sphere nanoantennas are discussed in [10]-[11]. Examples of applications of these antennas are ultra-high-density data storage, super-resolution microscopy, integrated nano-optical devices and surface-enhanced Raman scattering [2]-[3].

In this paper, we apply the method of moments (MoM) to the problem of the electromagnetic scattering from complex shape nanoparticles in optical frequencies. To test our algorithm, we compare our numerical results with the exact Mie theory for a gold metal sphere. The Lorentz-Drude theory with one interband term is used to model the complex permittivity of the gold sphere. We present the spectral response, resonances and the localizations with the maximum of the near field.

II. DESCRIPTION OF THE PROBLEM

Fig. 1 shows the geometry of the problem, where a gold sphere of radius a is centered in the origin of the coordinate system. The surrounded medium is the free space. This sphere is illuminated by an E_x -polarized, z -directed plane wave:

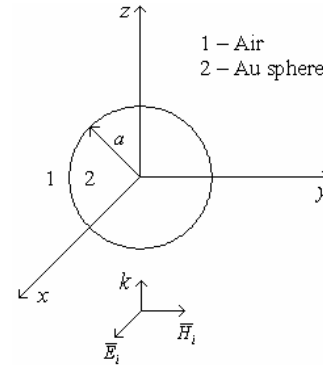

Fig. 1. Incident EM plane wave on a gold sphere

$$\vec{E}_i = E_{i0} e^{j(\alpha x - kz)} \vec{a}_x \quad (1)$$

$$\vec{H}_i = \frac{E_{i0}}{\eta} e^{j(\alpha x - kz)} \vec{a}_y \quad (2)$$

where E_{i0} is the amplitude of the incident electric field, ω the angular frequency, $k = \omega(\mu_0 \epsilon_0)^{1/2} = 2\pi c/\lambda$ the wave number, λ is the wavelength of operation, c is speed of the light, μ_0 the free space permeability, ϵ_0 the free space permittivity, $\eta = 120\pi$ the impedance of the free space. The complex permittivity of the gold sphere is $\epsilon_2 = \epsilon_0 \epsilon_r$, where [2]

$$\epsilon_r = 1 - \frac{\omega_p^2}{\omega^2 - j\Gamma\omega} + \frac{\tilde{\omega}_p^2}{\omega_0^2 - \omega^2 + j\gamma\omega} + 6 \quad (3)$$

being the parameters of this equation: $\omega_p = 13.8 \times 10^{15} \text{ s}^{-1}$, $\Gamma = 1.075 \times 10^{14} \text{ s}^{-1}$, $\omega_0 = 2\pi c/\lambda_0$, $\lambda_0 = 450 \text{ nm}$, $\tilde{\omega}_p = 45 \times 10^{14} \text{ s}^{-1}$, and $\gamma = 9 \times 10^{14} \text{ s}^{-1}$.

III. THEORETICAL ANALYSIS

The numerical analysis of this scattering problem was done with the exact Mie model [12], and the MoM proposed in [13], which takes account the tensor integral equation of the electric field. In the present analysis, the relative permittivity used for the gold sphere is give by (3).

With these mathematical models, it is possible to calculate the total electric field in all space of the problem (i.e. inside and outside the sphere).

IV. NUMERICAL RESULTS

Two computational programs were developed to analyze the scattering problem. Figs. 2-4 show the calculated electric field along the coordinate axes near the sphere. The radius of the sphere and the wavelength used in the simulations are $a=25\text{nm}$ and $\lambda=700\text{nm}$.

Fig. 2. Normalized E_x field along the x -axisFig. 3. Normalized E_x field along the y -axisFig. 4. Normalized E_x field along the z -axis

From the above Figures, we can observe that the electric field is more enhanced near the sphere (Fig. 2), where the field is normal to the sphere. The field is approximately 3.4 times more than the incident electric field. This result was obtained for $\lambda=700\text{nm}$, but in other wavelengths this enhancement is different. In the full paper version, the complete analysis in the region $500\text{nm} < \lambda < 1200\text{nm}$ will be presented, with the resonance frequencies of this sphere and the correspondent enhancement of the near fields. We shall present also some results for nanoparticles of some others geometries.

V. CONCLUSIONS

In this paper, we presented an algorithm based on the method of moments for the near field analysis for nanoparticles of complex shapes. As an example, we calculated the scattered fields from a gold sphere and compared them with those obtained by Mie's theory. The numerical results achieved by the MoM code are in good agreement with the exact solution. In the full paper variant, we shall give some results for the particles with more complex geometry.

Eigenvalue analysis of lossy waveguide structures using hybrid $H(\text{curl})$ second order finite elements

Christian Scheiber and Oszkár Bíró

Institute for Fundamentals and Theory in Electrical Engineering

Graz University of Technology, Austria

Email: christian.scheiber@tugraz.at

Abstract—Using a hybrid finite element method, a full wave description for lossy dielectric waveguides is presented. $H(\text{curl})$ -elements span the transversal field components, whereas a scalar potential is described by nodal elements. Second order elements are used on a rectangular mesh. The losses are taken into account by rewriting Maxwell's equations with a complex permittivity term. Using an $A - V$ -formulation the resulting generalized eigenvalue problem has been solved for fully complex eigenvalues.

Index Terms—Lossy waveguides, eigenvalue problems, $H(\text{curl})$ -elements

I. INTRODUCTION

Various numerical methods and different formulations have been presented in the past for solving dielectric waveguide problems. Typical methods are the method of moments [1], spectral-domain methods [2], finite difference methods [3], and finite element methods [4]. Among them, the latter has proved to be a very general and efficient tool. A serious problem for the description of electromagnetic field quantities involving finite elements is the occurrence of spurious modes. In order to overcome these difficulties mainly two approaches have been taken. One is to impose the divergence-free condition, mostly in the case of nodal finite elements approaches. The other is to use $H(\text{curl})$ -tangential elements that are capable of correctly representing the properties of the curl-curl operator [5].

In [6] a waveguiding structure, showing lossy material properties, is considered using triangular hybrid elements. A study covering the anisotropic case is presented in [7]. The work [8] suggests a method to overcome unreliabilities for low frequencies by presenting an algorithm for employing a tree-cotree splitting in order to accomplish an inexact Helmholtz decomposition. There, hierarchical elements are presented.

In this paper we are following the approach of [8] using an $A - V$ -formulation with hybrid finite elements approximating potential functions. In contrast to [6], rectangular elements of second order are used. Imposing an axial gauge, i.e. setting the z -component of the vector potential to zero, the fully complex propagation constant is determined for given operating frequencies by solving a generalized eigenvalue problem.

II. FORMULATION

We consider an $A - V$ -formulation for a source free region and isotropic, lossy material properties. Using ϵ_c as a complex

quantity describing both permittivity (ϵ) and conductivity (σ),

$$\epsilon_c = \epsilon - j\frac{\sigma}{\omega}, \quad (1)$$

and sinusoidal time dependencies the Maxwell equations in the frequency domain can be written as

$$\begin{aligned} \nabla \times \mathbf{E} &= -j\omega\mu\mathbf{H} & \nabla \times \mathbf{H} &= j\omega\epsilon_c\mathbf{E} \\ \nabla \cdot \mathbf{D} &= 0 & \nabla \cdot \mathbf{B} &= 0 \end{aligned} \quad (2)$$

The material properties for a waveguiding structure being uniform in the z -direction, the fields can be described as

$$\begin{aligned} \mathbf{E}(\mathbf{r}, t) &= \mathbf{E}(x, y)e^{-\gamma z}e^{j\omega t} \\ \mathbf{H}(\mathbf{r}, t) &= \mathbf{H}(x, y)e^{-\gamma z}e^{j\omega t} \end{aligned} \quad (3)$$

with \mathbf{r} being a point vector in the waveguide with a cross-section lying in the x, y -plane. γ is the propagation constant built up by the attenuation constant α and the phase constant β :

$$\gamma = \alpha + j\beta. \quad (4)$$

The electromagnetic fields can be rewritten in terms of a vector potential \mathbf{A} and a scalar potential ϕ

$$\begin{aligned} \mathbf{B} &= \nabla \times \mathbf{A} \\ \mathbf{E} &= -j\omega\mathbf{A} - c\nabla\phi \end{aligned} \quad (5)$$

where c is the velocity of light.

In order to arrive at a linear eigenvalue problem, an axial gauge is imposed by choosing $A_z = 0$. With the splitting of the nabla operator to $\nabla \rightarrow \nabla_\tau - \gamma\hat{\mathbf{e}}_z$, Maxwell's equations (2) can be rewritten as

$$\begin{aligned} 0 &= \nabla_\tau \times \frac{1}{\mu_r} \nabla_\tau \times \mathbf{A}_\tau - \gamma^2 \frac{1}{\mu_r} \mathbf{A}_\tau - k_0^2 \epsilon_r \mathbf{A}_\tau + jk_0 \epsilon_r \nabla_\tau \phi \\ 0 &= -\gamma \nabla_\tau \cdot \frac{1}{\mu_r} \mathbf{A}_\tau - jk_0 \gamma \epsilon_r \phi \\ 0 &= -jk_0 \nabla_\tau \cdot \epsilon_r \mathbf{A}_\tau - \nabla_\tau \cdot \epsilon_r \nabla_\tau \phi - \gamma^2 \epsilon_r \phi \end{aligned} \quad (6)$$

In order to ensure a unique solution, the boundary conditions $\mathbf{A}_\tau \times \mathbf{n} = 0$ and $\phi = 0$ are imposed for the simplest case of a perfect electric conductor (PEC).

III. FINITE ELEMENT REPRESENTATION

We represent \mathbf{A}_τ by $H(\text{curl})$ basis functions (\mathbf{N}_i) and ϕ by H^1 basis functions (N_i). The trial functions \mathbf{a}_τ and a_z can be expressed as

$$\mathbf{a}_\tau = \sum_{i=0}^{n_\tau} c_{\tau i} \mathbf{N}_i \quad a_z = \sum_{i=0}^{n_z} c_{zi} N_i \quad (7)$$

Applying Galerkin's method to (6) and considering the boundary conditions, the following generalized eigenvalue equation is obtained:

$$\left[\begin{pmatrix} [A] & [B] \\ [B]^T & [C] \end{pmatrix} - \gamma^2 \begin{pmatrix} [D] & 0 \\ 0 & [E] \end{pmatrix} \right] \begin{bmatrix} \mathbf{c}_\tau \\ \mathbf{c}_z \end{bmatrix} = 0, \quad (8)$$

where \mathbf{c}_τ and \mathbf{c}_z are the coefficient vector for the edge and nodal basis functions. The matrices are given by

$$\begin{aligned} [A] &= \int_{\Omega} \left\{ \frac{1}{\mu_r} (\nabla \times \mathbf{N}_i) \cdot (\nabla \times \mathbf{N}_j) - k_0^2 \epsilon_r \mathbf{N}_i \cdot \mathbf{N}_j \right\} d\Omega \\ [B] &= jk_0 \int_{\Omega} \{ \epsilon_r \mathbf{N}_i \cdot \nabla N_j \} d\Omega \\ [C] &= \int_{\Omega} \{ \nabla N_i \cdot \nabla N_j \} d\Omega \\ [D] &= \int_{\Omega} \left\{ \frac{1}{\mu_r} \mathbf{N}_i \cdot \mathbf{N}_j \right\} d\Omega \\ [E] &= \int_{\Omega} \{ \epsilon_r N_i \cdot N_j \} d\Omega \end{aligned} \quad (9)$$

IV. BASIS FUNCTIONS

The H^1 -nodal basis functions are built from a linear combination of quadratic polynomials in the x- and y-directions. The $H(\text{curl})$ -edge basis functions can be expressed as a linear combination of the nodal basis functions ($f_i(\xi, \eta)$) times the gradient of the respective local coordinate. For the reference element they are obtained through

$$\begin{aligned} \mathbf{N}_i(\xi, \eta) &= f_i(\xi, \eta) \cdot \nabla \xi \quad \text{for } i = 1, 5 \\ \mathbf{N}_i(\xi, \eta) &= f_i(\xi, \eta) \cdot \nabla \eta \quad \text{for } i = 6, 10 \end{aligned} \quad (10)$$

where ξ and η are the coordinates of the reference cell ranging from -1 to 1 .

V. NUMERICAL APPLICATION

As numerical example we consider the case of a microstrip in a dielectric medium. The geometry and the material properties of the substrate are chosen as described in [6]. We are interested in the determination of the dominant propagation mode and therefore are only considering one half of the geometry due to symmetry, as done in [6] too. The variation of the phase and attenuation constant with the frequency is depicted in Fig. 1 and 2.

ACKNOWLEDGMENT

This work has been undertaken as a part of the project DK "Numerical Solution in Technical Sciences", jointly funded by the Graz University of Technology, the Karl Franzens University Graz and the Austrian Science Fund (FWF).

Efficient Interface Conditions for Finite Difference Time Domain Methods

Dirk Schulz
High Frequency Institute
Friedrich Wöhler Weg 4, 44227 Dortmund, Germany
schulz@hft.e-technik.uni-dortmund.de

Abstract — Finite Difference Time Domain Methods are important for the design of microwave devices. The ordinary Yee scheme commonly used is extended to describe interface conditions between different media adequately in general, when isotropic media are investigated.

I. INTRODUCTION

Finite Difference Time Domain (FDTD) Methods have been extensively used in microwave techniques and have been proposed first by Yee [1]. FDTD methods offer several advantages in contrast to traditional frequency domain approaches. The electromagnetic field is calculated fully vectorial in the time domain while reflection and fringing effects are selfconsistently included. The method exhibits second-order accuracy and does not yield unphysical solutions (spurious modes). A single simulation run allows the extraction of scattering characteristics within a large frequency range. FDTD is easily applicable to a wide range of different structures. Furthermore, the approach allows both exact modelling of field discontinuities at material boundaries and the inclusion of nonlinear effects. Furthermore different material models, i. e. gyromagnetic media, can be included.

In the following we show, that the ordinary discretization scheme does not allow an independent inclusion of interface conditions at interfaces between different media with different permittivities. Therefore, modifications are necessary, which will be introduced. The modifications are simple, but to my knowledge have not been proven and published before.

Yee proposed a discretization scheme according to Fig. 1. The algorithm described is formulated by discretization of Maxwell's curl equations over a finite volume approximating the derivatives with centered difference approximations. Due to the natural choice of the grids and the allocation of the unknown components in space, $\nabla \cdot \vec{D} = 0$ and $\nabla \cdot \vec{B} = 0$ hold. Field vectors are determined at different time steps.

Fig. 1. Yee cell indicating the electric field E, the magnetic field H, the electric flux density D and the magnetic flux density B

II. INCLUSION OF INTERFACE CONDITIONS

All steps of the standard algorithm will be investigated. According to Yee a homogenous medium will be assumed in each discretization cell. Consequently the magnetic field and the electric flux are not absolutely defined at the interfaces. As the electric flux density D is a tangential field component and the magnetic field H is a normal component at the interface, they have to be handled as they are discontinuous [Fig. 2]. The arising difficulties will be discussed. For this purpose all steps needed for the simulation are described.

Fig. 2. Field components at an interface

Maxwell's curl equations in integral form have to be applied

$$\oint \vec{H} \cdot d\vec{s} = \iint \frac{\partial \vec{D}}{\partial t} \cdot d\vec{A}, \quad (1a)$$

$$\oint \vec{E} \cdot d\vec{s} = - \iint \frac{\partial \vec{B}}{\partial t} \cdot d\vec{A}, \quad (1b)$$

as well as arbitrary material equations

$$\vec{E} = f_E \{ \vec{D} \}, \quad (1c)$$

$$\vec{H} = f_H \{ \vec{B} \}. \quad (1d)$$

In the following the equations are evaluated in the x-z-plane to simplify the investigation without restriction to the general case.

A. 1st step

According to Yee's scheme the discretization of (1b) leads

to the relation

$$E_1 \Delta x - E_2 \Delta z - E_3 \Delta x + E_4 \Delta z = -\frac{B_{new} - B_{old}}{\Delta t} \Delta x \Delta z \quad (2a)$$

$$\Leftrightarrow B_{new} = B_{old} - \Delta t \left(\frac{E_1 - E_3}{\Delta z} - \frac{E_2 - E_4}{\Delta x} \right). \quad (2b)$$

B_{new} and B_{old} describe the magnetic flux density at time steps $(n+1/2)\Delta t$ and $(n-1/2)\Delta t$. Δx , Δy and Δz are the discretization widths in space. The electric field components E represent the values at time $n\Delta t$. All field components are well defined, so (2b) can be applied at interfaces and included in the algorithm.

Fig. 3. Numerical evaluation of (1b)

B. 2nd step

The corresponding magnetic material equation (1d) is not uniquely applicable, because the magnetic field components H_a and H_b result from the magnetic flux density B [Fig. 3]. Indeed the values H_a and H_b are of no relevance for the discretization of (1a). According to Fig. 4 the evaluation leads to the following result:

$$\oint \vec{H} \, d\vec{s} \rightarrow H_1 \Delta x - H_2 \Delta z - H_3 \Delta x + H_4 \Delta z \quad (3a)$$

$$\text{with } H_n = \frac{H_{n,a} + H_{n,b}}{2}. \quad (3b)$$

Of course the magnetic material equation has to be solved separately and the calculation of the mean value has to be carried out then increasing the calculation time.

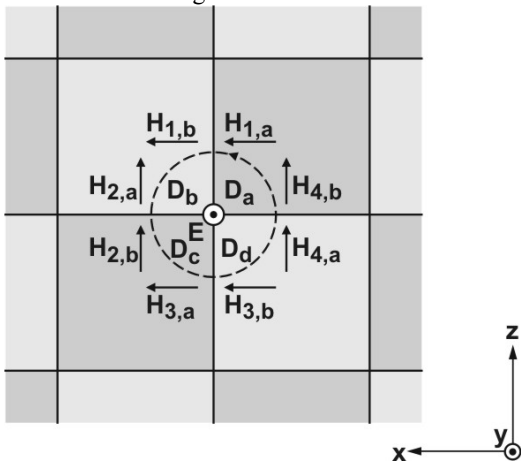

Fig. 4. Numerical evaluation of (1a)

C. 3rd step

Furthermore the discretization of (1b) leads to

$$\oint \vec{H} \, d\vec{s} \rightarrow \frac{D_{a,new} - D_{a,old}}{\Delta t} \cdot \frac{\Delta x}{2} \cdot \frac{\Delta z}{2} + \frac{D_{b,new} - D_{b,old}}{\Delta t} \cdot \frac{\Delta x}{2} \cdot \frac{\Delta z}{2} + \frac{D_{c,new} - D_{c,old}}{\Delta t} \cdot \frac{\Delta x}{2} \cdot \frac{\Delta z}{2} + \frac{D_{d,new} - D_{d,old}}{\Delta t} \cdot \frac{\Delta x}{2} \cdot \frac{\Delta z}{2}. \quad (4)$$

D_{new} and D_{old} describe the magnetic flux density at time steps $(n+1/2)\Delta t$ and $(n-1/2)\Delta t$. Because of the discontinuous electric flux density D (4) includes four separate discretization values for D_a and D_b . According to the chosen discretization for the magnetic field H , the discretized values cannot be calculated separately. This is the mentioned restriction.

D. 4th step

Applying (1c) the electric field components E_a and E_b can be calculated using D_a and D_b . The tangential electric field component must be continuous. Therefore, all discretized electric field values are equivalent.

III. EFFECTIVE PERMITTIVITIES

For isotropic media we can rewrite (3b)

$$H = \frac{H_a + H_b}{2} = \frac{1}{2} \left(\frac{B}{\mu_a} + \frac{B}{\mu_b} \right) = \frac{B}{\mu^*}. \quad (5)$$

The magnetic field component H can be directly evaluated from the magnetic flux by using the effective permittivity

$$\mu^* = \left[\frac{1}{2} \left(\frac{1}{\mu_a} + \frac{1}{\mu_b} \right) \right]^{-1} = \frac{2\mu_a\mu_b}{\mu_a + \mu_b}, \quad (6)$$

so the separate calculation of H_a and H_b is no longer needed. With (6) both steps A and B are carried out simultaneously, leading to

$$H_{new} = H_{old} - \frac{\Delta t}{\mu^*} \left(\frac{E_1 - E_3}{\Delta z} - \frac{E_2 - E_4}{\Delta x} \right). \quad (7)$$

Furthermore the electrical flux density can be calculated according to

$$D^* = \frac{1}{4} (\varepsilon_a + \varepsilon_b + \varepsilon_c + \varepsilon_d) = \varepsilon^* \cdot E \quad (8b)$$

introducing an effective permittivity ε^* . Analogously we will arrive at

$$E_{new} = E_{old} - \frac{\Delta t}{\varepsilon^*} \left(\frac{H_1 - H_3}{\Delta z} - \frac{H_2 - H_4}{\Delta x} \right). \quad (10)$$

By introducing effective permittivities the indicated difficulty is resolved by rearranging (7) and (10).

FDTD Analysis of UHF-band RFID for Metallic Objects

Yuta Watanabe, Kota Watanabe, and Hajime Igarashi
 Graduate School of Information Science and Technology Hokkaido University
 Kita 14 Nishi 9 Kita-ku Sapporo, 060-0814, JAPAN
 ywata@em-si.eng.hokudai.ac.jp

Abstract— This paper presents an FDTD analysis of communication properties of UHF-band RFID system where IC tags are placed near metallic objects. When the distance between the tag antenna and a metallic plate is increased from zero, the tag antenna impedance also increases; its magnitude is first smaller than those in free space, then the former becomes greater than the latter when the distance is longer than a threshold. Moreover, it is found that the power feeding into the IC chip becomes the maximum at an optimum distance.

I. INTRODUCTION

Radio Frequency Identification (RFID) has widely been used for various industrial and social applications. In particular, RFID based on magnetic induction has been applied to various areas such as rechargeable contactless smart card system, security cards system and retail item management [1]. However, since the magnetic fields reduce in proportion to $1/r^2$ in the quasi-static case, the communication range cannot be longer than several cms. For this reason, the UHF-band RFID using the electromagnetic waves that reduce in proportion to $1/r$ has been studied in order to increase communication range [2]-[4]. The passive UHF-band RFID, where electromagnetic energy is transmitted from the RFID reader to an IC tag, has advantages in its maintenance over active RFID that requires batteries. One of the potential applications of the passive UHF-band RFID is remote sensing of physical and chemical data such as temperature, humidity and material concentration. The remote sensing based on the RFID can be used in, e.g., non-destructive testing, automatic control and environmental monitoring. In these applications, IC tags must often be mounted on metallic surfaces. Hence, the radiation from such metallic surfaces must be carefully considered in the design of the RFID systems. For this reason, special designs of IC tag considering radiation from metallic plates have been studied [5], [6].

This paper presents an FDTD analysis of communication properties of the passive UHF-band RFID system where IC tags are placed near metallic objects. In the followings, the FDTD analysis of tag antenna impedance with near metallic objects will be presented. Then, dependence of the input power of the IC tag on the distance between the tag and metallic plate will be discussed.

II. ANTENNA IMPEDANCE WITH METALLIC OBJECTS

Since impedance matching between the IC tag antenna and the tag chip influences communication range, a proper

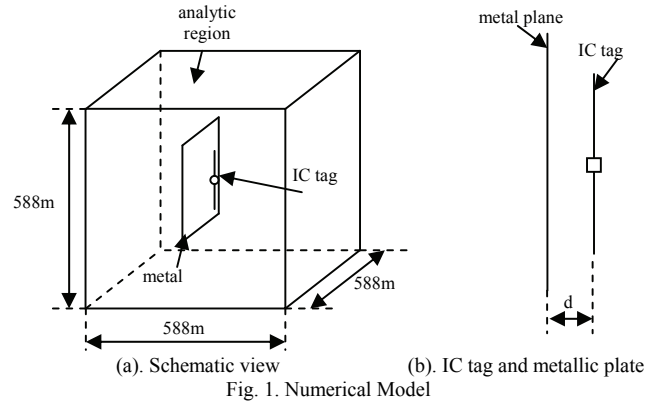

Fig. 1. Numerical Model

Fig. 2. Antenna Impedance versus distance d

impedance matching between them is very important. For this reason, the impedance of the tag antenna set near the metallic objects is analyzed using FDTD method.

The analysis model is shown in Fig.1. The tag antenna is the half-wave dipole antenna that operates at 1 [GHz], thus the dipole length is set to 150 [mm]. The square metal plane of 180×180 [mm²] is set behind the RFID tag at distance d . The tag antenna and metal plane are divided into 51 and 61 FDTD cells, respectively. The boundary condition for free space environment is the perfect matched layer. The tag antenna impedance $Z_a = R_a + jX_a$ is computed from

$$Z_a = \frac{V(\omega)}{I(\omega)}, \quad (1)$$

where $V(\omega)$ and $I(\omega)$ are the feeding voltage and current which is determined from closed path integral with Ampere's law. The dependence of tag impedance on the distance d is shown Fig. 2. The dipole antenna impedance in free space obtained by FDTD is $Z_a^f = 94.29 + j64.9$. When the distance between the tag antenna and the metal plane is very short, the magnitude of

tag antenna impedance is smaller than Z_a^f . On the other hand, the distance becomes longer, the impedance increases and both real and imaginary part become greater than those of Z_a^f .

III. RECEIVED POWER NEAR METALLIC OBJECTS

The input power received by the tag antenna depends on the antenna gain, the antenna impedance as well as the matching condition between the antenna and IC chip. For this reason, when the IC tag is placed near the metallic objects, the input power changes depending on the distance from the metal.

The numerical model to analyze the influence on the input power from metal objects is shown in Fig.3. The setting and computational conditions are the same as those of the prior analysis. The RFID reader is assumed to be sufficiently away from the IC tag so that the plane wave is illuminated to the IC tag. The power P feeding to the IC chip is computed from

$$P = |I(\omega)|^2 R_c, \tag{2}$$

where $I(\omega)$ is the current induced by the input wave and R_c is the IC chip resistance. The power P normalized by P^f which denotes the received power in free space is plotted against the distance d for two different conditions in Fig.3; in the first condition the chip impedance Z_c is matched to Z_a , that is, $Z_c = Z_a^*$, and in the second they are not matched where $Z_c = R_a - j1.5X_a$. It can be seen in Fig.3 that when the tag antenna is sufficiently close to the metal plane, the feeding power P is smaller than P^f . On the other hand, when the distance between the tag antenna and the metal plane increases, P becomes greater than P^f .

Fig. 3. Input wave and backscatters

Fig. 4. Normalized feeding powers for matched and unmatched conditions

This would come from that fact that the tag antenna receives the backscatter wave from the metal plane in addition to the input wave. Moreover, there is the optimal distance at which P becomes the maximum that is about three times greater than P^f . These facts suggest that the IC tag for metallic objects could be designed by placing an adequate gap between the IC tag and the metallic surface.

The feeding power P under the matched condition is larger than that under unmatched condition, as expected. It can be found from a further analysis that differences in the real parts of the impedance give little changes in P whereas the differences in imaginary part lead to significant changes. For example, when the relative differences in the imaginary parts are increased from 20% to 70%, the maximum power becomes 87.9 to 51.2 % of the matched case.

IV. CONCLUSION

This paper has presented FDTD analysis of IC-tag antenna impedance and received power when the IC tag is placed in the vicinity of metallic objects. It has been shown that when the distance between the tag antenna and metallic plate is increased from zero, the tag antenna impedance almost monotonously increases and its magnitude becomes greater than that in free space. Moreover, the power feeding to the IC chip placed near a metallic plate can be greater than that in free space. There is an optimal distance between them at which the power becomes the maximum.

The power feeding to the IC chip could be improved by inserting dielectric medium between the IC tag and the metallic plate. This model will be discussed in the long version. Moreover, different antennas such as meander line antenna and loop antenna will be considered to test if the conclusions obtained here is general.

The Auxiliary Problem For Transient Lossy Transmission Lines With Non-Matched Loads

Karaguler T

Beykent University, Department of Mathematics and Computing,
Sisli-Ayazaga Campus, 34396 Istanbul, Turkey
turhankaraguler@yahoo.com

Abstract—Solving transmission line problem when both transient and lossy states exist is not an easy task. One way of reducing the complexity of the problem is to introduce an auxiliary problem which has previously been applied to the problems of gas dynamics. This approach replaces the actual problem of telegrapher's equations with the equations of auxiliary problem such that non-oscillatory classical finite difference model can be built.

I. INTRODUCTION

A typical lossy transmission line requires all four parameters R, G, L and C to be considered in the model for finding voltage and current distribution along the line. The following equations (1) and (2) named as the telegrapher's equations are in fact the governing equations, or called as the main equations, of the transmission line problem.

$$L \frac{\partial i(x,t)}{\partial t} + \frac{\partial v(x,t)}{\partial x} + Ri(x,t) = 0 \quad (1)$$

$$C \frac{\partial v(x,t)}{\partial t} + \frac{\partial i(x,t)}{\partial x} + Gv(x,t) = 0 \quad (2)$$

These parameters are all taken in per unit length convention as the distance between source and load may be quite large. This further implies that the wave property also exists in the problem as a time delay from source to load can not be ignored. The wave characteristics of the problem can be also noticed from the equation which is obtained by eliminating either voltage or current from the governing equations. The problem will be complete if the boundary conditions of the line are set. These conditions are specified as the input voltage and current profiles applied at the beginning of the line and the Ohm's law at the load end.

Usual way of solving these equations is the direct approximation of the main problem in the time domain [1]. However there is a high possibility that the solution can cause oscillations due to strong dependence of the equations upon the line parameters. Therefore some care should be taken while choosing and applying the numerical method. Here the auxiliary problem is formed and used for the solution.

II. AUXILIARY PROBLEM

The auxiliary problem approach detailed in reference [2] has been applied to some engineering problems such as hydrodynamics and gas dynamics. The simplest case of lossy transmission line problem which is the matched line at the load end is also tested [3]. The method simply replaces the

line functions $i(x,t)$ and $v(x,t)$ with the $I(x,t)$ and $V(x,t)$ auxiliary functions which aim to avoid the space derivatives in the main equations. The following integral equations provide the basis for the main-to-auxiliary problem conversion.

$$L \int_0^x \frac{\partial i(\xi,t)}{\partial t} d\xi + \int_0^x \frac{\partial v(\xi,t)}{\partial \xi} d\xi + R \int_0^x i(\xi,t) d\xi = 0 \quad (3)$$

$$C \int_0^x \frac{\partial v(\xi,t)}{\partial t} d\xi + \int_0^x \frac{\partial i(\xi,t)}{\partial \xi} d\xi + G \int_0^x v(\xi,t) d\xi = 0 \quad (4)$$

The auxiliary and main current and voltage functions are related as below.

$$i(x,t) = \frac{\partial I(x,t)}{\partial x} \quad (5)$$

$$v(x,t) = \frac{\partial V(x,t)}{\partial x} \quad (6)$$

The equations (3-6) will lead to the final form of the auxiliary problem equations which are solved first.

$$L \frac{\partial I(x,t)}{\partial t} + v(x,t) - v(0,t) + RI(x,t) = 0 \quad (7)$$

$$C \frac{\partial V(x,t)}{\partial t} + i(x,t) - i(0,t) + GV(x,t) = 0 \quad (8)$$

III. DISCRETIZATION OF AUXILIARY METHOD AND RESULTS

The conventional finite difference method is applied to the auxiliary problem to obtain the solution. The line is divided into a grid with time and space steps specified beforehand. The integrals are calculated by using common quadrature formula. Then at a grid point, the finite difference equation for the auxiliary voltage is obtained as

$$V_{i,k+1} = V_{i,k} - \frac{\tau}{hC} I_{i,k+1} - \frac{G\tau}{C} \sum_{j=1}^i V_{j,k} - \sum_{j=1}^{i-1} (V_{j,k+1} - V_{j,k}) + \frac{\tau}{hC} i_0(t_k)$$

The current formula can also be obtained in the same way.

In the initial test, the line is assumed to be linear, homogeneous and matched. The line parameter values are given as $R=7.5$ Ohm/m, $L=10$ mh/m, $C=0.4$ F/m and

$G=0.003$ S/m. The length is 1 m and input pulse is 2 Volt with 0.004 ms width. As seen from figure 1 that the output voltage obtained from the method is close enough with the analytical result. The more detailed problem specifications and results can be found in reference [3]. In this paper, the work will be extended to more complex lines with different type of inputs and loads.

Abstract—A full micromagnetic code has been implemented on a low cost and low latency parallel and distributed architecture based on OpenMP and MPI over Infiniband. Extensive profiling of the original sequential micromagnetic code has been done in order to obtain better parallelization results. Since the most time consuming part of the code resulted in the magnetostatic field calculation algorithm, OpenMP and MPI directives allowed a significant improvement of the performance.

I. PROBLEM FORMULATION

Magnetization dynamics in a nanomagnet is described by the following Landau-Lifshitz-Gilbert (LLG) equation:

$$\frac{\partial \mathbf{m}}{\partial t} = -\mathbf{m} \times \left(\mathbf{h}_{\text{eff}}[\mathbf{m}] - \alpha \frac{\partial \mathbf{m}}{\partial t} \right), \quad (1)$$

where $\mathbf{m} = \mathbf{m}(\mathbf{r}, t)$ is the magnetization vector field normalized to the saturation magnetization M_s , time is measured in unit of $(\gamma M_s)^{-1}$ (γ is the absolute value of the gyromagnetic ratio), α is the dimensionless damping parameter, $\mathbf{h}_{\text{eff}}[\mathbf{m}(\mathbf{r}, t)]$ is the effective field operator which can be obtained by the variational derivative of the free energy functional [1]:

$$\mathbf{h}_{\text{eff}}[\mathbf{m}] = -\frac{\delta g_L[\mathbf{m}]}{\delta \mathbf{m}}, \quad (2)$$

where

$$g_L[\mathbf{m}] = \frac{1}{V_\Omega} \int_\Omega \left[\frac{l_{\text{ex}}^2}{2} |\nabla \mathbf{m}|^2 - \frac{1}{2} \mathbf{h}_m \cdot \mathbf{m} + \varphi(\mathbf{m}) - \mathbf{h}_a \cdot \mathbf{m} \right] dV, \quad (3)$$

$\varphi(\mathbf{m})$ is the anisotropy energy density and $l_{\text{ex}} = \sqrt{(2A)/\mu_0 M_s^2}$ is the exchange length (A is the exchange constant and μ_0 the vacuum permeability), \mathbf{h}_m and \mathbf{h}_a are the demagnetizing and applied fields, respectively, and V_Ω is the body volume. In addition, the homogeneous Neumann boundary condition $\partial \mathbf{m} / \partial \mathbf{n} = 0$ is imposed at the body surface. In order to obtain a spatially discretized version of eq. (1) we consider a partition of the region Ω in N cells Ω_k , with volume V_k and assume that the cells are small enough that the vector fields $\mathbf{m}(\mathbf{r}, t)$ and $\mathbf{h}_{\text{eff}}[\mathbf{m}(\mathbf{r}, t)]$ can be considered spatially uniform within each cell. We denote with $\mathbf{m}_k(t)$ and $\mathbf{h}_{\text{eff}k}$ the vectors associated with the generic k -th cell. Beside the cell vectors, we will consider also the mesh vectors $\mathbf{m} = (\mathbf{m}_1, \dots, \mathbf{m}_N)^T \in \mathbb{R}^{3N}$ containing the whole collection of cell vectors.

If the cells are small enough that $\mathbf{m}(\mathbf{r}, t)$ is spatially uniform in each cell, we can reasonably assume that the magnetization

amplitude is

$$|\mathbf{m}_k| = 1. \quad (4)$$

Now we can write down the discretized LLG equation in the following form that consist of a system of ordinary differential equations:

$$\frac{d\mathbf{m}_k}{dt} = -\mathbf{m}_k \times \mathbf{h}_{\text{eff}k}[\mathbf{m}] + \alpha \mathbf{m}_k \times \frac{d\mathbf{m}_k}{dt}, \quad (5)$$

where \mathbf{m}_k is the average magnetization of the k -th cell. It is worth noting that the effective field in the k -th cell depends on the magnetization of the whole cell collection due to the magnetostatic interaction, namely $\mathbf{h}_{\text{eff}k} = \mathbf{h}_{\text{eff}k}[\mathbf{m}]$.

For the numerical solution of eq. (5), we use the implicit mid-point rule scheme [2]. The midpoint discretized version of eq. (5) is

$$\begin{aligned} \mathbf{m}_k^{n+1} - \mathbf{m}_k^n &= \\ &= -\mathbf{m}_k^{n+\frac{1}{2}} \times (c_\alpha \mathbf{h}_{\text{eff}k}^{n+\frac{1}{2}} + \alpha' \mathbf{m}_k^{n+\frac{1}{2}} \times \mathbf{h}_{\text{eff}k}^{n+\frac{1}{2}}) \Delta t \end{aligned} \quad (6)$$

where the index n refers to time instants, and the following midpoint formulas have been used:

$$\mathbf{m}_k^{n+\frac{1}{2}} = \frac{\mathbf{m}_k^n + \mathbf{m}_k^{n+1}}{2}, \quad (7)$$

$$\mathbf{h}_{\text{eff}k}^{n+\frac{1}{2}} = \mathbf{h}_{\text{eff}k} \left[\frac{\mathbf{m}^n + \mathbf{m}^{n+1}}{2} \right]. \quad (8)$$

The solution of the time-stepping equation (6) requires solving a system of $3N$ nonlinear algebraic equations and provides, at each time step, the $3N$ unknowns \mathbf{m}_k^{n+1} at each mesh element Ω_k . To solve this nonlinear system we use a quasi-Newton technique similar to one described in ref. [2].

The discretized effective field in Eq. (5) is the gradient of a discretized free energy $g_L(\mathbf{m}) = g_L(\mathbf{m}_1, \dots, \mathbf{m}_N)$ which approximates the free energy functional $g_L[\mathbf{m}]$:

$$\mathbf{h}_{\text{eff}k} = -\frac{\partial}{\partial \mathbf{m}_k} g_L(\mathbf{m}_1, \dots, \mathbf{m}_N). \quad (9)$$

The effective field $\mathbf{h}_{\text{eff}k}$ can be represented as

$$\mathbf{h}_{\text{eff}k} = \mathbf{h}_{\text{ex}k} + \mathbf{h}_{\text{an}k} + \mathbf{h}_{\text{m}k} + \mathbf{h}_{\text{a}k} \quad (10)$$

where $\mathbf{h}_{\text{ex}k}$ is the exchange field, $\mathbf{h}_{\text{an}k}$ is the anisotropy field, $\mathbf{h}_{\text{m}k}$ is the magnetostatic field, and $\mathbf{h}_{\text{a}k}$ is the applied field. In our formulation we subdivide the magnetized domain Ω into N tetrahedral elements. The magnetostatic field contribution to the effective field is computed by means of an hybrid

procedure: inside the region Ω occupied by the magnetic body, the magnetostatic problem is formulated by using the Finite Formulation scheme [3] where the magnetic vector potential is assumed as unknown. Conversely, in the exterior region extending to infinity, the magnetic scalar potential at the boundary of the magnetized domain Ω is analytically computed through an integral formulation [4]. Using this method, the resulting stiffness matrix is sparse and all coupling terms between the two formulations are on the right-end-side (RHS) [5]. Starting from a known magnetization distribution, the RHS is computed by a matrix-vector product and the resulting linear system is solved by using a direct method in which the stiffness matrix is LU factorized once and for all at the beginning of the procedure. The computational cost of the LU factorization of the stiffness matrix is $O(N^3)$ and the cost of each subsequent magnetostatic computation is $O(N^2)$. Regarding the calculation of exchange field, as vector \mathbf{m} is approximated by a piecewise constant vector field (at each element Ω_k), there is not a direct way of evaluating the term $|\nabla\mathbf{m}|$ in eq. (3). The exchange field is then computed following a procedure similar to that described by Fredkin in [6].

II. IMPLEMENTATION

A. Hardware and software architecture

Since the most time consuming part of the code is the magnetostatic field algorithm, many existing parallel implementations, such as [7], use Ethernet-based clusters. In our approach we will use a low latency Infiniband network coupled with a low cost multi processor, multi core cluster. The hardware architecture includes a low cost 16 cores cluster composed by two double processor computers each based on the Intel Server Board S5000PSLSATAR motherboard, two quad-core Intel Xeon E5420 2.5GHz, and 32GB RAM. The two computers are connected by means of an Infiniband network [8], composed by two Mellanox ConnectX IB MHGH28-XTC DDR HCA PCI-e 2.0 x8 Memory Free. The Infiniband cards are directly connected together, without using a switch and are put on one PCI Express slot x16 version 1.1. The Operating system is Gentoo Linux. The programming language is FORTRAN. Several tests have been done comparing Intel *ifort* and *gcc* compilers. We have chosen *gcc* for the greater possibilities of the open source approach. With optimal choice of compiler optimization switches, the two Fortran compilers appear very similar from the performance point of view, at least with our code. On each machine, OpenMP [9] has been used for parallel computations, in particular the version included in *gcc*. The Infiniband link is a network channel selected for the MPI communication system [10]. The OpenMPI implementation has been chosen after extensive tests and comparisons with MVAPICH2. Infiniband latency has been experimentally verified as compatible with the Mellanox board specifications.

B. Profiling

Profiling by means of *gprof* [11] has been extensively used in order to better understand the internal structure of the micromagnetic code. Analyzing the profiling results, the most

time consuming part of the code resulted in the magnetostatic field calculation algorithm. It is important to note that, even if Amdahl's law significantly reduces the maximum improvement of performance, in particular in distributed computers, it appears very interesting, given profiling results, the possibility to speedup the micromagnetic code, in particular given the high complexity of some simulation scenarios.

C. Parallelization

At first any standard sequential loop is parallelized to fully exploit all the eight cores each single machine can offer; this has required setting up proper shared/private variables lists. Afterwards, the loop is split in two (n in the general case) data sets, before executing OpenMP. Eventually data is exchanged by means of MPI and merged back. This work has been done repeatedly, until the most computational-expensive functions have been correctly parallelized, always verifying results through the profiler and taking in consideration the optimization flags inserted.

III. RESULTS

A dynamic micromagnetic test case was developed in order to test different implementations of the code. In Table I is reported timing information given OpenMP and/or MPI insertion. Moreover, it is possible to see simulation times for the magnetostatic related functions before parallelization and with OpenMP and/or MPI. The overall speedup for the considered section is consistent with the initial statement. Results show that the optimized part of the micromagnetic code scales accordingly to the number of processors.

TABLE I
SIMULATION RESULTS

	Magnetostatic code [s]	Overall simulation [s]
Normal	71.2	249
MPI	42.1	174
OpenMP	14.1	129
OpenMP+MPI	7.9	59

Abstract — Conventional MRAM and STT MRAM have same the critical problem that decreases an injection current for high Gb/Chip. In this paper, we present the various MRAM design for solving the problem. As a solution, we proposed new MRAM design that has two additional high permeable poles. Proposed new MRAM design has a strong switching field owing to two poles added on both sides of the free layer, just like perpendicular magnetic recording heads. This structure is usefully more conventional MRAM for simple design and decreasing injection current. We show results that are variation of a switching field owing to two poles added on both sides of the free layer by thickness of the free layer and cell square size, injected current density with injected current density of $5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$.

I. INTRODUCTION

By portable computers and communication products, the nonvolatile memory is demanded with unlimited read/write endurance. Flash technology is expected by the value and memory capacity but has limited ($10^5 \sim 10^6$) write cycles and low write speed. Conventional MRAM has unlimited read/write endurance but has a low capacity than flash technology. Partly because conventional MRAM has a faulty structure using a simple write current injection system. For downsize scalability, the major problem that is the mere write current is required at the smaller bit size should be solved with a new design [1]-[2].

STT MRAM technology has advantages conventional (toggle) MRAM on injected current and cell size. STT writing technology, by directly passing a current through MTJ, overcomes these hurdles with much lower switching current, simpler cell architecture which results in a cell that can be as small as 6F2 (for single-bit cells) and reduced manufacturing cost, and more importantly, excellent scalability to future technology nodes [3].

We present a various MRAM design that has advantages conventional MRAM on injected current and cell size in this paper. This system is using the added high permeable pole. By the added pole, conventional MRAM or STT MRAM can have a more than simple design, increasing strong switching field and decreasing injection current.

II. DESIGN AND DRIVE OF VARIOUS MRAM

Fig. 1 shows a schematic drawing of the various MRAM elements. Fig. 1 (a) is conventional MRAM. For downsize scalability, the major problem that is the mere write current is required at the smaller bit size should be solved with a new design. We proposed a new design MRAM for a this critical

problem. The system is PTP MRAM and shows Fig. 1 (b). PTP MRAM element has two poles added on both sides of the free layer. The material of these poles has high permeability and then this system is able to have enhanced switching field. We call bit pole for the one on top of the free layer and word pole for the other beneath the free layer. Both poles have a single current line at the side. PTP MRAM has pMTJ on the bottom of the word pole. Fig. 2 (a) ~ (c) describes the write process of PTP MRAM. Memory status is “0” in fig. 2 (a) because having same direction of magnetization in the free layer and the fixed layer. When bit current and word current are injected. Magnetization of the free layer is changed rapidly by the switching field assisted by the bit pole and word pole as fig. 2 (b). Finally the state of the free layer is changed like fig. 2 (c) and then the cell has the status “1”. Usually the name of pMTJ stands for a set of free layer, fixed layer and junction but in this paper pMTJ shows only junction part like fig. 2 (d).

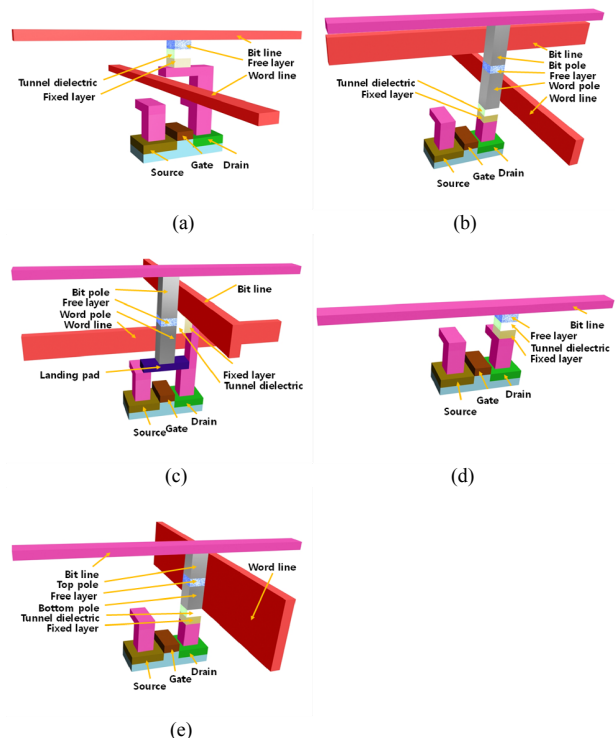

Fig. 1. Schematic drawing of the various MRAM elements. (a) conventional MRAM (b) PTP MRAM has a two high permeability poles added on both sides of free layer, named bit pole on top of free layer and word pole beneath the free layer. (c) SJP MRAM has a two high permeability poles as like PTP MRAM but this system uses a common MTJ. (d) STT MRAM. (e) PTSTT MRAM has a two high permeability poles as like PTP MRAM but this system have a additional current word line.

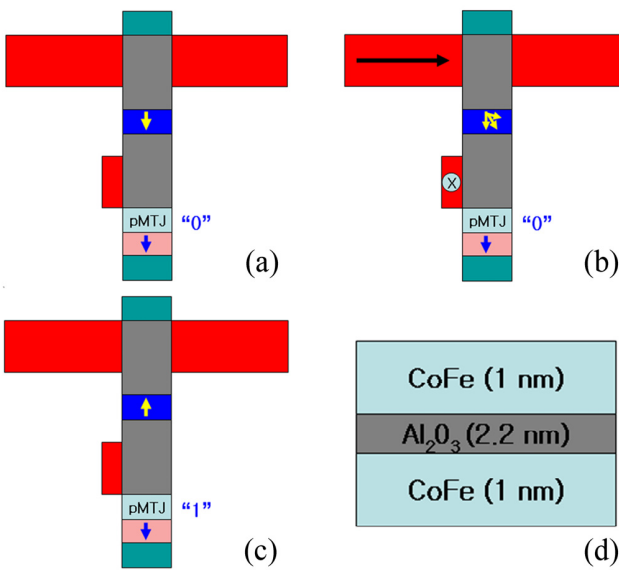

Fig. 2. . Write process of the PTP MRAM and structure of the pMTJ. (a) shows “0” status. When direct current is injected in bit and word line, status of free layer is changed like (b). Finally status of the free layer is stabilized to be ‘1’ status as (c). (d) shows the structure of the pMTJ.

The PTP MRAM has superior magnetic field efficiency than conventional MRAM because this novel system has additional high permeability poles, which are expected to generate stronger switching field than conventional MRAM system. So this system has downsize scalability and high coercivity magnet can be used in the free layer. Figure 3 shows magnetic field intensity on the center of the free layer in PTP MRAM and conventional MRAM with direct current densities $I = 5 \times 10^6 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$. Clearly the stronger switching field is generated in PTP MRAM than in conventional MRAM at the same direct current.

Fig. 4 shows write process of the side junction perpendicular MRAM (SJP MRAM). This system uses a common MTJ and added two poles. SJP MRAM system has same results on the switching field but for different MTJ solution, SJP MRAM has a complex structure than PTP MRAM and SJP MRAM have a troublesome problem on the fabrication for perpendicular fabricated MTJ

Fig. 3. Comparison of magnetic field intensity on the center of the free layer of PTP MRAM and conventional MRAM with a direct current densities factor $I = 8 \times 10^7 \text{ A/cm}^2 \sim 6 \times 10^8 \text{ A/cm}^2$. Clearly the graph shows PTP MRAM has a stronger field than conventional MRAM on the same current density injected.

Fig. 4. . Write process of the SJP MRAM (a) shows “0” status. When direct current is injected in bit and word line, status of free layer is changed like (b). Finally status of the free layer is stabilized to be ‘1’

Fig. 5. . Write process of the PTSTT MRAM (a) shows “0” status. When direct current is injected in bit and word line, status of free layer is changed like (b). Finally status of the free layer is stabilized to be ‘1’

SST MRAM technology has advantages conventional (toggle) MRAM on injected current and cell size. Fig. 1 (d) shows SST MRAM element. SST writing technology, by directly passing a current through MTJ, overcomes these hurdles with much lower switching current, simpler cell architecture which results in a cell that can be as small as 6F2 (for single-bit cells) and reduced manufacturing cost, and more importantly, excellent scalability to future technology nodes.

For decreasing the current density, we added pole system on the SST MRAM. It is Pole Type SST MRAM (PTSTT MRAM). Fig. 1 (e) shows a schematic drawing of the PTSTT MRAM element. PTSTT MRAM has a added strong switching field for spin torque reversal as like fig. 5 then this system can decrease current density.

III. CONCLUSION

This paper presents various the MRAM design for breakthrough the critical problem. Next time we will optimizing system for high Gb/Chip.

Abstract — The use of surface-plasmons-polaritons (SPPs) is one of the promising ways to develop optical components below the diffraction limit. It was recently demonstrated that gallium nitride (GaN) can play an important role in the improvement of subwavelength optical media, in particular, to serve as a material for plasmon waveguides. We report here a theoretical investigation concerning manipulation of SPPs in a waveguide made of cylindrical nanorods with silver core and GaN cladding. A hexagonal lattice of these rods forms a 2D waveguiding structure. An algorithm based on FDTD method was developed to calculate distribution of optical power of the light beam propagating in the waveguide. Attenuation of the optical signal is also calculated and compared to the results obtained for the analogous device without GaN cladding. Our results show that Ag/GaN waveguiding structure can have lower attenuation.

I. INTRODUCTION

Surface plasmons-polaritons (SPPs) are electromagnetic waves that propagate along a metal-dielectric interface by a resonant interaction between photons and free electrons at the conductor surface [1]. In information technology, SPPs are a suitable choice to implement photonic circuits with subwavelength dimensions. In other words, it can concentrate and guide optical signals through structures much smaller than the wavelength of light, yielding mechanisms for manipulation of photons at nanoscale with unprecedented transmission, processing and storage capacities. In the last five years, it was a high increase in researches in the field of nanoplasmonics.

The main challenge for construction of nanoplasmonic devices is to provide reduction of the large losses encountered by SPP waves along the direction of propagation. Such losses are due to scattering and absorption of SPPs by the involved materials. In order to overcome this problem, different types of conductor-dielectric configurations were already proposed. For instance, thin metal stripes and metallic trenches were considered in [2] and [3], respectively. A photonic crystal composed by silver nanorods is proposed in [4] where SPP propagation over a micrometric length was obtained.

This presentation reports the theoretical investigation of a waveguide composed by nanorods arranged in a hexagonal lattice. Using a developed algorithm based on FDTD (Finite Difference Time Domain) method for dispersive media [5], we show that light propagation is due to coupling between SPPs at the boundary between metallic core and dielectric cladding of the rods. The core is formed by silver and the cladding corresponds to a thin layer of gallium nitride (GaN). As it was experimentally demonstrated in [6], 2D periodic arrays of this

semiconductor can reduce optical losses in subwavelength regime when compared with bulk-GaN applications.

The aim of our work is to employ combination of GaN and silver in the design of the periodic plasmon waveguide in order to achieve lower losses in comparison with the analogous device made only by silver rods.

II. SPP PROPAGATION THROUGH HEXAGONAL LATTICE WAVEGUIDE MADE OF AG/GaN NANORODS

The structure under investigation is made of silver nanorods with diameter of 80 nm, each one surrounded by a thin layer of GaN such that the obtained cylinder has a radius of 50 nm. The rods are periodically organized in hexagonal unitary cells with lattice constant $a=200$ nm. The geometry of this structure is depicted in Fig. 1.

Fig. 1. Geometry of the plasmon waveguide based on nanorods arranged in a hexagonal lattice. Each rod is composed by a silver core and a thin GaN cladding.

The refractive index of GaN is assumed 2.5 and the dielectric function of silver is described by the Drude dispersive model (1).

$$\varepsilon(\omega) = \varepsilon_{\infty} - \omega_p^2 [\omega(\omega - i\Gamma)]^{-1}. \quad (1)$$

The constants that appear in (1) were experimentally determined [7] and they are listed in table I.

TABLE I
CONSTANT VALUES OF DRUDE MODEL

Constants of Drude model	Values
ϵ_∞	3.70
ω_p	13673 THz
Γ	27.35 THz

The simulations were carried out employing our numerical algorithm based on FDTD method for dispersive media [5]. The peculiarity of this approach is the presence of the polarization current density \bar{J}_P (2) in the update equation for electric field \bar{E} by virtue of dependence on frequency of the dielectric constant.

$$\bar{J}_P^{n+1/2} = \left(\frac{2}{2+\Gamma\Delta t} \right) \bar{J}_P^n + \frac{\epsilon_0 \omega_p^2 \Delta t}{4+2\Gamma\Delta t} (\bar{E}^{n+1} + \bar{E}^n), \quad (2)$$

where ϵ_0 is permittivity of vacuum, Δt is the time increment and n is the time step.

To perform numerical calculation we used a Gaussian beam as source with waist of 200 nm. The boundaries of the computational domain where modelled by PML (Perfectly Matched Layer) technique [5]. The light incident into the waveguide is a TE (E_z , H_x , H_y) polarized wave. Intensity distribution in a single Ag/GaN nanorod and in the plasmon waveguide for a Gaussian beam at wavelength of 600 nm is depicted in Fig. 2(a,b).

The mechanism of optical power flow along the waveguide is coupling between surface plasmons excited from one set of Ag/GaN nanorods to the subsequent one.

Fig 2: Optical intensity distribution in the waveguide based on Ag/GaN nanorods in hexagonal lattice. A Gaussian beam at wavelength of 600 nm is used as source. (a) Intensity distribution in a single nanorod. (b) Intensity distribution along the waveguide.

The attenuation of light in the waveguide is showed in Fig. 3. Comparison to the attenuation related to simple silver nanorods in hexagonal lattice is also presented. For both cases, the guided wave has lower attenuation for wavelengths longer than 550 nm. Notice that application of GaN layer around the metallic rods leads to a reduction of losses for wavelengths lower than 600 nm and greater than 700 nm. A possible explanation for such decrease is the stronger confinement and coupling of SPPs waves provided by the periodic array of GaN claddings.

Fig. 3: Attenuation in the periodic plasmon waveguide calculated for incident Gaussian beam at wavelengths in the range 450-800 nm.

Our numerical analysis shows that the used thickness of the GaN cladding can be regarded as the optimum value. Lower thicknesses only slightly decrease the attenuation peak approximately by 1%, having no appreciable impact for other wavelengths in the range. On the other hand, a greater value of thickness cladding diminishes the coupling of SPPs between adjacent rows of nanorods and this leads to increasing of attenuation factor.

III. CONCLUSION

A theoretical investigation of a plasmon periodic waveguide composed by nanorods with silver core and GaN cladding in hexagonal lattice is presented in this work. The numerical simulations show that light can be guided through such structure by coupling of SPPs excited at the Ag/GaN boundaries. A comparison with the analogous waveguide made only by silver rods shows that, for the spectrum under analysis, there are wavelength ranges where light undergoes lower attenuation if GaN is used as cladding material. Thus, our results show that such metal-dielectric composition can potentially be useful for projects including optical waveguides and other photonic components in subwavelength regime.

Abstract — This paper presents a model applied to find the best antenna base station (BS) positioning of indoor wireless systems. The model uses a mono-objective Particle Swarm Optimization (PSO) code, associated to a 2D ray-tracing (RT) algorithm. The PSO optimizes the antenna location by maximizing fitness. For a given BS location, the fitness is obtained by calling a RT algorithm that returns the lower electric field value in the regions of interest. The proposed model was applied in a practical indoor environment. The use of PSO in this application was compared with a validated Genetic Algorithm (GA) applied in the same problem. From several simulations, we observed that PSO presented more satisfactory results than GA for this electromagnetic problem.

I. INTRODUCTION

Nowadays, wireless communications systems are present in several applications. The diffusion of these this kind of systems (e. g, IEEE 802.11 standards), caused by the technological progress and the decreasing prices of wireless devices, suggests a more accurate design of these systems in order to have the same quality of wired communication networks, but maintaining the wireless network advantages.

One of the requirements to achieve this quality is through appropriate positioning of the base station (BS). The ideal BS location is that providing good communication between the BS and all users of the cell. Almost all quality parameters of a wireless system are related to the signal level provided by the BS to the network users. Nevertheless, the excessive power from BS can cause interference in near cells sharing the same frequencies, which requires appropriate design.

This paper considers the problem of maintaining, as best as possible, good signal level for all users in the cell covered by BS. The way used to apply this idea was done by maximizing the lower electric field in the regions of interest.

Thus, this paper proposes a new model that uses a optimization code based on the concept of a Particle Swarm Optimization (PSO) algorithm associated with a 2D Ray-Tracing (RT) method for determining the electric fields in all interest regions of the cell by using Geometric Optics (GO) and Uniform Theory of Diffraction (UTD).

In order to validate the proposed model and evaluate the PSO in this type of application, we analyzed a practical indoor scenario where the optimal BS antenna position must to be found for providing proper signal to all network users. We simulated both the present PSO/RT model and the model proposed in [1], which uses Genetic Algorithm (GA) associated to a RT code. As will be shown, the proposed model gives better results for the analyzed example.

II. PROPOSED MODEL

Although the techniques used to develop the model proposed here are well known, the association of these techniques for antenna positioning problems in indoor scenarios is an original work.

The Particle Swarm Optimization (PSO) is a population-based stochastic technique developed by Kennedy and Eberhart [2]. As PSO is effective for electromagnetic optimization problems, it was chosen to be used in the model proposed in the present paper.

The PSO is based on social behavior taken from nature observation, but excluding eventual cognitive factors. Similar to GA, the PSO initiates with a population (composed of many particles) of random solutions [3]. To each potential particle (x_{id}) is assigned a randomized velocity (v_{id}). After the first evaluation of the fitness associated to each particle, it keeps track of the coordinates (p_{id}) in the problem space associated with the best solution ($pbest$) [3]. The overall best value ($gbest$) and its location (p_{gd}) are also stored during the procedure.

With a simple procedure, these stored data are iteratively updated using random parameters and fixed constants (w , c_1 , c_2), changing the particles velocities in order to intelligently explore the search area at each iteration.

$$v_{id} = w * v_{id} + c_1 * rand(\cdot) * (p_{id} - x_{id}) + c_2 * rand(\cdot) * (p_{gd} - x_{id}) \quad (1)$$

$$x_{id} = x_{id} + v_{id} \quad (2)$$

The PSO used in the present model adopts the acceleration constants (c_1 and c_2) both equal to 2.0 [3] and a zero inertia weight ($w = 0$).

In the application example consider here, corresponding to the BS antenna positioning, it is necessary to evaluate the fields in the regions of interest, where users can be connected to the wireless network. Here, the fitness for each BS position corresponds to the lower value of electric field in these regions. The reason behind this choice is that, if the lower field is maximized in the regions of interest, all the users will receive a good signal level. This fitness evaluation is done using a code based on Ray Tracing (RT) technique. RT is an asymptotic method widely used in the prediction of high frequencies coverage problems, with good results. The RT code used in the proposed model is based on image theory (IT) and includes an accurate approach to take into account the shift of the rays transmitted through obstacles [1].

The formulation used in the RT code (based on IT) considers the more relevant paths that leave the BS antenna and reach the reception points. The IT permits field

computation only in the regions of interest. After path definition, the sum of all fields is done. Fields corresponding to each path are computed using a GO/UTD formulation.

The proposed model is intended to be used for indoor environments, where the main mechanisms involved are reflection and transmission through the obstacles. Hence, we neglect the effects of edge diffractions for this application, which allows a significant computation time reduction, given that the code is called many times for the optimization program.

Thus, as said, for a given reception point, the total electric field is given by the sum of the fields due to all considered paths, where the field due to each path is given by:

$$E_R = A_s E_0 e^{-j\beta s} \left\{ \prod_i \Gamma_i \right\} \left\{ \prod_k T_k \right\} \quad (3)$$

where A_s is the spreading factor, s is the total distance (in the air) of the path from a reference point to the receiver; ρ is the distance between the transmitter and the reference point; E_0 is the electric field calculated at this reference point considering a free space propagation in the far-field region; β is the phase constant; Γ_i is the reflection coefficient due to i -th reflection and T_k is the transmission coefficient due to k -th transmission of the ray (taking into account the propagation through lossy obstacles [1]).

III RESULTS

The proposed model was applied in a practical scenario, located at GRUCAD / UFSC laboratory, aiming to optimize the *access point* (i.e., BS) location of the 2.4 GHz WLAN (Wireless Local Area Network – IEEE 802.11g) used in this *indoor* environment.

The reception points do not correspond to the whole scenario, but only in certain regions of interest. The obstacles considered in the environment are the walls, doors and windows, with different types of lossy materials.

To validate the proposed PSO/RT model, the same problem was also simulated with the GA/RT model presented in [1]. In both cases, we used more restrict interest regions compared with [1], in order to decrease the simulation time and permit a more adequate number of iterations/generations. As said, the PSO/RT parameters were $c_1 = c_2 = 2$ and $w = 0$. For the GA/RT case, the crossover probability was 0.95 and the mutation probability was set to 0.05.

In order to compare the models, we used the same number of individuals (equal to 20) and the same number of iterations/generations (equal to 70) for each algorithm. Thus, the whole optimization process requires 1400 RT runs for both models. For the analyzed problem, the large majority of the computation time is spent in computing the field values by the RT tool. Thus, an equal number of RT runs indicates approximately the same computation time for both algorithms.

Fig. 1 shows the fitness of the best individual (g_{best} , for PSO) as a function of the number of RT runs. The curves have been obtained by averaging the results of six simulations

carried out with different initial populations (randomly chosen) for each model.

From the curves, we observed that the PSO/RT converged faster than the AG/PSO model.

Fig. 1. Comparison between PSO and GA simulations.

Fig. 2 presents the electric field mapping in the environment with the access point antenna placed at the optimal location corresponding to Fig. 1, namely, $X = [6.2311 ; 6.4517]$ (m). The computation for each simulation is about 3h 30min using a 1.6 GHz Intel Dual-Core processor, with a 1 GB RAM memory and an 80 GB HD.

Fig. 2. Field mapping corresponding to the optimal antenna location.

IV CONCLUSION

The PSO/RT presented in this paper was shown to be effective in indoor wireless design applications. The comparison with the GA/RT model in the same problem shown that the PSO/RT presented better results in terms of convergence, which allows obtaining a reduction in the computation time for a given stop criterion.

The extended version of the paper gives more details on the model formulations. Also, we present the results for another application example and a discussion concerning the convergence criterion to be used.

alaudani@diees.unict.it

Abstract— In this paper a ray tracing procedure for the prediction of indoor EM fields based on a new accurate formula for the transmission path is presented. The novel formula is derived by using the Snell law and analytically relates the incidence angle and the transmission angle to the wall thickness; this new expression leads to very accurate results in the predictions.

I. INTRODUCTION

The increasing number of wireless communications systems, including WLAN and micro-cell networks, requires a more detailed planning in order to assure adequate covering within the interesting region keeping field levels within the bounds allowed by regulations. The prediction of the EM field strength in indoor environments is generally obtained by using a ray optical method (ray tracing) able to take into account the presence of multipaths, reflections, and diffractions[1]. The ray tracing technique is based on optical geometry (GO) and on its generalization, the geometric theory of diffraction (GTD). The main assumption of GTD is that all the obstacles must have a size larger than the signal wavelength. In Ray Tracing propagation models for indoor and outdoor environments the EM field computing is carried out through separate evaluations of all the field components, due for example to reflection, refraction, diffraction and scattering coming out from the interaction with various obstacles. The field strength is computed by a coherent sum of all those field components [1]. A complicate field distribution arise because of these interactions, so an high accuracy in the evaluation of each single component is required. Two different approaches can be pursued for the determination of propagation loss: the Shooting and Bouncing Rays (SBR) or brute force ray tracing and the Image Theory (IT). The former launches from transmitter a set of rays equally angularly spaced and it computes the field at receiving points by adding all the contributions due to rays arrived or passing in proximity of them. The latter uses image sources in order to compute relevant paths and leads to more accurate results and to a reduction of the computational cost [2]. The main inconvenient of this approach is the need of a more accurate computation of the geometrical characteristic of the various paths, above all regarding the angle of incidence for the transmitted components [3-4].

In this paper a new approach is presented for the evaluation of the transmitted component of the field by using an innovative formula for the accurate computation of the

transmission path in order to enhance electromagnetic field prediction precision in indoor environments. The new deterministic expression uses an iterative procedure to compute the transmission path contribution leading to extremely accurate value of the incident angle after a few iterations. An example of application to a simple indoor environment is also presented in order to show the accuracy of the approach.

II. RAY TRACING TECHNIQUE AND NEW EXPRESSION FOR THE TRANSMISSION PATH COMPUTATION

The construction of EM field strength maps by means of the ray-tracing algorithm consists of two main phases: in the first the visibility between elements of the environment is represented by a visibility tree; in the second phase all the propagation multipaths between a transmitter T and a receiver R (measurement point) are determined and the contributions of these multipaths to the total field strength are computed. The multipaths and the propagation environment is modelled by means of a set of objects O_k , belonging to the various obstacles, which act as virtual sources with respect to the various phenomena of diffraction, scattering and reflection. They contribute to the total field by adding a specific component computed according to appropriate formulas. In order to reduce the time needed for the construction of all the possible paths between T and R (considering also that usually we have to deal with many measurement points), we use “the visibility tree”, which contains a propagation path in each branch. In this way the complete search of all the admissible paths can be easily obtained by visiting the visibility tree. The number of levels of the visibility tree corresponds to the maximum number of interactions between the objects considered in the ray optical propagation model. At the first level there is only the root represented by the transmitting source T. The branches originated from this root T constitute the second level, to which all the objects O_k directly visible from T belong. In this second level each object O_k represents the root for the successive level of the tree constituted by all the objects O_j directly visible from O_k . In this way in the branches of each level it is possible to find all the objects directly visible from the objects belonging to the preceding level, and the connections are in such a way to specify all the admissible paths from T to each object. The construction of the tree can be made recursively and the only condition to check in the extraction of the admissible paths from the visibility tree is that each O_k be present only once for each propagation path. The determination of direct visibility is

performed by using simple geometrical concepts such as intersection of a line with a face and a plane, which represent obstacles. Even in this case a pre-processing of the environment, excluding some obstacles according to their position, allows a reduction of the computational effort. For the computation of the various field contribution (reflected/transmitted/diffracted/scattered from obstacles, etc) apposite expression are used, considering the characteristic parameters of the material constituting each obstacle [1]. The EM field strength is obtained by coherently adding all the field components as follows:

$$E_{tot} = E_{los} + \sum E_r + \sum E_t + \sum E_d + \sum E_s$$

where E_{los} indicates the direct line of sight components and E_r , E_t , E_d and E_s indicate the reflected, transmitted diffracted and scattered components.

When considering a transmission path the accuracy of the ray-tracing field computation is strictly dependent on the evaluation of the transmission coefficient T. For this reason a new closed form expression for obtaining T has been derived based on a geometrical analytical approach, relating the incidence angle and the transmission angle to the wall thickness. The expression is based on relative positions of the source, the wall and the receiver. Starting from geometrical considerations it is possible to obtain:

$$\tan \vartheta_m = \frac{(l_1 + l_2)}{l_1 + l_2 + d} \tan \vartheta_i + \frac{d}{l_1 + l_2 + d} \tan \vartheta_r$$

Fig. 1 – Schematization of the transmission path computation

Then, by using the Snell Law, for the relation between the angles, it is possible to obtain the following expression:

$$\begin{aligned} \tan \vartheta_m (l_1 + l_2 + d) - d \frac{n_1}{n_2} \left(\sqrt{\frac{n_2^2 - n_1^2}{n_2^2} + \frac{1}{\tan^2 \vartheta_i}} \right)^{-1} \\ = \frac{(l_1 + l_2)}{l_1 + l_2 + d} \tan \vartheta_i \end{aligned}$$

where n_1 and n_2 are the refractive indexes of the regions; l_1 , l_2 and d are, respectively, the distance between the source and the wall, the thickness of wall and the distance between the wall and the receiver.

$$\vartheta_i = \arctan \left(\frac{2n_2}{\sqrt{n_2^2 - n_1^2}} \frac{\sigma}{1 - \sigma^2} \right)$$

in which σ is the only solution of the following equation:

$$\sigma^4 + 2 \frac{B-1}{A} \sigma^3 + 2 \frac{B+1}{A} \sigma - 1 = 0,$$

where

$$A = \tan \vartheta_m \frac{l_1 + l_2 + d}{d} \sqrt{\left(\frac{n_2}{n_1} \right)^2 - 1} \quad B = \frac{l_1 + l_2}{d} \frac{n_2}{n_1}$$

By using this new expression very accurate results have been obtained in the predictions. More details including comparison with other approach will be given in the full paper.

III. EXAMPLE OF APPLICATION

The following numerical experiment regards the application of the prediction procedure to the determination of intensity of a known EM sources in a real indoor environment (Fig. 2).

Fig. 2 – indoor environment used for numerical experiment and color map of field strength

The region contains obstacles having different dimensions and different electrical features. The source (whose position is shown in the same figure) produces a complicate field distribution because of reflection, refraction, diffraction and scattering due to the interaction with obstacles. In the colour map shown in Fig.2 the distribution of the transmission field component intensity is reported.

Abstract— This kind of interference may be caused by couplings between the terminals and the circuit lines. This work allows to study the effect of the metal post in the middle, and the radiated energy and the coupling between post. Through the WCIP (wave concept interactive procedure), which uses concepts of incident waves, can be estimated the effect of the fields of posts in metal laminate as the radiation and coupling between the post.

I. INTRODUCTION

Once the circuit conception companies dominate a relatively established technology competence, nowadays the researches attention has focused on the demand for more integration and reduction size of these devices. This integration can be done with the use of the multilayer laminate (and bridges accesses), increasing the packing densities of device or also with the introduction of antennas in chip [1]-[3]. The need for a large flow of data has grown the clock frequency resulting in the increase devices electrical length. Therefore, it inevitable increases the parasitic electromagnetic (EM) coupling between the elements.

In the multilayer configuration the interconnection between layers are made using via of access. In some cases these structures can be characterized as cylindrical metal post. This via high frequency current generates an electric field distribution in the region around it. This field can cause coupling in others via and/or printed circuit nearby.

Can be used the post also isolating a region of electromagnetic interference [4]. This can be used to isolate devices who generate or cannot get much electromagnetic interference.

The representation of electromagnetic fields by waves is used since many years [5]. The WCIP (wave concept interactive procedure) method is based on full wave transverse formulation. The incident wave concept the multiple reflection on the region. The incident wave and scattered wave in the spatial domain and in the spectral domain.

This work studied the effects of via. Will be observed the electric field generated by a source near and one way to minimize this effect.

II. WAVE CONCEPT INTERACTIVE PROCEDURE

The formulation of the iterative method has been described in [6-8]. This method allows representing the electromagnetic (electric and magnetic field) as a function of incident waves (a) and reflected (b), the waves are defined from a surface, see Fig.1.

Fig.1. Emitted and reflected waves on surface.

$$\begin{cases} \vec{A} = \frac{1}{2\sqrt{Z_0}} (\vec{E}_T - Z_0 \vec{H} \times \vec{n}) \\ \vec{B} = \frac{1}{2\sqrt{Z_0}} (\vec{E}_T + Z_0 \vec{H} \times \vec{n}) \end{cases} \quad (1)$$

$$\vec{J} = \vec{H} \times \vec{n}$$

With Z_0 is the wave impedance, E and H , the electric and magnetic fields tangential to the surface and n the vector normal to the surface.

Two operators are successively applied to these waves. The scattering operator \hat{S} [6], which takes into account the boundary conditions in the spatial domain ($E_{t1} = E_{t2}$) and $J_1 + J_2 = 0$ on the dielectric, $E_{t1} = E_{t2} = 0$ on the metal. This means when metal $S = -1$ and dielectric on $S = 1$.

The reflection operator $\hat{\Gamma}$, which takes into account the environment's reaction in the spectral domain, is defined as:

$$\hat{\Gamma} = \frac{Y_0 - \hat{Y}}{Y_0 + \hat{Y}} = -1 + \frac{2Y_0}{Y_0 - \hat{Y}} \quad (2)$$

Where \hat{Y} is the admittance the region, and using de induction law of Faraday and the auxiliary potential, can be find de relation of E and J .

$$\hat{Y} = \frac{E}{J} = \frac{(\nabla^2 + k_0^2)}{j\omega\mu_0} \quad (3)$$

Replace (3) in (2), and rewriting the reflection operator

$$\hat{\Gamma} = -1 + \frac{2jY_0\omega\mu_0}{(\nabla^2 + k_0^2 + jY_0\omega\mu_0)} \quad (4)$$

Can approximated the second term of (5) by Hankel function second kind and zero order.

$$\hat{r} = -1 + 2jk_0^2 \int_{r'} H_0^{(2)}(k|\vec{r} - \vec{r}'|) d^2 r' \quad (5)$$

k_0 is the wave number in the free space.

III. SIMULATION

Simulations were made for situations with an operating frequency of 10GHz. Initially is not considered the height of the post, is only the distance d . Considers the post is the cylindrical shape of radius equal to 0.5 mm. Now is considered the case of 1D, but the formulation of the study 3D case was in progress.

The simulations initially are compared when there is only one post in the free-space and three post, with the central is the source and observing the coupling between the central and the two sides.

Fig.2. Distribution of post in space

Fig.3. Compared electrical field one post and three post in the free-space.

Fig.4. Compared electrical field three post and five post in the free-space.

In Fig.3, is seen the field generated by a source close. Can be seen the effect of coupling between the post. The electric field at the surface of the side post generates a current density, and causing interference.

In Fig.4, note the reduction in the electric field in the lateral post. With the introduction of two new posts may be to reduce interference between the side posts.

With the introduction of side post can notes that there is a decrease in electric field in the region. Notes that the region is the side posts is a reduction of the intensity of field. This effect allows use these post to cause an effect of shielding the region.

IV. CONCLUSION

The use of vias can cause effects of electromagnetic interference in integrated circuit, when using high frequency, as shown in Fig.3 and Fig.4. But the vias or metal post can also be used to reduce the effect of electromagnetic interference in integrated circuits, as can be observed in the simulations. The WCIP method, which uses the concept of incident wave, can characterize the metal post in the central region of the laminate. And thus determining values of distances between post but, also the introduction of post to minimize the effect of electromagnetic interference.

Abstract — The Partial Element Equivalent Circuit method (PEEC) is well suited to extract the conducted electromagnetic disturbances parameters from wiring systems. It provides an efficient tool for the EMC study relevant to automotive cables. However the complete EMC analysis of embedded systems requires also reliable models for the radiated emissions especially at high frequencies. In this paper a new approach based on the PEEC method and involving 3D field calculation is developed to evaluate emissions from radiating cables.

I. INTRODUCTION

In automotive industry the functional safety of electronic systems is a crucial challenge. Actually, the integrated circuits (ICs) and transistors used to construct these electronic systems become more vulnerable to interferences and damages from Electromagnetic (EM) disturbances. The main reasons are : the feature size decrease, the operational speed increase, and the operating voltages fall. Such developments make electronic equipments more easily corrupted by a given electromagnetic disturbance which can be induced inside the car due to the fact that power systems and control systems stand together in the same closed environment. In fact, the majority of these disturbances are propagated between sub-systems through cables in a conducted and/or radiation form, resulting in inaccuracy, malfunction, or failure of these systems. For these reasons, adequate EMC studies are necessary and the prediction of EM behavior is of vital importance to ensure reliable and EM compatible systems.

Therefore, several numerical methods of electromagnetic modeling are available and can be used for electromagnetic analysis. Among these methods, the Partial Element Equivalent Circuit method (PEEC) [1][2] is particularly well suited. In comparison to Finite Element Method or Finite Difference Method, PEEC only needs the discretization of conducting regions or dielectric materials avoiding the mesh of surrounding air environment. Usually the PEEC approach is an efficient way to deal with circuit simulation of distributed structures. In [3] a 3D model based on the PEEC method was proposed in order to take into account the size of automotive wiring systems. It includes resistive, inductive and capacitive effects. Such 3D approach was shown to accurately predict the conducted disturbances by cables above large ground planes. In automotive applications electronic systems are used with increasingly higher frequencies and the radiation of cables cannot be neglected.

In this paper a new approach is developed to evaluate the radiated fields with the PEEC method. The originality of this work is considering both radiated and conducted disturbances in the framework of a PEEC method for large size structures. In a first step the current carried by the conductors are determined from the circuit model deduced with the 3D PEEC method. Then in a second step the field radiated by the wiring systems is evaluated using an analytical calculation deduced from the distribution of currents. The advantage of this approach is a lower processing time for the same desired accuracy as a full wave numerical method.

II. 3D RADIATED FIELD

The PEEC method is based on three main steps. In a first stage, the structure is discretized into a series of cells. An equivalent circuit is deduced in a second step. The third step is to implement this equivalent circuit in a SPICE simulator [4] : the output data are the current and voltage values in each point of the structure. The analytic calculation of the magnetic near-field is based on the equation (1) which uses the previously determined current:

$$\vec{A}_\gamma = \frac{\mu}{4\pi} \vec{J}_\gamma \iiint_{V'} \frac{e^{-jkR}}{R} dv' \quad (1)$$

where $\gamma = x, y, z$ and k is the wave number, \vec{J}_γ is the current density crossing the volume V' , \vec{r} and \vec{r}' defines respectively a point M from where the vector potential has to be determined and a point P in the volume (Fig. 1.).

The distance R between P and M is given by:

$$R = |\vec{r} - \vec{r}'| = \sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2}$$

Fig. 1. Cell crossed by \vec{J}_x current

The vector potential can be calculated analytically if each cell is considered as an equivalent 1D dipole [5][6]. But this approach is not realistic because only one dimension of the cell is taken into account: it may lead to inaccurate results near to the conductor. In order to improve the computation, an analytical method extended to 3-D is proposed in the next section to calculate the magnetic near field. Once the magnetic vector potential is computed, the magnetic field can be deduced from the equation (2):

$$\vec{H} = \frac{1}{\mu} \nabla \times \vec{A} \quad (2)$$

III. 3D-CALCULATION OF THE MAGNETIC FIELD WITH A MACLAURIN SERIES

In the proposed approach, the three dimensions of the cells are considered. To insure a high accuracy, no approximation is performed on the current cross section: a 3D series MacLaurin method is used. It is assumed that the dimensions of the discretization cells are very small compared to the wavelength. Therefore, a multivariable function f can be written in a form of a MacLaurin series expansion:

$$f(X) = \frac{e^{-jkR}}{R} = f(0) + \sum_{i=1}^3 \frac{\partial f(0)}{\partial x_i} x_i + \frac{1}{2} \sum_{i=1}^3 \sum_{j=1}^3 \frac{\partial^2 f(0)}{\partial x_i \partial x_j} x_i x_j + \dots \quad (3)$$

where the origin corresponds to the center of the cell.

In the work the expansion is limited to the third order. From the 3D integration of this function an analytic expression of the vector potential can be deduced and then the magnetic near field in the whole area can be determined. The technique has been first validated in different canonical configurations. In the next section a realistic test case is considered.

IV. APPLICATION TO THE RADIATION OF A CABLE: SIMULATION AND MEASUREMENT

The method is tested in the case of a conducting cable (Fig 2.) made up by a wire located 5mm above a ground plane. Such configuration was chosen in order to illustrate the ability of the approach to handle large size systems. The length of the wire is 2 m. It is connected to a 50Ω resistance at an extremity of the ground plane.

Fig. 2. Description of the studied system

A Vector Network Analyzer (VNA) is used to measure the S11 parameter of the system from which the input impedance is deduced. The comparison of the simulated and measured input impedance is shown on fig. 3. The magnitude and position of the resonance peaks are well recovered.

Fig. 3. Measurement and simulation of input impedance

A source current excitation is prescribed at the other extremity. The frequency is 30 MHz. The magnetic field cartography determined by the PEEC method combined with the analytic calculation is compared to measurement results (Fig. 4.a and Fig. 4.b). The values are located on a plane at 2cm above the ground plane. The measurements are obtained with a near-field test bench [7]. A good agreement is shown between the two plots. In the conference different configurations will be analyzed and the influence of the frequency will be studied.

Abstract — This paper presents the behavior of a grounding mesh in presence of a high-frequency overvoltage transient caused by switch closing in electrical substation. The simulation of the mesh is based on Transmission Line Method (TLM). The output of the simulation is the sum of induced and conducted currents caused by such high-frequency overvoltage input in some spot of the mesh. The conductors of the mesh are modeled by thin wires developed by Naylor and Christopoulos. This way, the simulation runs much faster than those with short-circuit nodes. Details on the soil properties such as resistivity and dielectric constant are provided.

I. INTRODUCTION

Electronic devices are widely used in power substations for measurement and control of electrical quantities. It is known that, frequently, these devices are seriously damaged by high frequency outbreaks provoked by operational maneuvers and atmospheric discharges [1], [2]. Therefore, it becomes necessary to implement a simulation method to predict the distribution of electric and magnetic fields through a mesh and develop methods to avoid the problems that such outbreaks might cause to the equipments.

Transmission line modeling (TLM) has been applied as a method for the solution of electromagnetic field, diffusion and network problems [3]. Due to the fact that TLM is a time-domain simulation method, it is possible to verify transient effects in a wide range of frequencies. In that manner, the TLM will be used as the simulation method. Formerly, the conductive nodes in TLM were represented by a node called short-circuit node, which represents the property of the tangential electrical field at the conductor surface. Because of the small radius of most conductors in grounding systems, such node becomes very time-consuming when large volumes are required to be simulated. To overcome this problem, Naylor and Christopoulos proposed a large node that represents a small radius conductor in one direction [4]. This way, larger volumes can be simulated with less time requirements. Previous simulations performed by the authors have shown that the use of the node proposed by Naylor and Christopoulos requires only 5% of the time for the short-circuit node simulation. Moreover, the memory requirements are far lower because of the reduction on the number of nodes.

The authors propose the use of TLM to the simulation of grounding meshes to optimize system protection. A small grounding system is presented in order to show that the effectiveness of the simulation can be extended to big systems such as electrical substations.

The reduction of the simulation time makes possible testing several configurations in order to determine which one is the most efficient with respect to voltages and currents

distributions throughout the grounding mesh. And so, the damages to the electronic devices tend to be reduced.

II. TRANSIENT EXCITATION OF THE MESH

The waveform used as input of the simulation is a real transient overvoltage caused by a switch closing in a 500 kV substation in Itaparica, Northeast Brazil. The measurements were performed using the methodology used in [5]. The measured transient in that occasion is shown in Fig. 1.

Fig. 1. Measured overvoltage transient in Itaparica electrical substation.

The waveform in Fig. 1 was acquired at the grounding connection of the switch. In other words, that voltage waveform is the one injected in the grounding mesh of the substation during the transient event.

Still in Fig. 1, one sees that peak of more than 1.5 kV is achieved (more than 2.5 kV peak-to-peak). Performing the Fourier Transform in that waveform, frequency components in the order of hundreds of kHz may have considerable levels. Analysis of the frequency components of the measured transient voltages injected in the mesh will be presented.

III. SIMULATION SETUP

The simulated mesh is shown in Fig. 2. The conductors' radii are set to 1 cm; the TLM discretization is $\Delta l = 0.1$ m, and so, the relationship $r \ll \Delta l$ holds [4]. The total dimensions of the simulated volume are $2 \times 4.5 \times 3$ m.

Capacitive nodes were inserted in order to model the soil properties such as variation of dielectric constant and losses [6]. The conductive nodes were modeled based on an admittance model developed by [3], as follows:

$$Y_{cm} = \frac{\sqrt{\epsilon_r}}{60 \ln(0.54 \Delta l / r)}, \quad (1)$$

where Y_{cm} is referred to as common-line admittance, Δl is the length discretization of the TLM model, r is the conductor wire diameter and ϵ_r is the dielectric constant of the medium where the conductor is inserted in. Because the lack of symmetry of the thin wire model node, 3 matrixes were implemented in the simulation routines, one for each of the coordinate axis.

Fig. 2. Simulated grounding system.

The model of the soil regards one layer, whose dielectric constant and resistivity are $\epsilon_r = 3$ and $450 \Omega \cdot m$, respectively. The dielectric constant value was obtained according to the technique outlined in [7]. On the other hand, the resistivity value was measured according to the Wenner method [8].

Absorbing boundary conditions were imposed to the simulated volume so that no reflections are observed at the boundaries of the model.

IV. RESULTS AND DISCUSSIONS

The behavior of the propagating fields, currents and voltages in this mesh indicates whether the grounding system has to be optimized or not. Fig. 3 shows the current in the middle vertical conductor as a result of the incident voltage from Fig. 1. As well as the current, the results can be easily extended to the voltage along the conductors to verify whether electronics devices can be connected to each other (data cables connections, for instance) if they are submitted to different ground potentials during a transient event.

Fig. 3. Simulated current through the middle vertical conductor.

Currently, voltage simulations are being carried out as well as a real grounding mesh prototype is being constructed. Measurements will be performed in the prototype mesh in order to validate the simulated results. Results concerning the distribution of transient voltages in the mesh will be presented.

V. CONCLUSIONS

Effects of a transient in a small grounding system are simulated. Because of the time-saving benefit of thin wire models in TLM, these simulations can be extended to bigger grounding systems such as in electrical substations. The simulation outputs might be current, voltages and electromagnetic fields in one or several spots in the mesh. Thus, grounding systems can be optimized to mitigate high frequency transient effects in electrical substations.

Abstract — The conservativeness of the homogeneous flat phantom filled with head tissue equivalent liquid for the Specific Absorption Rate (SAR) conformity assessment of body-worn wireless communication devices is investigated. Numerical simulations are performed using three flat phantom models – homogeneous, two-layer and three layer structures– and a previously validated commercially available mobile phone model. The SAR is calculated for several distances of the mobile phone with respect to the three phantoms at 900 MHz and 1725 MHz. Results show that the homogeneous phantom is not conservative for some distances at 1725 MHz.

I. INTRODUCTION

The SAR (Specific Absorption Rate) conformity assessment of wireless communication devices operated in close proximity to the ear is currently based on standardized measurement procedures such as IEEE1528 [1] and IEC62209-1 [2]. The SAR measurements are performed using the SAM (Specific Anthropomorphic Mannequin) head-phantom filled with an appropriate tissue equivalent liquid for several intended use positions of the handset. The morphology of the SAM phantom is chosen to be representative of the adult population. The conservativeness of the dielectric properties of the tissue equivalent liquid with respect to the inhomogeneous head counterpart was previously demonstrated [3].

Following the advent of hands-free kits, the intended use position of mobile phones shifted from the ear position to other parts of the body. For example, mobile phones can be worn at the belt or placed in the shirt's or trouser's pocket. An appropriate phantom and corresponding tissue equivalent liquid have therefore to be defined for such novel use positions. Current standardization bodies recommend a flat phantom for measuring the SAR of body-worn wireless communication devices [4]. For practical reasons, it is desirable to use the same tissue equivalent liquid as the one employed for the head SAR conformity assessment. However the characteristics of the biological tissues present in the head are different from those found in other parts of the human body.

A few studies have investigated the conservativeness of the homogeneous flat phantom for the body-worn SAR assessment. For example, numerical simulations based on the FDTD (Finite Difference Time Domain) method were performed using a dipole antenna placed at a number of distances from a homogeneous flat phantom and several multi-layered planar phantoms which were derived from the visible human model [5]. The application of a correction factor – dependent upon the frequency, the considered multi-layered

structure and the distance of the dipole with respect to the phantoms – appeared necessary in order to preserve the conservativeness of the homogeneous flat phantom.

Herein a commercially available dual-band – 900 MHz / 1800 MHz – mobile phone representative of an actual wireless communication device is considered for a similar analysis. The numerical model of the mobile phone consisting of the different components – PIFA (Planar Inverted-F Antenna), PCB (Printed Circuit Board), display, battery, etc.– was previously validated using experimental data [6]. Two multi-layered structures are selected for this study: (a) a two-layer structure consisting of skin and fat tissues representing the abdomen and (b) a three-layer structure consisting of skin, fat and muscle tissues representing the thorax. The calculations are performed for several distances of the mobile phone with respect to the homogeneous phantom and the two multi-layered structures. The relative distance of the antenna and the phantom is expected to influence the return loss and consequently the SAR value. Therefore the mobile phone is considered with either the front side or the back side positioned against the phantoms. The impact of the antenna mismatch on the SAR values can thus be examined.

II. NUMERICAL MODELING

Electromagnetic solvers based on time domain methods such as FDTD are nowadays commonly adopted for SAR calculations. Herein a commercial package of the Transmission Line Matrix (TLM) method is chosen [7]. Fig. 1 shows the main components present in the commercial mobile phone used for the study. These components are embedded in a dielectric support (not shown). The dielectric casing of the mobile phone (also not shown) is drawn to have planar faces. The exact dielectric properties of some components are unknown: approximate values are therefore used. The PCB is modeled as a thin conducting plate i.e. the dielectric substrate and electronic circuits are not considered. All numerical simulations are performed at the two resonance frequencies of the mobile phone: 900 MHz and 1725 MHz.

Fig. 2 shows the three flat phantoms considered for the numerical simulations: (a) homogeneous, (b) two-layer structure and (c) three-layer structure. The thickness of the different layers for the two-layer and three-layer models is provided in Table I. The dielectric properties and mass densities of the tissues are provided in Table II. The homogeneous phantom has the same overall dimensions as the other two phantoms. The dielectric properties and mass density are those of the tissue equivalent liquid recommended

by the standards for the head SAR assessment at a given frequency.

Fig. 1. Numerical model of the PIFA-based commercial mobile phone (the dielectric support and casing are not shown).

Fig. 2. Flat phantoms considered in this study: (left) homogenous, (middle) two-layer structure (abdomen), and (right) three-layer structure (thorax).

TABLE I
THICKNESS OF THE BIOLOGICAL TISSUES

Tissue	Tissue thickness for the two-layer model [mm]	Tissue thickness for the three-layer model [mm]
Skin	2	2
Fat	98	12
Muscle	NA	86

TABLE II
PROPERTIES OF THE BIOLOGICAL TISSUES

Parameters at given frequency		Skin	Fat	Muscle
900 MHz	Relative permittivity	41.41	5.46	55.03
	Conductivity [S/m]	0.87	0.05	0.94
	Mass density [kg / m ³]	1010	920	1040
1725 MHz	Relative permittivity	39.00	5.36	53.65
	Conductivity [S/m]	1.27	0.08	1.45
	Mass density [kg / m ³]	1010	920	1040

III. RESULTS

Fig. 3 and 4 show the results obtained at 900 MHz and 1725 MHz, respectively, for the configuration of the front side of the mobile phone facing the phantoms. At 900 MHz, the homogeneous phantom provides conservative SAR values for all the considered distances. At 1725 MHz, the three-layer model provides higher SAR value than the homogeneous model for distances greater than 10 mm. The same phenomenon is observed for the configuration of the back side of the mobile phone facing the phantoms. At 1725 MHz, a correction factor is therefore needed in order to obtain conservative SAR values when using the homogeneous phantom.

Fig. 3. SAR calculated for several distances of the mobile phone with respect to the phantoms at 900 MHz.

Fig. 4. SAR calculated for several distances of the mobile phone with respect to the phantoms at 1725 MHz.

Abstract — This paper presents a theoretical evaluation of the phase-shifting excitation and load effects in a Transmission Line Excitation Chamber. It is suggested as an alternative for immunity tests because of the restrictions related to canonical chambers. Here, two methods are used to calculate the E-field: a semi-analytic approach and a numerical one. The semi-analytic method is based on the well-known modal expansion while a commercial software is used for numerical simulations. The results regarding the field profile and the related statistical indexes of merit are presented and used to evaluate the chamber performance.

I. INTRODUCTION

Canonical chambers - that is Reverberation Chambers (RC) and TEM Chambers - are generally used for electromagnetic immunity testing despite their particular operational restrictions. RCs using mechanical paddles or frequency stirring provide a statistical E-field uniformity in all the directions inside the work volume [1]-[2]. Nevertheless, the frequency operation of RCs is inversely proportional to the chamber dimensions and it is a constraint for low frequencies tests. The International standards recommend the RC configuration for immunity tests over 80 MHz frequencies [2]. TEM Chambers present for low frequencies a deterministic E-field uniform over a work area parallel to the septum, but not in all directions in the chamber volume [3]. Recently, a concept called Transmission Line Excitation Chamber (TLEC) has been proposed, based on a phase-shifting excitation of several transmission lines (TL). For a sake of illustration, a configuration constituted of three-conductor phase-shifting excitation has been investigated in [4].

In this work, we present semi-analytical and numerical approaches for evaluating the performance of a TLEC. Basically, a chamber excited by several TL presents several TEM modes inside the closed metallic cavity. The resulting standing waves depend on the position of the TL as well as the phase-shifting excitation and the loading. Those parameters are important in the search for a suitable chamber working volume; they can be modified electronically, resulting in a random standing wave profile. Based on this, a set of parameters combination can be chosen to improve and satisfy the pre-defined uniformity criteria within a wide frequency range, even at frequencies lower than 80 MHz.

II. SEMI-ANALYTIC AND NUMERICAL APPROACHES

A. Analytic expression of a single TL

Considering the TL geometry given by Fig.1, the E-field of a TEM mode inside the chamber can be evaluated by the following analytical expressions:

$$E_{TEMX}(x, y) = \eta_0 \sqrt{\frac{2}{a}} \sum_{m=1}^{+\infty} \cos\left(\frac{m\pi}{a}x\right) \times \begin{cases} \alpha_{1m} \operatorname{sh}\left(\frac{m\pi}{a}(y-l_1)\right) & y > 0 \\ \alpha_{2m} \operatorname{sh}\left(\frac{m\pi}{a}(y+l_2)\right) & y < 0 \end{cases} \quad (1)$$

$$E_{TEMY}(x, y) = \eta_0 \sqrt{\frac{2}{a}} \sum_{m=1}^{+\infty} \sin\left(\frac{m\pi}{a}x\right) \times \begin{cases} \alpha_{1m} \operatorname{ch}\left(\frac{m\pi}{a}(y-l_1)\right) & y > 0 \\ \alpha_{2m} \operatorname{ch}\left(\frac{m\pi}{a}(y+l_2)\right) & y < 0 \end{cases} \quad (2)$$

with

$$\alpha_{1m} = \frac{J_m \operatorname{th}\left(\frac{m\pi}{a}l_2\right) / \operatorname{ch}\left(\frac{m\pi}{a}l_1\right)}{\operatorname{th}\left(\frac{m\pi}{a}l_1\right) + \operatorname{th}\left(\frac{m\pi}{a}l_2\right)}; \quad \alpha_{2m} = -\frac{J_m \operatorname{th}\left(\frac{m\pi}{a}l_1\right) / \operatorname{ch}\left(\frac{m\pi}{a}l_2\right)}{\operatorname{th}\left(\frac{m\pi}{a}l_1\right) + \operatorname{th}\left(\frac{m\pi}{a}l_2\right)} \quad (3)$$

where η_0 is the vacuum wave impedance and J_m the harmonic coefficients related to the current density on the central conductor. Assuming the conductor as an infinitely thin wire along z axis, one finds:

$$J_m = I_0 \sqrt{\frac{2}{a}} \sin\left(\frac{m\pi}{a}x_0\right) \quad (4)$$

The dependence with z direction is decoupled and equal to e^{-jk_0z} , when an incident wave is considered.

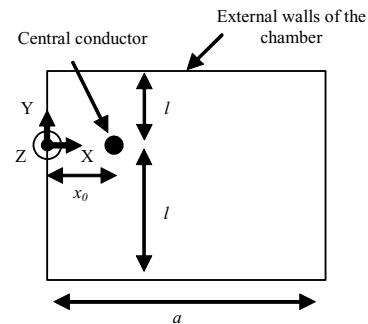

Fig. 1: geometry of a TL in the transverse plane

4. Electromagnetic Compatibility.

B. Phase Shifting and Load Effects Modeling

Several TL can be treated by superposition. When the TLs are ended with the same load, the E-field can be written using the separation of variables in the transverse plane and in the longitudinal direction. The phase shifting between the TLs has then an effect on the repartition of the fields in the transverse plane:

$$\vec{E}_{TOT}(x, y) = \sum_i \vec{E}_{i\text{TEM}}(x, y) e^{j\phi_i} \quad (5)$$

where $E_{i\text{TEM}}$ is the E-field due to the i^{th} TL and ϕ_i represents the applied excitation phase.

The load introduces a reflection coefficient Γ that affects the longitudinal repartition of the field:

$$\vec{E}_{TOT}(x, y, z) = \vec{E}_{TOT}(x, y) \times (e^{-jk_0 z} + \Gamma e^{+jk_0 z}) \quad (6)$$

If we consider when $|\Gamma| = 1$, a stationary wave is expected but the maximum of E-field can be moved changing the phase of Γ . Thus, it is possible to homogenize the field in z direction even if the TL is unmatched.

C. Numerical Approach

Numerical evaluation was performed using FIT [5]. The loads are imposed by boundary conditions while the phase-shifting excitation is implemented by a post-processing approach.

D. Indexes of Merit calculation

Standard deviation for the distribution of E-field in the chamber can be calculated from the definitions in [1] [4] and [6]. Due to the phase and load shifting, the E-field considered at any point of the chamber is the average field.

III. APPLICATION AND RESULTS

A TLEC with dimensions of $0.6m \times 0.6m \times 1.2m$ has been considered. The semi-analytical approach has been applied in the transverse plane $\{x, y\}$ since the variation of E-field in z direction can be canceled using a suitable load-shifting. The area under evaluation is a rectangular $0.3m \times 0.3m$ centered at the middle of the chamber. The study concerns the influence of the phase-shifting when several TL are considered. Results are reported in Table I. It appears that the number of TL is important: the standard deviation decreases of 3 dB when 4 TL are introduced instead of 2 TL. Moreover, the phase-shifting improves of 0.5 dB the performance. A TEM stripline like the one used in TEM Chambers has also been simulated and the E-field uniformity is presented.

TABLE I
STANDARD DEVIATIONS FOR SEMI-ANALYTICAL APPROACH

Chamber Configuration		Standard Deviation (dB)		
Number of TL	Phase-shifting	$\hat{\sigma}_x$	$\hat{\sigma}_y$	$\hat{\sigma}_{x,y}$
1	-----	5.7	6.0	5.9
2	No	6.5	3.3	5.3
2	Yes	6.4	2.0	5.0
4	No	3.2	3.2	3.3
4	Yes, random	2.8	2.6	2.8
TEM Chamber	-----	5.1	3.1	4.6

Fig. 2 (a) Position of two TL in the chamber (b) E-field distribution in the horizontal plane at the middle of the chamber (load 50Ω).

Fig. 3 E-field distribution with different loads (a) $-j500\Omega$ (b) $j500 \Omega$.

3D simulations using commercial software have also been carried out. The interest is that this approach is more realistic since it takes into account the connection of the TLs outside the chamber, which introduces a discontinuity. Table II presents the statistical E-field indexes calculated when the TLs are terminated by a 50Ω load. The volume is defined with the same cross section as previously, and a $0.6m$ length in the z direction. The influence of the phase-shifting on E-Field profile is also given at Fig. 2 in a 2 TL configuration.

TABLE II
STANDARD DEVIATIONS FOR NUMERICAL APPROACH (LOAD 50Ω)

Configuration		Standard Deviation (dB)		
Number of TL	Phase-shifting	$\hat{\sigma}_x$	$\hat{\sigma}_y$	$\hat{\sigma}_{x,y}$
1	-----	7.7	6.6	7.3
2	No	9.0	4.4	6.4
2	Yes, random	7.0	5.1	6.2
4	No	7.1	7.1	7.1
4	Yes, random	5.0	6.3	5.6

The effect of the load is presented in Fig. 3: the maximum of E-field moves between a $-j500\Omega$ and $j500 \Omega$ load.

Abstract — In this paper a 3D Near field characterization method is presented for the EMC analysis of power printed circuit boards. From a measured magnetic field cartography an equivalent set of magnetic dipoles is deduced solving an inverse problem. The use of Legendre functions in the field expressions allows to address the general case where the distance between the cartography and the circuit is small. This model is devoted to DC-DC complex real case. In this version some theoretical aspects and results on a simple case are presented.

I. INTRODUCTION

Switched mode power supplies (SMPS) are widely used, they provide good power-volume and power- weight ratios. However, they are source of electromagnetic pollution generated by switching mechanisms. In presence of such phenomena malfunction risk is not negligible and sometimes important, depending on the surrounding structures. To avoid such consequences, manufacturers have to make sure their products are electromagnetically compatible. To obtain such a guarantee it becomes necessary to know with a good accuracy the electromagnetic behavior of the switching devices. Near field characterization recently became an efficient way for the analysis of radiated emissions from electronic circuits and components [1]. The cartography of the radiated fields gives meaningful insights of the electromagnetic disturbances and adequate models can be directly build from the cartography. In [2] the radius of a circular loop equivalent to the switching cell is deduced from the maximum of the magnetic field. In [3] an array of equivalent dipoles lying on the printed circuit board and having predefined position is determined by a root mean square procedure. The model presented in [4] addresses a more general case where the position and orientation of equivalent dipoles are unknown : these dipoles are determined from the near field cartography by solving an inverse problem using genetic algorithms. Interesting results have been obtained for a simple case. However, the mathematical approximations used in this model assume that the radius of each magnetic dipole is very small compared to distance between each elementary part of the dipole and the observation point. These approximations allow an easy way to express the model and a reduced computing time. Nevertheless the solution quality tightly depends on the complexity of the studied case and realistic configurations of

power circuits including several radiation sources are difficult to be analyzed.

In this paper a new model without approximations is presented. In this approach the 3D dipoles are generated from the measured values of the magnetic field whatever the distance between the measured cartography and the circuit. The expressions of the radiated field use the Legendre functions which govern the general case relevant to the magnetic dipoles. Preliminary results are presented on a simple case. More complex configurations will be presented in the conference.

II. CHARACTERIZATION METHOD

The characterization method is an inverse-problem based resolution. It aims at finding a set of elemental electric and magnetic dipoles which radiate the same near-field values as the original device by minimizing the following function:

$$J(\vec{X}) = \left\| \vec{H}_{mes} - \vec{H}_{mod} \right\| \quad (1)$$

Where \vec{X} is the vector of the dipoles parameters.

Fig. 1. Magnetic field radiated by a magnetic dipole

The magnetic field in the observation point P is the sum of the contribution of each elementary length along the magnetic dipole (Fig. 1). The magnetic field, radiated by a magnetic

4. Electromagnetic Compatibility

dipole using the Legendre functions (L1, L2), expression for one observation point is:

$$\vec{H} = B \cdot \vec{H}_{cyl} \quad (2)$$

Where \vec{H}_{cyl} is the magnetic field in the cylindrical local coordinates (o', x', y', z') has the following expression [5]:

$$\vec{H}_{cyl} = \begin{cases} \frac{\mu_0 I k}{4\pi\sqrt{a\rho}} \left(-L_1(k) + \frac{a^2 + \rho^2 + z^2}{(a-\rho)^2 + z^2} L_2(k) \right) \\ 0 \\ \frac{\mu_0 I k}{4\pi\sqrt{a\rho}} \left(L_1(k) + \frac{a^2 - \rho^2 - z^2}{(a-\rho)^2 + z^2} L_2(k) \right) \end{cases} \quad (3)$$

B is the coordinates transformation matrix from the cylindrical local coordinates to the global Cartesian coordinates (o, x, y, z). For one magnetic dipole, the parameters vector $\vec{X} = (\phi, \theta, x_0, y_0, I_d, a)$ has dimension (1,6).

For N magnetic dipoles the vector \vec{X} dimension is (1,6*N). The fitness function in (1) becomes highly non linear with a lot of local minima. To optimize this function a genetic algorithm is used. In the conference more details will be given about the theoretical aspects of the inverse problem and the improvement provided by this model when compared to [4].

III. RESULTS

In this part results obtained using the proposed approach for a simple DC-DC converter, are presented.

Fig. 2. Simple DC-DC converter (Black area: switching cell)

Field distributions obtained using the new model are presented in figures 3, 4.

Fig. 3. Measured magnetic field

Fig. 4. Calculated magnetic field

In the conference the efficiency of the new model will be illustrated by studying a complex DC-DC case (figure. 5) and will be also compared with the results obtained using the former model.

Abstract—This paper reports a study-case concerning the assessment of shielding effectiveness within a typical operating room in order to evaluate and manage electromagnetic compatibility in health care facilities. Measurement techniques and numerical simulation (using TLM Method) are employed to identify and evaluate critical sources and frequencies, providing a reliable appraisal of the electromagnetic environment.

I. INTRODUCTION

Nowadays, it is possible to observe that Health Care Facilities (HCF) have been endeavoring to incorporate the use of new technologies to provide a number of different medical solutions and improve the quality of clinical procedures. This situation increases the challenge to promote the electromagnetic compatibility (EMC) in clinical environments in order to grant the proper performance of a growing number of equipment operating simultaneously within the same area.

The electromagnetic profile presented in a clinical environment is characterized by a set of complex conditions, which comprises several different sources, wide frequency range, and substantial amplitude variation. This situation complicates the establishment of an associated electromagnetic interference (EMI) potential for electromedical equipment (EME). Hence, it is well known that the awareness of electromagnetic behavior shown by these environments can represent an important tool in order to promote EMC management and avoid the appearance of undesirable phenomena such as EMI [1-2]. As a result of this assessment, a better understanding about the real situation concerning the electromagnetic environment in HCF can be achieved, allowing clinical engineers to define better directives to implement a management program which is adequate to the real need of these hospitals.

During the current research, a number of hospitals have been evaluated by measurement techniques in order to identify important electromagnetic features (critical sources and frequencies) presented in these environments. Some of them were already evaluated by computational means according to specific issues concerning wave propagation, as previously published in [1]. In this paper we deal with another study-case whose main characteristic is related to high electric field levels due to the influence of external sources, such as TV and FM radio broadcasting. In this scenario, clinical engineering staff was designing an RF shielding with the use of appropriated metallic layers in order to coat operating room (OR) walls. Although this approach seems to be a good preliminary option to solve the problem at hand, a detailed evaluation concerning other EMC aspects is needed. So, this

is the main topic of this paper, whose main purpose is to evaluate other important issues regarding EMC management, and to assess the effectiveness of a wall shielding implementation within operating room areas.

II. METHODOLOGY

In order to accomplish the desired results, the methodology used in this research was developed in two main steps, combining measurement techniques and numerical simulation. The idea of the first step is to perform a number of *in situ* electric field measurements within the clinical environment under test. The main energy sources and critical frequencies are then identified with spectral analysis (from 30 MHz to 3 GHz) and classified according to EMI risk stated by IEC 60601-1-2 (EMC collateral standard for EME). During the second step, a numerical model is developed using the *Transmission Line Modeling* (TLM) method. Preliminary measurement results are used as inputs for the numerical simulation and the electric field distribution is estimated to evaluate the influence of significant sources of energy, such as electrosurgical unit (ESU), TV and FM radio broadcasting.

A. TLM Method

The TLM is a differential numerical technique which has been successfully applied to modeling electromagnetic fields for decades [3]. It was developed to take advantage of the analogy between representative equations of transmission-lines and electromagnetic fields. The scattering process is based on light propagation principle stated by Huygens. In this method, the propagation medium is modeled by a network of interconnected transmission-lines (TLM mesh), and material properties are represented by the equivalent lumped circuit components [3]. Figure 1 shows a single network circuit unit named shunt node.

Fig. 1. TLM-2D Shunt Node.

The analogy between Kirchhoff laws for shunt node circuit and wave Maxwell's equations in time domain can define the relation between voltage/current and electrical/magnetic field:

$$E_z = \frac{V_z}{\Delta l} \quad H_x = \frac{I_y}{\Delta l} \quad H_y = \frac{-I_x}{\Delta l} \quad (1)$$

Likewise, it is also possible to establish the relations between TLM cells and medium parameters:

$$\mu = L_d \quad \varepsilon = \left(2C_d + \frac{C_s}{2} \right) \quad \sigma = G_s \quad (2)$$

III. THE ENVIRONMENT UNDER TEST

In this analysis the environment under test is a typical OR of approximately 25 m². The disposal of EME and objects within the room follows clinical staff directives to configure a usual setup for the HCF standard procedure (fig. 2).

Fig. 2. Typical Environment Under Test.

Concerning computational prediction, the environment under test was modeled by a 600x700 TLM nodes. Each node has an area of 1 cm², and it is characterized by the medium electric parameters: concrete ($\varepsilon = 5.0$, $\sigma = 0.0133$ S/m); wood ($\varepsilon = 4.0$, $\sigma = 0$ S/m); equipment ($\varepsilon = 1.0$, $\sigma = 10^3$ S/m); metal ($\varepsilon = 1.0$, $\sigma = 3e^7$ S/m); plastic ($\varepsilon = 4.0$, $\sigma = 1.0$ S/m); foam ($\varepsilon = 1.3$, $\sigma = 0$ S/m); air ($\varepsilon = 1.0$, $\sigma = 0$ S/m); human body (ε_r and σ values depends on the frequency). All mesh borders are modeled as open boundaries, simulated by a TLM “matched” (absorbing) boundary condition, as described in [3].

IV. PRELIMINARY RESULTS

A. Field Measurements

Figure 3 shows the result of electric field strength measurement. It illustrates two different spectrum situations, both in operation case (with EME turned on) and in rest case (with EME turned off).

Fig. 3. Electric Field Strengths Measurements (30 MHz to 3 GHz)

Most important sources observed within the room were TV and radio broadcasting. However, ESU electromagnetic content can not be ignored since it was the main responsible for the spectrum rises when EME were turned on. Due to the limited space, in this digest the simulation will be focused only at the 204 MHz contributions of the main sources.

B. Field Prediction

Figure 4 shows the electric fields distribution for individual sources oscillating at 204 MHz. Figure 4a is related to an

incident TV broadcasting wave-front reaching the OR external wall. Figure 4b shows ESU contribution when it is operating in close proximity to the B3 point.

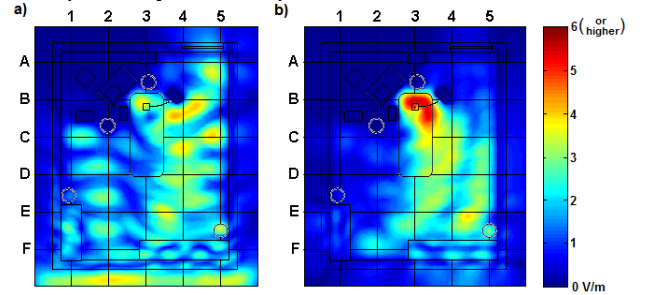

Fig. 4. Field Distribution at 204 MHz: a) TV broadcasting; b) ESU.

On a second simulation scenario, metal conductor layers were included, modeling the designed shielding to the OR walls. Figure 5 compares field distribution profiles for both scenarios: original OR (fig. 5a) and OR with RF shielding (fig. 5b), when both sources from fig. 4 are operating simultaneously.

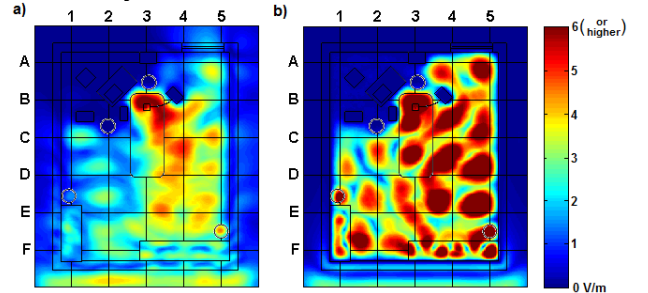

Fig. 5. Field distribution for: a) original OR; b) OR with RF shielding.

It is possible to observe that shielding effectiveness concerning EMC aspects is not only related to the capability of isolating undesired signals individually, but also evaluates the system as a whole. As can be seen on fig. 5, the use of OR wall complete shielding may not be the best alternative, since it confines significant signal sources inside the room raising the average environmental energy level. Although it is an efficient solution to avoid the analyzed external signals (TV and FM broadcasting), it can lead to a worse EMC condition.

V. FINAL CONSIDERATIONS

In the full paper, a better detailing is given to the treatment of this problem, allowing more discussion about the subject. Other important sources and frequencies should be also evaluated by numerical means providing a thorough analysis of EMI situations. Finally, an optimization process will be employed in order to verify different shielding configurations and evaluate its efficiency regarding EMC management.

Full Wave Solution for Intel CPU with a Heat Sink for EMC Investigations

Junwei Lu, Boyuan Zhu, and David Thiel
 Centre of Wireless Monitoring and Applications, Griffith School of Engineering
 Griffith University, Nathan, Qld, 4111, Australia
 j.lu@griffith.edu.au

Abstract — A CPU with a heat sink (e.g. Intel Pentium 4 and Intel Pentium dual core) is one of the challenging problems for IEEE EMC. A Very Large Scale Integrated (VLSI) device was modelled using the Finite Element Method (FEM) frequency domain as this provides a 3D full wave solution. The electromagnetic (EM) radiation emitted from these high power microelectronic circuits connected to a heat sink was found to have resonant frequencies around 2.4 GHz and 5 GHz with a reflection coefficient less than 19 dBi and 8 dBi. Those resonant frequencies are very close to the operating frequency of both IEEE and Bluetooth wireless communication systems. This paper proposes a new benchmark model based on a dual core CPU.

I. INTRODUCTION

Modern silicon wafer fabrication facilities easily produce component densities that exceed 1 million transistors per die. The power generated from processor currents can exceed 100W with increasing high clock speeds. This combination of switching frequency and power level, in conjunction with the layout of the common mode current paths through the heat sinks, results in a significant level of radiated Electromagnetic Interference (EMI). As a result, circuit designers require an understanding of the radiated emissions from the CPU and its heat sinks. Designers also need to find ways to reduce these emissions. Components such as the Intel Pentium 4, Intel Pentium dual core CPU, and AMD Athlon dual core CPU require separate cooling procedures provided by a fan built into their heat sink or by a fan or cooling device located adjacent to the processor. Since these high-power and high-speed processors are common in recent designs, special techniques are required for EMI suppression and heat removal at the component level. In addition, 3D EM full wave based numerical analysis tools are required to model the radiated emissions. This paper focuses mainly on RF radiated emission problems that consider the EMC source modelling for the CPU and heat sink as a RF radiator [1].

II. EMC SOURCE MODELLING AND MODEL ATTRIBUTES

A. CPU Source Model Consideration

EMC/EMI models are commonly represented as three distinct parts: the source of RF energy, the geometry of the model components, and the remaining problem space [2]. To model the CPU with a heat sink structure, it is useful to further divide the structure into three regions; the ground plane, source region and heat sink. A realistic representation of a VLSI circuit must consider the electromagnetic source characteristics and an actual physical representation such as a

conducting patch [3]. Although real heat sinks have fins to increase the thermal convection loss, Brench [4] found that the heat sink could be modelled as a solid block. Das and Roy [5] modelled the source as a monopole that passes through the circuit. This EMC source model was used to address the previous problem confronting the IEEE EMC (486 CPU). The Intel P4 and Intel dual core CPU with a heat sink have completely different structural configurations, therefore a new EMC source model is required for modelling and simulation.

B. Intel P4 CPU Heat Sink and Source Model

The Intel P4 processor with the 478-Pin has different packaging and a different structural configuration (see Figure 1a). In the Intel P4 configuration, a heat spreader is located on top of the VLSI. This heat spreader is electrically isolated from the VLSI packaging. A new EMC source model consists of a multi layered structure forming a microstrip patch antenna structure, which is resonant at frequencies of around 2.4 GHz and 5 GHz respectively. This is shown in Figure 1(b). Several clock frequencies in the band from 1.40 GHz through 2GHz are considered for demonstration purposes, where A1 is 2.378mm, A2 is 1.080mm, L is 2.030mm, L1 is 88.9mm, W1 is 38.1mm, W2 is 31.75mm and W3 is 35mm.

(a) Intel P4 CPU and packaging (b) EMC source model with a heat sink
 Figure 1. Intel P4 CPU heat sink configuration and simulation model.

C. Intel Dual Core CPU Heat Sink Model

A transverse cross-section of the Intel dual die processor with a heat sink is illustrated in Figure 2. The package is a Flip-Chip Land Grid Array (FC-LGA6) and the die is located upon the substrate with the help of die attach material. The sealing is also the integrated heat spreader (IHS) covering the dies in order to protect them. Adhered by the thermal interface material (TIM), the heat sink is in full contact with the top of IHS. Like the Intel P4 CPU model, this dual core CPU model can be simplified to a dual feed microstrip patch antenna structure. The location of feed points is a critical factor that affects the accuracy and validation of the simulation results. Based on the heat distribution on an existing Intel dual die CPU [7], the hottest point is predicted to be the area of highest current distribution where the electromagnetic interference

generated is very significant. Thus the feed points of the equivalent patch were allocated to these regions for the EMC source model assuming a 50 ohm source. Note that the highest current density for a driven patch antenna is immediately adjacent to these probe feeds. The size of the equivalent patch antenna model is simply the resonant size at 2.45 GHz and the second frequency at 5 GHz.

(a) Intel Dual Die packaging (b) EMC source model with a heat sink
Figure 2. Intel dual core CPU heat sink configuration and EMC source model.

III. FULL WAVE SOLUTION

A. Frequency Domain Modelling in EMC/EMI

The most accurate modelling of EMC requires a 3D full-wave solution in which Maxwell's equations are solved. With numerous fast numerical algorithms now available, the FEM in the frequency domain is relatively efficient. The technique finds approximate solutions of partial differential equations and integral equations. The frequency domain vector wave equation for the \mathbf{E} field is:

$$\nabla \times \frac{1}{\mu} \nabla \times \mathbf{E} + \sigma_e \omega \mathbf{E} + \omega^2 \epsilon \mathbf{E} = -j\omega \mathbf{J} \quad (1)$$

where ω is angular frequency, \mathbf{J} is the source current, σ_e is the effective conductivity, and μ and ϵ are the permeability and permittivity of the problem space respectively.

B. Full Wave Solutions for CPU Heat Sink Models

The computation model for the Intel P4 and Intel dual core CPU heat sink fits within the source models developed in this work. These are shown in Figures 1 and 2, where the absorbing boundary condition, PML, is used to surround the computation model to obtain accurate results. The excitation is a vertical probe extending from the ground plane to the base of the conducting patch.

Figure 3. S_{11} impedance matching for the Intel P4 CPU heat sink model.

Figure 4. S_{11} impedance matching for the Intel dual core CPU heat sink, where — line indicates the excitation at port 1, and ... line indicates the excitation at port 2. The mark position is indicated by m1, m2, m3 and m4.

This is electromagnetically coupled to the heat sink through the substrate. Figures 3 and 4 show the scattering parameter S_{11} (with a 50 ohm source) across the frequency band. Both models have two resonant frequencies. The S_{11} results indicate that there is maximum radiation from the structure at these two frequencies. The CPU heat sinks cause significant radiated emissions at these frequencies, assuming it is possible that currents in the VLSI circuit have Fourier components at these frequencies.

IV. CONCLUSION

This paper presents a FEM based computation technique for radiated emissions from CPU heat sink models. The CPU heat sink model is significantly different to the conventional CPU heat sink model of IEEE EMC challenge problems. The Intel P4 and Intel dual core CPU heat sink models with insulated configurations were found to radiate at 2.4 GHz and 5 GHz respectively. These two frequencies lie very close to the wireless communication range in computing systems. The source model selection is critical for the CPU heat sink model as it affects the resonant frequencies associated with the CPU clock speed, the CPU core and heat sink structures. The far field radiation patterns from those CPU heat sink models and validation of the CPU dual core benchmark model will be discussed in the full paper.

Abstract— This paper presents a multi-objective optimization approach based on numerical, statistical and fitness evaluation concerning the conductor positions in a Transmission Line Excitation Chamber (TLEC). The field profile and the related indexes of merit, like the statistical ones, regarding the working volumes are used to evaluate the chamber configuration performance. The compromise between working volume and E-field standard deviation are show through the Pareto's Front.

I. INTRODUCTION

In previous works the Transmission Line Excitation Chamber (TLEC) performance evaluations have been carried out using different approaches. These were presented in [1] and [2] in which FIT and TLM, and also an optimization tool were used to evaluate the field uniformity within the working volume on a predefined TLEC configuration. The TLEC configuration here presented is based on three-conductor phase-shifting excitation configuration and proposed as an alternative when low frequencies are taken into consideration [3]. Fig.1 shows a sketch of a three-wire reverberation chamber configuration. Thus, the optimization problem aims to maximize the working volume and the E-field, which is restricted to uniformity constraints.

In this work, the main focus is to find the better transmission lines configurations, i.e., wire positions, which present the best TLEC performance related to the aforementioned indexes. A good TLEC performance is associated to a high working volume and E-fields average values. To obtain the wire configuration and the corresponding TLEC performance, a numerical approach has been implemented by applying multi-objective optimization. Deterministic and statistical approaches are applied in the analysis.

Fig. 1. Sketch of the three-wire reverberation chamber configuration

II. OPTIMIZATION PROCEDURE

A working volume is assumed to be a region inside the reverberation chamber (Fig. 1) where the homogeneity of the electric field attains a prescribed level. EMC tests could be performed only with this minimum homogeneity level, and the mean value within the working volume should be as high as possible considering low input power.

In this work, the main interest is to understand how the reverberation chamber works when associated to a set of transmission lines positions and its related working volumes. It should be mentioned that when the working volume increases the mean electric field decreases. This means that a multi-objective optimization algorithm should be employed (two or more antagonistic goals).

Here, the optimization problem has twelve optimization variables: three pairs coordinates (TL positions), two equatorial radii, polar radius and three parameters associated to the ellipsoid translation (shift) from the chamber's centre (these six last variables define the working volume). In this set, inside some working volume the electric field is high, whereas the volume is low.

There are other working volumes, which belong to this set, but have low electric field and high volume. Inside the working volumes the field homogeneity is constrained by pre-defined values. When the chamber characterization is performed, the engineer could make a choice to obtain the most suitable set of TL to design the TLEC.

In order to solve it, the optimization problem is assumed as an unconstrained optimization problem, where inequality constraint was treated as a penalty function.

A. Modeling the chamber

The mean E-field (\bar{E}_x), the Standard Deviation (σ_x) and Standard Deviation in dB ($\hat{\sigma}_x$) are calculated by (1), (2) and (3)

$$\bar{E}_x = \frac{1}{N} \sum_{k=1}^N E_{xk} \quad (1)$$

$$\sigma_x = \sqrt{\frac{1}{N-1} \sum_{k=1}^N (E_{xk} - \bar{E}_x)^2} \quad (2)$$

$$\hat{\sigma}_x = 20 \log_{10} \left(\frac{\bar{E}_x + \sigma_x}{\bar{E}_x} \right) \quad (3)$$

4. Electromagnetic Compatibility.

Similar equations could be obtained to the y-axis, z-axis and to the combined E-field [1], [2] and it is assumed a value equal to 4 dB as the standard deviation for defining the working volume at frequencies lower than 80 MHz.

B. The Optimization Problem

The conductor position problem could be written as an optimization problem as follows:

$$\begin{cases} \text{Max Working Volume} \\ \text{Max } \bar{E}_{x,y,z} \end{cases} \quad (4)$$

S. t: $\text{Max } (\hat{\sigma}_x, \hat{\sigma}_y, \hat{\sigma}_z, \hat{\sigma}_{x,y,z}) \leq 4\text{dB}$

In order to bounder the optimization parameters, Fig 2 illustrates and shows a cross-section of the chamber to be analyzed. First of all, it is assumed that each wire is parallel to one of the three axis of the chamber as Fig 1 shows. So, each wire could only be placed in the grey region, because it could not be close to the wall, due to the standards. On the other hand, if we put it on the center of the chamber (the forbidden area) the associated working volume will be small. Thus the TLs can only be moved inside a space "close" to the walls in order to avoid solutions that are impossible for practical utilization.

Fig.2 Chamber Cross Section: the position wire

Multi-objective optimization (4) seeks to optimize the components of a vector-valued cost function. Unlike single objective optimization, the solution to this problem is not a single point, but a family of efficient points called Pareto-front. Each point on this surface is optimal in the sense that no improvement can be achieved in a cost vector component that does not lead to degradation in at least one of the remaining components. Each element in the efficient set constitutes a non-dominated (non-inferior or non-superior) solution to the multi-objective problem. With this set of solutions it is possible to understand the dependence between each objective.

The Pareto-set of this multi-objective problem was obtained by using the Multi-objective Genetic Algorithm (MGA)[4]. The MGA is derived from the Genetic Algorithm, which is a stochastic procedure based on the concepts of natural selection in genetics.

C. Coupling the Field Computation Software and the Optimization Environment

The adopted procedure has six fundamental steps:

- i) Random positions for TL are generated, as well the working volumes and ellipsoid radius;

- ii) TL positions are charged to the field computation software, that uses FIT [5];
- iii) The field computation inside the reverberation chamber is performed with FIT [5];
- iv) The values of the E-field are exported considering a regular grid;
- v) The working volume is calculated. For the determination of a particular working volume, Eq. (1) should be solved, and
- vi) The indexes of merit are applied to decide which one are the better TL configurations.

The third and fourth steps are computed by applying the FIT [5] At the end of step iv a file is exported to our optimization environment.

The EMC standards adopt a parallelepiped as a working volume[7]. In this work we have adopted another solid to characterize the volume: an ellipsoid[2].

III. RESULTS

Fig. 2 shows some results which allow us to know the compromise among the searched objectives (max E-field and max working volume), the constraints and the conductor positions.

Fig. 2. Compromise between working volume and E-field.

By inspection of Fig. 2 the maximal working volume, taking into account a defined E-field level, can be chosen. For instance, it yields approximately $15 \times 10^{-3} \text{m}^3$ for an E-field level of 15V/m considering the total chamber volume equal to $0,432 \text{m}^3$.

Abstract— In this paper the numerical prediction of the magnetic shielding of a coated aperture in a perfectly conductive planar shield is investigated. The single layer or multilayer thin film resistive coating is characterized and homogenized by using the transmission line approach. The electromagnetic analysis is performed by the finite element method (FEM). The results obtained in some test configurations are validated by other numerical and analytical methods.

I. INTRODUCTION

Evaluation of the shielding effectiveness (SE) is an important topic in electromagnetic compatibility (EMC) studies and is regulated by several standards (MIL-Std 285, IEEE 299, ASTM D4935,...). The experimental layout for the magnetic shielding measurement consists essentially in locating two oriented loop antennas in two positions: ahead and behind the shield under test. One loop (i.e., transmitting antenna) is used to generate the incident magnetic field H^i , while the other loop (i.e., receiving antenna) is used to measure the transmitted magnetic field H^t through the shield.

The parameter used to quantify the shielding performances is the magnetic shielding effectiveness SE_H defined as the ratio, in decibel, between the incident field, H^i , and the transmitted one, H^t , in a fixed point behind the shield: $SE_H = 20 \log_{10}(|H^i| / |H^t|)$. It should be noted that the incident field H^i is the field at the considered point in absence of the shield. The different standards require that the antennas must be oriented in two positions: coplanar and parallel arrangements, as shown in Fig. 1.

The SE_H of apertures has been studied by many authors using analytical, experimental and numerical techniques [1]-[6]. The new interest for this topic is in the extensive installation of new transparent coating materials to cover windows and apertures, mainly for thermal reasons, of apparatus and transportation systems (trains, cars, aircraft,...). These coatings are generally composed by several layers of conductive thin films of silver, indium tin oxide (ITO),..., combining characteristics of electrical conductivity and optical transparency. These thin films have shielding properties against incident magnetic fields that have to be analyzed.

In this study we consider a coated aperture in a plane conductive sheet or on the wall of an enclosure that is so large that the reflections from the other walls are insignificant compared to the fields that penetrate the aperture [5]. The magnetic shielding analysis is performed by a numerical method that is validated by comparison with other techniques based on approximate analytical and circuital methods [1], [6].

Fig. 1. Arrangements of coplanar (a) and parallel (b) loops.

II. CHARACTERIZATION OF THIN FILM COATING

Assuming the field propagating as a plane wave inside a thin shield as shown in Fig. 2, the electric and magnetic field components tangential the two faces (Γ_0, Γ_d) of a solid planar shield of thickness d are coupled by the lossy transmission line equations [4]-[6]:

$$\begin{bmatrix} E_{\tau 0} \\ H_{\tau 0} \end{bmatrix} = \begin{bmatrix} \Phi_{11} & \Phi_{12} \\ \Phi_{21} & \Phi_{22} \end{bmatrix} \begin{bmatrix} E_{\tau d} \\ H_{\tau d} \end{bmatrix} \quad (1)$$

where $E_{\tau 0}$, $E_{\tau d}$, $H_{\tau 0}$, $H_{\tau d}$ are the field tangential components, and the shield chain matrix $[\Phi]$ is given by

$$[\Phi] = \begin{bmatrix} \cosh(\gamma_s d) & \eta_s \sinh(\gamma_s d) \\ \sinh(\gamma_s d)/\eta_s & \cosh(\gamma_s d) \end{bmatrix} \quad (2)$$

being η_s the intrinsic impedance, γ_s the propagation constant of the solid shield with characteristics $\epsilon_s, \mu_s, \sigma_s$.

For very small values of d in conductive layer, (2) can be approximated by:

$$[\Phi] \approx \begin{bmatrix} 1 & 0 \\ \sigma_s d & 1 \end{bmatrix} \quad (3)$$

For a configuration of a n -layer shield, the total chain matrix $[\Phi]$ can be obtained by:

$$[\Phi] = [\Phi_1][\Phi_2][\Phi_3] \dots [\Phi_n] \quad (4)$$

where $[\Phi_i]$ is the chain matrix of the i th layer whose expression is given in (2) and is valid also for dielectric layers. The chain matrix $[\Phi]$ can be used to model any multilayer shield in frequency domain.

Fig. 2. Planar shield (a) and the equivalent two-port network (b).

III. FEM MODELING OF THIN FILM COATING

Simulation of conductive thin layers embedded in a FEM domain can lead to an excessive number of degrees of freedom (DoF) since the thickness of the thin film coating is very small, about tens of nanometers, and requires a lot of finite elements to discretize adequately the region under examination. To overcome this problem, a reduction of the DoF is necessary. We propose two different methods.

The first approach is based on the Impedance Network Boundary Conditions (INBCs) [3]-[4]. The basic idea of the INBC method is to eliminate from the computational domain the conductive shield by introducing new boundaries where the electric and magnetic tangential fields are coupled by the chain matrix $[\Phi]$ (or by equivalent admittance matrix $[Y]$ or impedance matrices $[Z]$) in order to model the penetration of the electric and magnetic fields inside the thin conductive wall. By considering conductive thin film, the transmitted fields must be constrained imposing on the boundary Γ_d :

$$E_{\tau d} = E_{\tau 0} \quad (5a)$$

$$H_{\tau d} = H_{\tau 0} - E_{\tau 0} \sigma_s d \quad (5b)$$

The second approach consists in synthesising a new shield whose chain matrix $[\Phi]$ is identical to that of the thin film shield, but with a much larger thickness. For simply resistive shields of very small thickness, the chain matrix is practically frequency constant, and therefore it can be simply modelled by a resistive layer of equivalent conductivity σ_e and thickness d_e obtained by $\sigma_e d_e = \sigma_s d$ when assuming $d_e \gg d$ and $d_e \ll \delta$, being δ the penetration depth.

IV. APPLICATIONS

The magnetic shielding performances of two different coatings applied to a circular aperture of 0.1 m radius have been analysed for both the parallel and coplanar loop configurations. Fig. 3(a) shows the calculated SE_H by the two proposed FEM methods for the coplanar loop configuration assuming $D = 0.4$ m. The aperture is loaded by a single layer silver coating with $d = 18$ nm and a multilayer sandwich coating (3 Ag layers separated by 2 dielectric layers) assuming $d = 18$ nm for each layer of Ag or dielectric, respectively. The FEM results can be compared with those obtained by approximate analytical [1], and circuit [6] techniques shown in Fig. 3(b), highlighting good accuracy. Finally, the calculated SE_H for the parallel loop configuration is also reported in Fig. 4.

Abstract— In this paper a numerical FEM analysis for the evaluation of the EM field exposure due to welding equipments has been proposed. The human body model has been reconstructed by means of a segmentation procedure using CT data. A comparison among models with different complexity in terms of organs and tissues has been proposed and discussed.

I. INTRODUCTION

European community has recently issued a directive about the risks deriving by the exposure to electromagnetic fields and has suggested that in working environments the employer must verify the electromagnetic field levels to assure the safety of employees.

In order to protect people from electromagnetic emissions ICNIRP (International Committee Non Ionizing Radiation Protection) [1] has suggested some limits in order to avoid acute effects which are an established consequence of the field exposure. For low frequency exposure between the most important magnetic field sources, welding equipments generate high intensity fields because of the high intensity of the welding current.

Actually for welding equipment few practical directives have been issued. Moreover the measurement of the “action values” in the surroundings of welding machine are very difficult to perform and analyze because of the very short pulsed currents. In this work some investigations about the use of numerical techniques and a modeling of the human body for the estimation of the magnetic field exposure have been presented. For welding equipments the analyzed quantities for the evaluation of the field exposure are the magnetic flux density and the induced current density because the frequency of the current source is under 100 kHz [1]. A three dimensional human model has been tested for the evaluation of worker exposure to the magnetic field produced by an arc welding equipment.

II. COMPUTATION MODELS

The human model has been built from real CT data. Each slice of the CT has been segmented using Amira software (Mercury) in order to generate a 3D mesh. The meshed volumes have been imported in a Finite Element software, and inserted in a volume which represents a simplified human body.

The magnetic flux density and the induced current density have been computed solving the electromagnetic (EM) problem in quasi-static condition [3] [4].

The simulated domain (Fig. 1) includes a conductive region (Ω_C) and two vacuum regions (Ω_V and Ω_R) one of them containing the magnetic field source (Ω_R). In the Ω_C region

the induced current density is computed and the EM problem has been solved using a time-harmonic A,V formulation:

$$\vec{E} = -j\omega\vec{A} - \nabla\dot{V} \quad (1)$$

where \vec{E} is the phasor of the electric field, \vec{A} the phasor of vector potential, \dot{V} the phasor of the scalar electric potentials and ω the angular frequency. From (1) the induced current

density can be derived.

Fig. 1. human body model

The source of the magnetic field is a wire supplied by an electrical current. The evaluation of the magnetic field in the vacuum volume Ω_R , the one that contains the source, is solved in the phasor of the reduced scalar potential, $\dot{\phi}_{RED}$:

$$\vec{H} = \vec{H}_j - \nabla\dot{\phi}_{RED} \quad (2)$$

where \vec{H}_j is the term due to the current source computed by means of Biot-Savart formula. Between Ω_C and Ω_R a region Ω_V has been interposed. In this region the EM problem is solved in terms of the only phasor \vec{A} . This part of the domain has been modeled to surround the conductive region where the EM problem is solved in terms of \vec{A} and \dot{V} potentials in order to properly describe interface condition between conducting and not-conducting regions. At the boundary between Ω_V and Ω_R proper interface conditions have been posed. In Ω_V region the Helmholtz equation has been solved:

$$\nabla^2\vec{A} + k^2\vec{A} = 0, \quad k^2 = j\omega\mu\sigma \quad (3)$$

where μ and σ are respectively the magnetic permeability and the conductivity of the medium and the Lorentz gauge has been imposed. At the boundary of the simulation domain, Ω_{INF} ,

infinite boundary conditions have been posed in order to let the magnetic field vanishing at infinite distance.

A. Data models

The simplified model considers a restricted set of organs in the abdomen and thorax regions listed in Table I, while the complete model contains also the head tissues, muscle and a more extensive set of thorax and abdomen organs. In addition, an homogeneous model describe the human body with constant resistivity value has been considered.

The human body tissues are described with the value of their resistivity, ρ , derived by the Gabriel model [5]. The values at 200 Hz frequency are presented in Table I. The magnetic field source is a cable with a current amplitude of 53.7 Arms.

TABLE I

TISSUES ELECTRICAL CHARACTERISTICS TISSUES ELECTRICAL

tissue	ρ [Ωm]	tissue	ρ [Ωm]	tissue	ρ [Ωm]
Midollus	35.4	Spleen	10.1	Body M_1	5
Kidney	9.3	Stomach	1.9	Body M_2	5
Liver	25.6	Colon	5.3	Body M_3	46.9
Pancreas	1.9	Intestine	1.9	Body M_4	46.9

B. Evaluation rules

In order to limit induced current density in human body tissues, ICNIRP guidelines provide basic restrictions that have been extrapolated from direct effects on human body. The induced current density is related to the electro-stimulation of nerves and muscles. From basic restrictions reference values have been derived by means of suitable models, in order to provide quantities easily measurable using simple instrumentation (e.g. magnetic flux density). Biological effects depends by the magnetic field frequency [1]. Consequently, the reference limits have been expressed as a function of the field frequency. In the present case the limit for the magnetic flux density is 125 μT and for induced current density is 10 mA/m^2 .

III. RESULTS

Four different human models have been developed using the set up shown in Fig. 1. The current density in organs evaluated in the homogeneous model (M_1) has been compared with the ones computed with more detailed models where the resistivity of tissues has been set with reference to the values of Table I. Models M_2 and M_3 contain only organs in abdomen without considering muscle tissue. In model M_1 the resistivity of the volume around organs has been set to the weight average value of all tissues (5 Ωm , as recommended by standards for numerical homogeneous models [6]) whereas the one in model M_3 has been set to the fat resistivity (46.9 Ωm). The model M_4 contains also thorax and head organs and muscle regions. In this case the volume around organs has been described with the fat resistivity.

Some results are shown in Table II. In this table the maximum values of the induced currents and magnetic flux density have been reported in each organ for the four models. The last row of Table II reports the induced current density evaluated in a homogeneous cylinder. Comparing M_1 and M_2 results it should be pointed out that organs that have a resistivity higher than the average value have a lower induced current density than

the one computed in the homogeneous case (M_1). The regions with a lower resistivity have higher induced currents. It should be underlined that the resistivity of the tissue that surrounds the organs affects the value of the computed induced current density. Sometimes, the induced current density considering the correct tissue resistivity is higher than the one computed with an homogeneous model. Models M_3 and M_4 have been built taking into account small differences in organ dimensions and their relative positions in the phantom to verify the reliability of the results.

TABLE II
INDUCED CURRENT DENSITY IN HUMAN BODY TISSUE AND
CORRESPONDING MAGNETIC FLUX DENSITY

tissue	B [μT]	M_1 [mA/m^2]		M_2 [mA/m^2]		M_3 [mA/m^2]		M_4 [mA/m^2]		
		R_L	J	R_L	J	R_L	J	R_L	J	
body	50	0.4	1.88	0.19	1.9	0.19	0.55	0.06	0.67	0.07
colon	44	0.4	0.95	0.10	0.91	0.09	0.76	0.08	1.23	0.12
liver	39	0.3	0.73	0.07	0.19	0.02	0.44	0.04	0.32	0.03
intestin	45	0.4	0.8	0.08	1.87	0.19	2.25	0.23	3.00	0.30
pancre	37	0.3	0.36	0.04	0.92	0.09	0.80	0.08	0.84	0.08
kidney	35	0.3	0.58	0.06	0.35	0.03	0.23	0.02	0.22	0.02
stomac	42	0.3	0.71	0.07	1.46	0.15	1.30	0.13	1.44	0.14
Spleen	42	0.3	0.75	0.08	0.4	0.04	0.31	0.03	0.33	0.03
midolla	29	0.2	0.43	0.04	0.09	0.01	0.08	0.01	0.09	0.01
Cylind.	67	0.5	1.06	0.11						

In the present case ICNIRP limits are satisfied both for magnetic flux density and induced current values. Nevertheless, it can be pointed out that the ratio R_L between the evaluated quantity and the induced current limit is roughly ten times lower than the correspondent ratio computed for magnetic flux density.

IV. CONCLUSION

Numerical models of human body have been investigated for the evaluation of the exposure to low frequency magnetic field in order to compute quantities comparable with basic restrictions. Finally, homogeneous cylindrical models can be useful applied for a preliminary evaluation of the exposure.

V. ACKNOWLEDGMENTS

This project has been developed in the frame of a research contract with Telwin SpA.

Abstract— New sensors of magnetic induction in near field, dedicated to studies of electromagnetic compatibility, are proposed according to the principle of the Standard CISPR16-1 coils. The new coil shape allows the sensors to be sensitive to only some specific components of the multipolar expansion, which is similar to a spatial filtering. Our proposition follows previous works. By means of rotations of the spherical harmonics functions, our aim is to simplify the geometry of the sensor coils introduced before. After a description of the tools required, the design method is described. Comparative robustness studies end the article.

I. INTRODUCTION

For electromagnetic compatibility studies, a compact model of the stray magnetic field generated by power electronic systems enables to reduce the design cost. To determine this model, our works focus on experimental approach. In this case, the use of large loop antenna offers advantages, especially by reducing the effect positioning inaccuracies. For instance, to identify the first order of a multipolar expansion (dipole) [1], Standard CISPR 16-1 [2], proposes to use three orthogonal loops (Fig. 1, on the right hand side). This standard applies for the medium frequency range: 9 kHz to 30 MHz.

The problem is that no source is composed of pure dipoles. Therefore, even the standard method can lead to errors. In previous works, we have proposed to take into account higher order terms in the expansion leading to a new and original coils sensors design and improving the accuracy [3]. Here, we introduce a simplification of the sensor design. The principle of this design and some improvements are reminded and a comparative robustness studies are proposed.

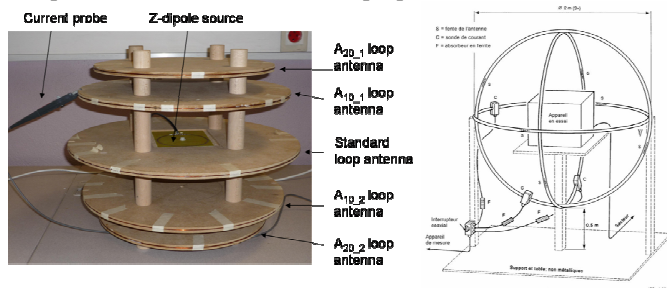

Fig. 1. On the left hand side, the whole system of loop antennas ('A₁₀', 'A₂₀' and 'Standard'). On the right hand side, the loop-antenna system from Standard CISPR 16-1 consisting of three orthogonal loop-antennas

II. MULTIPOLAR EXPANSION

For near field studies and the standard frequency range, the quasi-static approximation is suitable. Outside a sphere including all radiation sources, the magnetic field can be fully described by its magnetic scalar potential Ψ solution of the Laplace equation. For each frequency and in a given spherical coordinate system, the unique multipolar expansion solution is:

$$\mathbf{B} = -\nabla\Psi \quad \text{with:} \quad \Psi(r, \theta, \varphi) = \sum_{n=1}^{+\infty} \sum_{m=-n}^{+n} A_{nm} \cdot \frac{1}{r^{n+1}} \cdot Y_{nm}(\theta, \varphi) \quad (1)$$

where Y_{nm} is real harmonic spherical function of order n and degree m , (r, θ, φ) are the spherical coordinates whose origin is the centre of expansion and A_{nm} the unknown coefficients. This development is hierarchical: for elements of order n the field decreases as $1/r^{n+2}$. A decomposition limited to the order 2 gives a precision considered as sufficient beyond the distance of measurement. There are 8 coefficients to measure (3 for order 1, 5 for order 2).

III. SENSOR DESIGN

The measurement principle is similar to a spatial filtering: according to the coil shape, each sensor is just sensitive to its specific component of the multipolar expansion. Thanks to a rigorous approach, we proposed a system of coils, allowing the identification of the two first orders ($n = 1$ and 2) and not sensitive to the two followings (3 and 4). It leads to the realisation of 8 flux coils sensors topology located on a measurement sphere (radius r_{mes}). The method is detailed in [3]. The 8 sensors are presented on Fig. 2. These first shapes are linked to spherical coordinates: outlines within θ or φ constant. But this solution is too complex in order to make a practical realisation.

Fig. 2. 8 coils sensors for the identification of 1 and 2 orders. The flux is counted as positive for the red coils and negative for the blue ones

A. Rotation properties of Y_{nm}

We want to simplify this solution in order to build a practical sensor. The basis idea comes from properties of spherical harmonic functions. Indeed, thanks to rotations, it is possible to produce all components of the same n order with only one. Examples are given on Fig. 3. The first order rotation dependency is evident. This is more complex for the second order case. The idea is that it is possible to generalise this property to design sensors. Thus, to reach the simplification, we must start from simpler sensor coils. The A_{10} and A_{20} loop antennas are just constituted of coplanar coils (black frame on Fig. 2).

Fig. 3. By n order, same shape.

B. Sensor design

The full set and method are presented on Fig. 4. For the first order, the A_{10} loop antenna direction is just lined with targeted component. The second order case needs A_{20} sensor rotations and composition of the measured fluxes. We demonstrate that the totality of filtering capability is conserved with this new solution. Thus, 2 only different and simple shapes allow identifying the 8 first components of the multipolar expansion.

The complete validation is reached thanks to numerical (by Finite Elements Method) and experimental experiences. Our prototype is presented on Fig 1, on the left hand side. It concerns just the identification of A_{10} and A_{20} components. To these 4 coils, a loop-antenna ($r_{mes} = 0.225$ m) located on the middle plan is added to demonstrate the robustness of our new approach. It corresponds to the initial z -dipole sensor proposed in [2].

Fig. 4. Sensor set and the design process

C. Comparative robustness

Several cases have been studied. First, numerical experiences enable to demonstrate the efficiency of our solution toward punctual measurements. This integral processing method is more accurate. Furthermore, complete measurement process is faster than 3D mapping solutions with one punctual sensor.

Secondly, we check the robustness of the sensor in comparison with the solution proposed by the standard. This is achieved thanks to the shifting of the source loop versus the center of sensors itself. Only the dipole identification is concerned in this experiment. The measurement results on Fig. 5 show that an error on the dipole determination occurs. In our sensor cases, despite the source shifting, identification error keeps stationary and reasonable (less than 2% of error). With Standard sensor, the error raises to 11%. A decentered dipole implies a more complex field (i.e. higher orders in the decomposition). The error is mainly attributed to the contribution of order 3 multipolar induction term in Standard sensor. In contrary, our sensors are designed to filter this third order term.

Fig. 5. Comparison between Standard and our sensor identifications: relative error compared to the actual and theoretical z -dipole with different gaps

IV. CONCLUSION

We have shown that it is possible to improve the dipole components measurement of the Standard device. It is also possible to create simple systems of coils which measure di- and quadri-polar components by filtering exactly both high orders.

Furthermore, our identification method is validated by experimental and numerical results. Comparative robustness studies show the interest of using dedicated multipolar component sensors, which are more robust than punctual measurement solution. So, in future work, we can focus on the realization of the full coils system including rotation.

Abstract—SAR validation measurements are already an industry standard, necessary to enable the distribution of commercial mobile phones. Here it is discussed the full wave simulation of a SAR measurement system, used to certify mobile phones in the international market. The electric field measured in a phantom by a mechanical system is modeled and compared with simulations, so that a validation is achieved and further sensitivity analyses can be carried out.

I. INTRODUCTION

The present study covers the simulations of an experiment related to SAR (Spatial-Average Specific Absorption Rate) measurement. In order to get a better understanding of the dynamics of SAR measurements, a thorough analysis of the different parameters and their impact on the final results is carried out. As an example of the importance of this kind of analysis, it should be mention the fact that the liquid which emulates the brain tissue is subjected to variation in its electrical characteristics, due to temperature changes, and the estimation of how it will influence the measured electric field can assume a helpful role during the measurement process.

II. MODELED EXPERIMENT

The modeled experiment is depicted in Fig.1. The measurement setup is completely described in [1]. A plastic phantom is partially filled with a liquid, whose electrical characteristics (real and imaginary permittivity) emulate the human brain tissue. An electric field probe is moved by a robotic system inside the liquid, so that the electronic readout system gives the electric field in its 3 components. This field is generated by a resonant dipole located below the phantom.

Fig. 1. Picture of the measurement system. The electric field is measured along these 13 different lines, 10mm from the bottom.

The liquid and the dipole have their electromagnetic characteristics determined by [1]: namely, the liquid permittivity ϵ (real and imaginary), and the dipole length that are set for each frequency. Typical frequencies can be as low as 300MHz up to 3GHz. Here, we focus in the mobile phone service frequency, 900MHz. For this frequency, Table I lists the most important parameters for this specific measurement setup.

TABLE I
MAIN PARAMETERS FOR THE 900MHz EXPERIMENT SETUP

Parameter	Value	Meaning
ϵ_r	41.5	Real part of the liquid permittivity
σ	0.98S/m	Liquid Loss (conductivity)
h	15mm	Liquid height in the container
d	1mm	Distance center dipole to the bottom of the container
L	14.9mm	Dipole length

The container is made of plastic 0.5mm thick ($\epsilon_r=3.7$; $\sigma=0.0051\text{S/m}$), and it is an ellipsoid with axes 220mm and 300mm. Its height is 19.5mm, partially filled with liquid as Fig.1 suggests. The actual antenna is fed by a complex balloon system, which is a proprietary design. It was simulated only the dipole, fed by a balanced port. The electronic system assures that the input power at the antenna terminal is 16dBm (approximately 40mW), so all the computed field results are scaled to this power.

III. MEASURED RESULTS

The robotic probe sampled the electric field along the 13 lines, as Fig. 1 shows. The measurement plane is placed 10mm far away from the bottom of the phantom. Therefore the probe is immersed in the liquid.

IV. RESULTS

The simulation was carried out using the Finite Integration Technique (FIT) [2], [3]. The model was built inside the software interface, completely parameterized, so that scenarios for other frequencies can be easily changed, without necessity of starting from the scratch. The FIT method admits solutions both at frequency and time domains. Since we are dealing with a SAR environment (although, at this moment, we are not working directly with SAR values, but electric fields), the

transient (time domain) solver was used. It applies a pulse in the time domain to the structure, and the Maxwell equations are solved in a leap-frog scheme. The results are then displayed in both time and frequency domain, i.e., S-parameters, fields at different frequencies, signals in time domain, etc. Here we are interested in the electric field sampled along the lines displayed in Fig.1.

The results are depicted in Fig.2 and Fig.3, for two different sampled lines.

Fig. 2 Measured and simulated electric field for a line placed in the middle of the container (shown in dark color in the picture at the bottom).

Fig. 3 Measured and simulated electric field for a line placed in the extreme of the container (shown in dark color in the picture at the bottom).

Fig. 4 Computed Electric field for the line displayed in fig.4 bottom, for different relative permittivities.

The discrepancy between the measurement and computed results can be ascribed to the influence of the balloon and other circuitry in the antenna current. The simulated dipole is fed by a perfectly balanced source, so eventual differences in the mechanical system will generate another current pattern in the dipole, therefore generating a different shape in the electric field. The sensitivity of the electric field to accidental variations (with factors like temperature, aging, bacteria, etc) in the liquid characteristics is also analyzed. The result for a variation of ± 1 in the relative permittivity ϵ_r is displayed in Fig.4. From the results presented in Fig.5, it was possible to see that the electric field, in absolute value, is not very sensible to the relative permittivity. Further studies will determine how much this variation can happen with the liquid.

V. CONCLUSION

A numerical evaluation of a real SAR measurement system is presented. The computed numerical results proved to provide a helpful and fast insight into the pre-studies regarding the SAR measurements and the role of the electrical parameters in this process.

Abstract— This paper presents an accurate mathematical model for high frequency transient analysis in grounding systems based on electromagnetic field theory in frequency domain and Method of Moments. The only input data of resultant computational tool is grounding dimensions, soil electromagnetic properties and excitation. Results in both time and frequency domain are provided.

I. INTRODUCTION

Grounding systems are an important element for lightning protection and electromagnetic compatibility (EMC) related problems. Their basic function is to disperse the lightning current to earth without causing any potential differences or induced voltages that might endanger people or damage equipments. Grounding behavior at low frequencies is well understood using simplified analysis based on static approximation [1]. However, when energized by lightning currents, they present a very particular behavior and their analysis cannot be carried out with traditional methodologies employed in low frequency occurrences [1].

The transient analysis of grounding electrodes is usually developed based on three main different approaches [1]: i) electromagnetic field theory, ii) transmission line theory and iii) circuit theory. The first one is considered as the most accurate since it is based on least neglects in comparison to the methods based on transmission line and circuit theory [1]. Also the methodologies may be differentiated by the domain where the transient is solved: i) time domain or ii) frequency domain.

In this work a methodology based on the electromagnetic field theory is applied to investigate the impulsive behavior of grounding. The transient problem is solved in frequency domain taking the great advantage of robustness and easiness to computed electromagnetic fields in this domain. A computational tool is developed and few results of its application in response evaluation of a long horizontal ground electrode to an impulsive current is included.

II. ELECTROMAGNETIC GROUNDING MODEL

The proposed grounding model is based on the Hybrid Electromagnetic Model (HEM), with some suitable modifications [2]. Simulations are performed in frequency domain and the time domain response is obtained by application of an inverse Fourier transform.

The grounding system is represented by a set of cylindrical electrodes. Each electrode is source of a transversal current I_T and longitudinal current I_L , as illustrated in Fig. 1(a) [3]. The current I_T generates a divergent electric field at a generic point. Considering each pair of electrodes, this current promotes

capacitive and conductive couplings (self and mutual ones). The current I_L generates a nonconservative electric field and magnetic field at a generic point. Considering each pair of electrodes, this current promotes inductive and resistive couplings (self and mutual ones). The electromagnetic coupling between the electrodes can be computed by electromagnetic fields integration along each one (see Fig. 1(b)), and leads to the following equations [3]:

$$V_{ij} = \frac{1}{4\pi(\sigma + j\omega\epsilon)L_jL_i} \int_{L_i} \int_{L_j} \frac{e^{-\gamma r}}{r} dl_j dl_i, \quad (1)$$

$$\Delta V_{ij} = -j\omega \frac{\mu}{4\pi} \int_{L_i} \int_{L_j} \frac{e^{-\gamma r}}{r} d\vec{l}_j \cdot d\vec{l}_i, \quad (2)$$

where V_{ij} refers to average potential of electrode i due to the transversal current dispersed by electrode j ; ΔV_{ij} is the voltage drop along electrode i due the longitudinal current flowing along electrode j ; σ , ϵ and μ are, respectively, the medium electric conductivity, electric permittivity and magnetic permeability; γ is the propagation constant and ω is the angular frequency.

Fig. 1. (a) Current sources in each electrode and (b) Electrodes interaction

The problem formulation and its final solution are obtained by the application of Moments Method (MoM) [4]. The electrode is divided into N elements. The value of N is determined in a way that the thin-wire approximation is valid for the longitudinal current along the element [3], [4]. Also, the length of each one is sufficiently small, so that longitudinal and transversal currents may be considered constant in each element. Naturally each current can change from an element to other. Based on these assumptions, the piecewise-constant current approximation is used [3]. From the above considerations and by applying (1) and (2) to the N elements, two systems of linear equations can be obtained [3]: $V = Z_T I_T$ and $\Delta V = Z_L I_L$. The terms of V and I_T corresponds, respectively,

to the average potential and transversal current in each element and the terms of Z_T corresponds to the transversal impedance between the elements i and j [3]. The terms of ΔV and I_L corresponds, respectively, to the voltage drop and longitudinal current in each element and the terms of Z_L corresponds to the longitudinal impedance between the elements i and j [3]. In Z_T and Z_L computation, the influence of air-soil interface is taken into account approximately by the modified image theory and the reciprocity theorem is valid, what permits a substantially reduction of computational time [3]. The two systems of linear equations relations may be reduced to a unique system by means of two fundamental considerations [2], [3]: i) the average potential in each element is equal to the arithmetic media of nodal potentials and the voltage drop in each element is equal to the difference of nodal potentials; ii) the Kirchhoff's current law is explicitly enforced on all element's junction points. Considering these two assumptions, an only system of linear equations of kind $Ax=b$ is composed and its solution leads to final results.

III. RESULTS

In this section is simulated a 60-m long horizontal electrode with 1-cm radius imbedded in earth with 1.000- Ωm resistivity and relative permittivity of 15. The electrode excitation is made by the injection of two different double exponential current waves: i) a fast one of 1 kA and 1.2/50- μs and ii) a slow one of 1 kA and 12/50- μs .

Fig. 2 illustrates the magnitude of the harmonic grounding impedance $Z(\omega)$, independent of excitation, along typical spectrum of a lightning discharge. As can be observed, at low-frequency range the harmonic impedance is frequency independent and corresponds to the low-frequency resistance concept R . As frequency increases, the impedance value diverges from the resistance value and, after about 100 kHz, it exhibits inductive behavior and its value becomes larger than R . In the analyzed case, the electrode does not present significant capacitive behavior, mainly due to its large length.

Fig. 3(a) illustrates the response of the horizontal electrode to the slow wave: $v(t)$, which is the transient voltage at injection point and $z(t)$, which is the transient impedance, ratio between $v(t)$ and $i(t)$. The slow wave does not have high frequency components of sufficient intensity to excite the inductive behavior of $Z(\omega)$. The response is essentially determined by the frequency independent parcel of $Z(\omega)$. As a result, $v(t)$ is not significantly modified in comparison to current waveform $i(t)$ and their peaks occurs at the same time. The transient impedance $z(t)$ has high values in the first instants of transient, but quickly reduces to lower values and tends, around 8- μs , to the low frequency resistance value ($R=32.75\text{-}\Omega$). Fig. 3(b) illustrates the response of the same electrode to the fast wave. The fast wave has sufficient high frequency content to excite the inductive parcel of $Z(\omega)$ and, as can be observed, $v(t)$ is advanced in time in relation to $i(t)$. This inductive behavior causes larger value of transient voltage peak. The transient impedance $z(t)$ presents similar behavior of the previous case and tends, around 2.5- μs , to the resistance value. The results illustrate the significant influence of wave front time in grounding impulsive behavior.

Abstract — This paper presents an immunity measurement process that can be used to evaluate the performance of numerical methods. This simplified setup possesses the most important characteristics that a numerical model must include when dealing with EMC engineering problems. The results are compared with two numerical methods: one is based on FEM and the other on FDTD.

I. INTRODUCTION

Although the tests of components separately reduce the compatibility problems probability, they can't guarantee the correct functioning of these ones when installed in a vehicle [1]. The reason is that the diverse interactions between components inside a vehicle differ considerably from a model to another. Moreover, the tests performed on each component are not able to predict these phenomena.

To avoid this drawback, numerical methods appears as a solution to predict the radiated emission and to simulate immunity tests before the construction of prototypes, reducing the probability of failing in real EMC tests. The main problem is that the computing domain is very large, due to the fact that a vehicle volume is approximately $7,5\text{m}^3$ and radiated immunity tests use frequencies beyond 1GHz.

This work presents a critical analysis of computing models application for simulating a controlled experiment of radiated immunity in a vehicle. Two software of electromagnetic fields calculation have been used to handle a radiated immunity problem, being one based on the Finite Elements method (FEM) and the other on the Finite Differences method (FDTD). Even simplified, this problem includes the main challenges that are involved in this kind of issues. The results obtained are compared with experimental measures, and questions about accuracy and computational effort are treated.

II. THE IMMUNITY TEST

Figure 1 presents the geometry of the problem. The immunity test consists basically in evaluating the behavior of the device under test (DUT) in presence of an intense electromagnetic field. For this reason, the device is placed close to an antenna which irradiates a strong electromagnetic field. During the test, the device's position and the antenna's polarization must change to better evaluate the electromagnetic wave effects [2].

The antenna geometry and the mainly metallic structure of a vehicle require the use of integrals techniques, such as the

Fig. 1. The immunity test setup

Boundary Integral Equations Method (BEM) or the Moment Method (MM). However, the devices or regions of interest inside the vehicle are filled with different materials that have different electromagnetic and, for this reason, volumetric domain methods like FEM or FDTD are used instead of integration methods.

Due to these characteristics and the changes of the relative position between the antenna and the vehicle during the test, it is impossible to define a better computational technique to handle this problem and a solution that combine different methods must be applied to reduce the computational effort as presented in [3],[4].

In this context, a measurement setup is presented as a reference to evaluate the behavior of numerical methods to handle electromagnetic immunity tests. Although the proposed problem consists in a simplified geometry, this setup preserves the most important challenges for a numerical method which is to deal with immunity test in a vehicle.

III. MEASUREMENT BENCH SETUP

The geometry of the problem is presented in Fig. 2. It is made of a wideband horn antenna (200 to 2000 MHz) placed 1 meter distant from the vehicle. The vehicle height and width are similar to those of a typical vehicle, 1,70m x 1,45m. However, the vehicle length has been reduced to 1,62m considering only the region of the panel and the motor bay where the highest number of electro-electronic devices are placed.

The setup and the excitation system follow the recommendations proposed in the ISO11451-4 standard [2], except for the relative distances between the vehicle and the absorbing walls that have been decreased of 1 m in order to reduce the computing domain and insert dielectric and nonlinear objects, characteristic in the immunity test.

Fig. 2. The measurement setup

Characterizing the different materials inside a vehicle is not an easy task. The solution to introduce an inhomogeneous ambient in the test bench was to place the vehicle near the semi-anechoic chamber’s absorbing wall in order to consider the absorbing surface as non-ideal. Its effects have been introduced in the numerical methods as shown in Fig. 3. The main advantage of using the own absorbing wall consists in the precision of the electromagnetic parameters provided by the manufactory for the test frequency range.

Fig. 3. Magnetization as a function of applied field

IV. RESULTS

The vehicle has been submitted to a constant electromagnetic field, 100 V/m, in frequencies from 200 MHz to 1000 MHz. The simulations results that will be presented are those corresponding to the panel points. Indeed, they are these points that most witnessed the interaction with the semi-anechoic chamber’s wall. See Fig 3. Table I resumes the electric field at the measurement points inside the simplified vehicle (A1 to A4 in fig. 3) in comparison with the results obtained from the reference methods. The results at A5 are shown in Fig. 4. A good similarity has been observed, especially in the 200-600MHz frequency band. Even in the 700-1000 MHz, where the radiation lobe of the antenna used in the experimentation is very narrow, consequently, the nominal variation of the electromagnetic field sensor’s position is more sensitive the results still acceptable. We have to take into account that the measurement errors adopted in the radiated immunity tests are about 1,5 to 2,0 dB.

However, a high computational cost is observed, even with simplified vehicular structures been the main constraint in real applications.

V. CONCLUSION

In this paper the capacity of two numerical methods are analyzed to solve an EMC immunity test. Although simplified, this test retains the major characteristics that a numerical model must represent. The results point out that computational modeling can be considered as a useful tool for the prediction of electromagnetic fields in the radiated immunity test.

The previous knowledge of field strength in the areas in which the electronic devices and equipments will be located can effectively reduce the reprobation probability in the EMC tests, especially in design of vehicles where the physical tests are very posterior to the development of the components separately. However the computational effort still prohibits practical applications.

Effect of grounding system on Electromagnetic Fields around Building Struck by Lightning

Bo Zhang, Jinliang He, Rong Zeng, and Shuiming Chen

State Key Lab of Power Systems, Department of Electrical Engineering, Tsinghua University
Beijing, 100084, China
shizbcn@tsinghua.edu.cn

Abstract — In this paper, an approach is proposed to analyze the current distribution and the electromagnetic field of a building struck by lightning. This approach is based on the moment method and can consider the metallic grids under the ground and on the ground all together. Both the potential differences among the grounding parts and the electromagnetic interactions among the grids are taken into account.

I. INTRODUCTION

When lightning strikes building, high current will flow through the metallic grid and will dissipate into the soil from the grounding system. This accident will generate strong transient electromagnetic fields, which may affect the safety of the electrical and electronic units contained inside the building. Thus, the computation of the current distribution and of the electromagnetic fields is an interesting and important engineering problem [1-4].

To calculate the current distribution, the soil conductivity is usually considered to be infinite, which means that the grounding system can be neglected [1-4]. In fact, because the soil conductivity is finite, potential differences always exist among the grounding points. When lightning occurs, the inductance along the grounding electrode will also take effect and the ground potential will be distributed more unevenly. Then, the current distribution and the electromagnetic fields may be different from those with infinite soil conductivity. In this paper, an approach considering soil conductivity effect is proposed to analyze the current distribution and the electromagnetic field of a building struck by lightning. Moment method (MoM) is used to consider the metallic grids under the ground and on the ground all together.

II. NUMERICAL APPROACH

To calculate the electromagnetic field around the building struck by lightning, current distribution on the structure should be obtained first. MoM is used to calculate the current distribution and the multi-line structures should be divided into short segments [5]. Because the size of the building is much less than the wavelength associated with the maximum significant frequency of the lightning current waveform, near field theory can ensure a satisfactory numerical accuracy. By introducing the concept of complex resistivity, which is the combination of both the permittivity and the resistivity, all segments under the ground and on the ground can be taken into account. Then, the concept of leakage currents can be introduced. Meanwhile, some assumptions are used which are also shown in Fig. 1.

Fig. 1. Current distribution on the segments.

- 1) The longitudinal current in the same segment is constant and is centralized on the axis.
- 2) The leakage currents are distributed evenly around the nodes (the points of intersections between the segments), i.e. each current is leaked evenly from all the half segments connected to corresponding node.
- 3) Each segment can be considered as a filament.

On the surface of each segment, the boundary condition must be satisfied:

$$\mathbf{E}^i + \mathbf{E}^s = 0 \quad (1)$$

where \mathbf{E}^i is the longitudinal component of the external electric field caused by other segments, \mathbf{E}^s is the longitudinal component of the internal electric field. For all segments, by integrating (1) along the longitudinal direction between their two ends, following equation will be obtained [6]:

$$j\omega\mathbf{M}\mathbf{I}^l + \mathbf{A}\mathbf{V}^n + \mathbf{Z}\mathbf{I}^l = 0, \quad (2)$$

where \mathbf{M} is a matrix of the inductances between segments, \mathbf{V}^n is a column vector of the potentials at the nodes, \mathbf{I}^l is a column vector of the longitudinal currents in the segments, \mathbf{Z} is a diagonal matrix of the segments' internal self-resistances [7], \mathbf{A} is a matrix reflecting the connection relationship between segments and nodes. If node j is connected to the end point of segment i , A_{ij} is 1, if node j is connected to the start point of segment i , A_{ij} is -1, or else A_{ij} is zero. The entry M_{ij} in \mathbf{M} can be obtained by [6]

$$M_{ij} = \frac{\mu}{4\pi} \int_{l_i} \int_{l_j} \frac{1}{r} dl_j dl_i, \quad (3)$$

where l_i and l_j are the paths of segment i and segment j , and r is the distance between the source point and the field point. If i is equal to j , l_i is at the axis and l_j is at the surface of segment i . \mathbf{V}^n in (2) can be obtained by

$$\mathbf{V}^n = \mathbf{R}\mathbf{I}^e, \quad (4)$$

where \mathbf{I}^e is a column vector of leakage currents around nodes as shown in Fig. 1, and \mathbf{R} is a matrix of mutual resistances between nodes and leakage currents. From Fig. 1, it should be

noted that the leakage current around a node is distributed evenly from all the half segments connected to the node.

According to the longitudinal current and leakage current distribution in Fig. 1, I^l and I^e have following relationship:

$$I^e = A^T I^l. \quad (5)$$

where A^T is the transpose of A . By substituting (5) into (4) and then into (2), a group of equations is obtained as

$$j\omega MI^l + ARA^T I^l + ZI^l = 0. \quad (6)$$

If segment k has an injected current I_k^s , the corresponding equation can be substituted by $I_k^l = I_k^s$. The suspended segment can be considered as a segment having an injected current with 0 A. Thus, a group of equations with longitudinal currents as unknown variables is obtained from which the longitudinal currents can be solved.

Because the near field is like a quasistatic field, all the parameters are calculated in quasistatic field. The transient electromagnetic fields around the multi-line structures by near-field lightning strokes can be analyzed with the help of fast Fourier transform.

III. COMPLEX RESISTIVITY

In order to take account of the metallic grids under the ground and on the ground all together, concept of complex resistivity is used to calculate R in (4), which is the combination of both the permittivity and the resistivity of the medium:

$$\rho' = \frac{\rho}{1 + j\omega\varepsilon\rho}. \quad (7)$$

where ρ and ε are the resistivity and the permittivity of the medium. Both the air and the soil have their own complex resistivity. Based on the near field theory, by using the image theory, the effect of both the permittivity and resistivity of the medium can be counted for in the Green's function to calculate R in (4) and to calculate the electric field.

IV. VALIDATION AND APPLICATION

We have test the approach in this paper with published results of a simulated lightning current (1/40 μ s, 20 kA) fed into the upper corner of a Faraday's cage shown in Fig. 2 [2]. The cage is constituted by aluminum barrels having 5 \times 30 mm cross section and has a regular 8 \times 8 \times 8 m mesh. The lightning current has a vertical channel length of 400 m. In Fig. 3 and 4 the attenuation along the line CD produced by the cage is shown, where the ratios between the EM field produced by the lightning with or without the presence of the cage are reported. In the case of the lightning without the cage, the lightning channel has been prosecuted until the ground. The variables used in the figures are $\eta = E_{\max}$ with the cage / E_{\max} without the cage and $\zeta = B_{\max}$ with the cage / B_{\max} without the cage. In paper [2], the soil is considered as perfect conductor. In this paper both the results with perfect soil and those with 1 m depth grounding system in 100 Ω m soil are presented.

Fig. 2. Calculated model.

Fig. 3. Profiles of the electric field attenuation along the line CD.

Fig. 4. Profiles of the magnetic field attenuation along the line CD.

It can be seen that when the soil is considered as perfect conductor, the results in this paper are in agreement with those in [2]. For the electric field, its attenuation along the line CD almost does not vary with the resistivity of soil. However, for the magnetic field, its attenuation near D varies greatly with the resistivity of soil. This may be because the current likes flowing to far place through conductor when the resistivity of soil is great. More details will be presented in the formal paper.

Conservativeness of the SAM Phantom for the SAR Evaluation in the Child's Head

Vikass Monebhurrin

Department of Electromagnetics, DRE-L2S, SUPELEC
3 rue Joliot-Curie, 91192, Gif-sur-Yvette Cedex France
E-mail: vikass.monebhurrin@supelec.fr

Abstract — The conservativeness of the SAM (Specific Anthropomorphic Mannequin) for the SAR (Specific Absorption Rate) evaluation in the child's head is investigated. The child's head model is derived from the visible human head model using a morphing technique. Numerical simulations are performed with the SAM phantom and the child head model for the four intended use positions using three excitations – dipole antenna, monopole antenna and PIFA (Planar Inverted-F Antenna)-based mobile phone – at three frequencies corresponding to the currently used mobile communications systems. Overall the SAR calculations show that the SAM phantom is conservative.

I. INTRODUCTION

The ever increasing use of mobile phones by the general public – from adults in the very beginning to children nowadays – has constantly raised questions about the level of electromagnetic exposure and the possible adverse health effects for the user. The basic restriction level was set by ICNIRP (International Commission on Non-Ionizing Radiation Protection) to a maximum 10 g averaged Specific Absorption Rate (SAR) value of 2 W/kg for the head exposure [1]. The SAR compliance test is a pre-requisite prior to the commercialization of a mobile phone. Currently the SAR conformity assessment of mobile phones can only be performed by measurements. The detailed procedures to assess the SAR compliance of mobile phones are provided by international standards such as IEEE1528 [2] and IEC62209-1 [3]. A standard head phantom – the Specific Anthropomorphic Mannequin (SAM) – filled with an appropriate tissue equivalent liquid is recommended for the measurements of the mobile phone according to four basic intended use positions: left cheek, right cheek, left tilt and right tilt. The morphology of the SAM phantom is chosen to be representative of the adult head. Numerical simulations confirm that the values recommended for the dielectric properties of the tissue equivalent liquid are conservative [4].

Since mobile phones are being increasingly adopted by children, the question has been raised about the electromagnetic power absorption in the child's head. It is recognized that the morphology of a child's head is different from an adult's head, especially at the early stages of growth. Little data is available on the dielectric properties of biological tissues of children. Furthermore, numerical models of children's heads are scarce. A simple size reduction of an adult's head model does not provide a good morphological shape of the child's head. A better approach is to perform a morphological transformation of the adult's head: each part of the head is reconstructed with its specific growth rate and the

different parts are recombined with appropriate transition areas to avoid discontinuities [5].

The conservativeness of the SAM phantom with regard to the morphological aspect of the child's head is herein investigated. The morphing technique is applied to derive the child head model from the commonly used visible human head model. Three different excitation sources – dipole, monopole and PIFA (Planar Inverted-F Antenna)-based mobile phone – are considered for the SAR calculations using this child head model and the SAM phantom.

II. NUMERICAL MODELING

Figure 1 shows the two head models used for the study: (a) the SAM phantom and (b) the child head model derived from the visible human head model. A commercial package of the Finite Integration Technique (FIT) is chosen for the numerical simulations. Because of its relatively small size, the full child head model must be considered for the calculations. However the numerical simulations are optimized by considering only the half-head SAM phantom since it can be shown that the other half can be safely neglected.

Fig. 1. (left) SAM phantom and (right) child head model (not to scale).

Figure 2 shows the three different sources considered for the SAR calculations: (a) half-wavelength dipole antenna, (b) quarter-wavelength monopole antenna mounted over a metallic box, and (c) PIFA-based mobile phone. All numerical simulations are performed for the three commonly used mobile communications systems: GSM (Global System for Mobile communication) at 900 MHz, DCS (Digital Communication System) at 1750 MHz and UMTS (Universal Mobile Telecommunication System) at 1950 MHz. The dielectric properties of the tissue equivalent liquids employed for the numerical simulations are provided in Table I for the three frequencies.

Fig. 2. Excitations used for the numerical simulations: (left) half-wavelength dipole antenna, (middle) quarter-wavelength monopole antenna mounted over a metallic box and (right) PIFA-based mobile phone.

TABLE I

DIELECTRIC PROPERTIES OF THE TISSUE EQUIVALENT LIQUID

Frequency [MHz]	Relative permittivity	Conductivity [S/m]
900 (GSM)	41.5	0.97
1750 (DCS)	40.0	1.40
1950 (UMTS)	40.0	1.40

III. RESULTS

Figures 3, 4 and 5 show the maximum 10 g averaged SAR results obtained for the different configurations using the dipole antenna, the monopole antenna mounted over the metallic box and the PIFA-based mobile phone, respectively. All SAR values are normalized with respect to the highest value obtained among the different configurations. Furthermore, for each configuration, the SAR value is normalized with respect to the accepted power i.e. the antenna mismatch is not taken into account. The highest SAR values are observed with the SAM phantom and the GSM system i.e. at 900 MHz. The PIFA-based mobile phone provides the highest SAR values for the cheek position. For a given antenna configuration, the SAR calculated with the child head model is at least two times lower than the maximum SAR value obtained with the SAM phantom. Overall the SAM phantom is found to be conservative.

Fig. 3. Normalized SAR values calculated using the half-wavelength dipole antenna.

Fig. 4. Normalized SAR values calculated using the quarter-wavelength monopole antenna over the metallic box.

Fig. 5. Normalized SAR values calculated using the PIFA-based mobile phone.

Abstract – In this paper, we present numerical method for determining the penetration of electromagnetic fields through a small aperture on enclosure having inside it a conducting component. To solve the problem of coupling between the radiated electromagnetic field and the metallic enclosure we developed a variational formulation in the interior region and an integral formulation in the exterior region by using the equivalent electric on exterior surface of the enclosure. Using a coupling between two methods: finite elements-boundary integral, we compute the electromagnetic field inside the enclosure and in particular on conducting wire. The numerical result obtained with this method show the influence of characteristic parameter (σ, ϵ, μ) and the thickness of enclosure on penetration of electromagnetic field inside the enclosure.

I. INTRODUCTION

Nowadays, more and more of electronics is embarked on board any type of terrestrial or air vehicles with electronic components functioning at frequencies increasingly higher. The multiplication of the possible sources of electromagnetic aggression and their increasing power thus generate new types of dysfunction of the electrical appliance and problems of incompatibility inter-equipment, which can go until their destruction. Electromagnetic compatibility, according to its "fundamental principles" is thus analyzed in terms of emission (not to disturb the environment) and of immunity (not to be disturbed). The two aspects occur at the same time in conduction and in radiation. Consequently, in the scenario of a problem of EMC, one will find three actors: a source of disturbance, a connection, and a victim of the disturbances thus coupled.

II. PHYSICAL MODEL

In our study we are interested in the radiated electromagnetic field. On figure 1 we present a configuration of a problem models related to the EMC.

Fig.1.Physical model

The metal enclosure with a small rectangular opening lit by an electromagnetic radiation of a source located in the exterior region. The source is considered harmonic in time.

This problem was the subject of certain work by using various numerical models [1][2][3]. In our study we apply, on the one hand, the finite element method inside and on enclosure and, on the other hand, we express the external field by an integral representation. This one is function of the equivalent electrical currents K carried by external surface of the enclosure. These surface current represent the jump of the tangential component of the magnetic field: $[n \times H]_{\Gamma} = K$

The physical system is defined by the following equations:

- In the enclosure without the conducting wire:

$$i\omega\mu_0 h + \text{Curl}(e) = 0 \quad (1)$$

$$-i\omega\epsilon_0 e + \text{Curl}(h) = 0 \quad (2)$$

- In conducting wire:

$$i\omega\mu_c h + \text{Curl}(e) = 0 \quad (3)$$

$$-(\sigma_c + i\omega\epsilon) e + \text{Curl}(h) = 0 \quad (4)$$

- In the exterior region without source:

$$i\omega\mu_0 h + \text{Curl}(e) = 0 \quad (5)$$

$$-i\omega\epsilon_0 e + \text{Curl}(h) = 0 \quad (6)$$

And we take in all system:

$$\text{div}\mu h = 0 ; \text{div}\epsilon e = 0 \quad (7)$$

III. FORMULATION

The wave equation in terms of the electric field can be obtained:

$$\nabla \times \frac{1}{\mu} \nabla \times E + i\omega(\sigma + i\omega\epsilon)E = 0 \quad (8)$$

Multiplying us the equation (8) by a function test E' :

$$\int_{\Omega} \nabla \times E \cdot \nabla \times E' d\Omega + \int_{\Gamma} (n \wedge \nabla \times E) \cdot E' d\Gamma + i\omega\mu(i\omega\epsilon + \sigma) \int_{\Omega} E \cdot E' d\Omega = 0 \quad (9)$$

Where Γ is the surface enclosing the domain Ω , n is the unit outward normal to Γ . We can write the wire term in the variational formulation as:

$$T_{Wire} = \int_{\Gamma} (n \times \nabla \times E) d\Gamma \cdot E' = \frac{-\partial}{\partial t} \int_S (n \times H) \cdot E' dS \quad (10)$$

$$n \times E = \rho (n \times H) \times n \quad (11)$$

Where S is the Surface enclosing the wire, and ρ is the surface impedance of the wire.

IV. NUMERICAL RESULTS

A. Representation a grid mesh

Fig.2. Tetrahedral grid of the enclosure

Number of internal nodes	489
Number of frontier nodes	302
Number of internal edges	3190
Number_of frontier edges	900
Number_of faces	600

It is supposed that the ray of the wire is very small compared with the dimensions of enclosure and we can take it as one or two stop attached, as a sequence of mesh edges. In HF domain, the equation (10) becomes:

$$T_{Wire} = \frac{\partial}{\partial t} \int_w \frac{1}{Z_w} \cdot E_{ij} \cdot E'_{kl} dl ; Z_w = \frac{1+j}{2\pi a} \cdot \sqrt{\frac{\omega \mu}{2\sigma}}$$

Where (a) is the wire radius, Z is the wire impedance per unit length in (Ω/m)

B. Representation of the Magnetic field H

Fig.6 $f=1$ GHz, DD=0.7, RHO= $1.6672 \cdot 10^{-8}$, $J_s = 100$, R=0.2

V. CONCLUSION

In this article we have some numerical results to evaluate the penetration of the electromagnetic field in a metal enclosure. We considered a radiant electromagnetic source in front of an aperture of the enclosure at a limited distance d. We realize a coupling between the boundary integral method outside and the finite element method inside the enclosure to solve our problem. The numerical results show the contribution of each parameter of the problem in the evaluation of the electromagnetic energy penetrated in the enclosure. On the one hand, according to the electromagnetic parameters: electric conductivity and permittivity (σ, ϵ) and magnetic permeability (μ) of the enclosure; in addition, according to the density of the current source, the geometrical position and the frequency of the radiant source, the numerical results show the variation in the values and the form of electromagnetic energy in each point inside the enclosure while varying each time only one parameter. Considering the number of parameters we cannot expose all the results in this paper.

The Dynamic Circuit Model of the Spark Plug for EMI Prediction

Zheng Ya-li, Yu Ji-hui, Wang Quan-di, Jia Jin
The College of Electrical Engineering, Chongqing University
Shapingba, Chongqing, 400044, People's Republic of China
E-mail: yaya9304@163.com

Abstract— In order to predicate the EMI of the ignition system, the accurate model of the spark plug is needed. This paper extracts the parasitic parameter of the spark plug using FEM approach and analyzes the discharge characteristics and mechanism of the spark plug. Then the dynamic circuit model of the spark plug in the ignition system is established. This model is verified by measurement and simulation results.

I. INTRODUCTION

The spark plug discharge is the main source of EMI in the ignition system of an automobile. For the EMI prediction of the ignition system, the accurate spark plug model is needed.

This article analyzes the internal discharge channel and the discharge characteristics of the spark plug at first, and then establishes the dynamic circuit model of the spark plug which includes the static parasitic capacitance and the non-linear resistance. The simulation and measurement results illustrate the dynamic circuit model is correct.

II. THE PARAMETER EXTRACTION OF THE SPARK PLUG IN THE DYNMAIC CIRCUIT MODEL

Supposed the frequency of the EMI is lower than 300MHz, the electric field of the spark plug can be regarded as electrostatic field and internal discharge channel can be equaled to the circuit model shown in Fig. 1.

Fig. 1. The discharge channel and dynamic circuit model of the spark plug

Fig. 2. Solution region of the spark plug

The parasitic capacitance can be extracted using FEM analysis^[1]. Fig. 2 is the solution region of the spark plug.

The spark plug internal electrostatic field satisfies the Laplace equation:

$$\frac{\partial^2 \varphi(x, y, z)}{\partial x^2} + \frac{\partial^2 \varphi(x, y, z)}{\partial y^2} + \frac{\partial^2 \varphi(x, y, z)}{\partial z^2} = 0 \quad (1)$$

To calculate the capacitance matrix, one can solve the problem with a Dirichlet boundary as follows:

$$\begin{cases} \varphi|_{\Gamma_1} = 1 \\ \varphi|_{\Gamma_2, \Gamma_3, \Gamma_4} = 0 \end{cases} \quad (2)$$

$$\varphi|_{\Gamma_0} = 0 \quad (3)$$

In the solution region, there are different mediums. So the medium interface condition is written as:

$$\varepsilon_0 \frac{\partial \varphi_0}{\partial n} = \varepsilon \frac{\partial \varphi}{\partial n} \quad (4)$$

The different medium interface condition (4) is satisfied automatically when functional obtains the minimal value. Therefore the variational problem equaled to (1) is as follows:

$$\begin{aligned} F(\varphi) &= \frac{1}{2} \int_{\Omega_0} \varepsilon_0 \left[\left(\frac{\partial \varphi}{\partial x} \right)^2 + \left(\frac{\partial \varphi}{\partial y} \right)^2 + \left(\frac{\partial \varphi}{\partial z} \right)^2 \right] dx dy dz \\ &+ \frac{1}{2} \int_{\Omega} \varepsilon \left[\left(\frac{\partial \varphi}{\partial x} \right)^2 + \left(\frac{\partial \varphi}{\partial y} \right)^2 + \left(\frac{\partial \varphi}{\partial z} \right)^2 \right] dx dy dz \\ &= \min \end{aligned} \quad (5)$$

Based on the principle of the finite element method, the integrated matrix can be written as:

$$[k][\varphi] = 0 \quad (6)$$

Where: $[K]$ represents contributions from all tetrahedral elements.

Solving (2), (3) and (6), we can obtain the potential function $\varphi(x, y, z)$. The electric field can be written as:

$$\mathbf{E}(x, y, z) = -\nabla \varphi(x, y, z) \quad (7)$$

The electric charge of the conductor is computed from (7):

$$Q_i = \varepsilon \oint_{\Gamma_i} \mathbf{E}(x, y, z) d\Gamma_i \quad (8)$$

Therefore the mutual capacitance is written as:

$$C_{ij} = \frac{Q_i}{\varphi_j} \Big|_{(\varphi_1, \dots, \varphi_{j-1}, \varphi_{j+1}, \dots, \varphi_m) = 0, \varphi_j = 1} \quad (i \neq j) \quad (9)$$

Using the physical structure data of the spark plug, the finite element model can be established. From computation, the parasitic capacitance can be obtained which written as follows: $C_q = 5.3986 \text{ pF}$, $C_r = 5.8701 \text{ pF}$, $C_p = 4.9849 \text{ pF}$.

III. THE AIR-GAP RESISTANCE MODEL OF THE SPARK PLUG IN THE DYNAMIC CIRCUIT MODEL

The spark plug experiences the off stage, the discharge stage and the self-excited discharge stage when it works. The air-gap resistance presents the non-linear nature. The dynamic circuit model of the spark plug in the ignition system is shown in Fig. 3^[2].

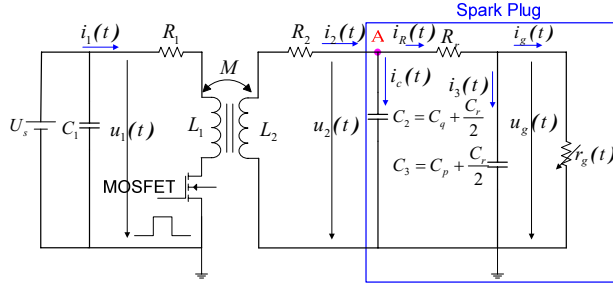

Fig. 3. The dynamic circuit model of the spark plug in the ignition system

A. The air-gap resistance model of the spark plug at the discharge stage

When primary circuit separates instantaneous, the current in primary coil $i_1(t)$ reduces to zero rapidly. The capacitance C_3 is charged rapidly by the induced electromotive force $u_2(t)$. When it increases to the breakdown voltage of the spark plug, the corona can be established between the two electrodes and the ionization starts. The spark plug discharges.

For $i_1(t)=0$ and $di_1(t)/dt \neq 0$, we can obtain the secondary circuit equations as follows:

$$\begin{cases} u_2(t) = -R_2 i_2(t) - L_2 \frac{di_2(t)}{dt} + M \frac{di_1(t)}{dt} \\ i_g(t) = i_R(t) + C_3 \frac{du_g(t)}{dt} \\ u_2(t) = R_3 i_R(t) + u_g(t) \\ u_g(t) = i_g(t) r_g(t) \end{cases} \quad (10)$$

The spark plug resistor can be computed as:

$$r_g(t) = l_g \left\{ \left(2\alpha/p \int_{t_1}^{t_2} i_g^2(t) dt \right) \right\}^{-0.5} \quad (11)$$

Combined (10) and (11), the simplified equations are written as:

$$\begin{cases} u_g'(t) = \frac{1}{C_3} i_g(t) \\ i_g'(t) = \frac{\alpha}{l_g^2 p} u_g^2(t) i_g(t) + \frac{1}{C_3} \frac{i_g^2(t)}{u_g(t)} \\ u_g(t_1) \cong V_{br} \\ i_g(t_1) \cong 0 \end{cases} \quad (12)$$

Where: V_{br} is the breakdown voltage of the spark plug.

B. The air-gap resistance model of the spark plug at the self-excited discharge stage

The plasma presents as soon as the spark plug discharges. The spark plug enters to the self-excited discharge stage. The voltage of the spark plug maintains at a constant value^[3]. In this stage the secondary circuit equations can be written as:

$$\begin{cases} u_2(t) = -R_2 i_2(t) - L_2 \frac{di_2(t)}{dt} \\ C_2 \frac{du_2(t)}{dt} = i_2(t) - i_R(t) \\ i_g(t) = i_R(t) = \frac{u_2(t) - u_g(t)}{R_3} \\ u_g(t) = U_0 \end{cases} \quad (13)$$

When the plasma fades away, the spark plug returns to the off stage.

IV. RESULTS

The dynamic circuit model of the spark plug in the ignition system is established in the circuit simulation software. The voltage of the spark plug is measured at the A point in Fig. 3 mentioned above. The measurement and simulation results are shown in Fig. 4. The results match well and illustrate that the dynamic circuit model can reflect the discharge characteristics of the spark plug accurately.

Fig. 4. Measurement and simulation results of the voltage of the spark plug

V. CONCLUSION

In this paper, the dynamic circuit model of the spark plug is established. According to the geometric structure of the spark plug, the parasitic capacitance of the spark plug is extracted by FEM approach. Analyzing the different stages of the spark plug discharge process and mechanism, the non-linear resistance circuit model of the spark plug air-gap is founded. Simulation and measurement results show the model of the spark plug is correct. The model proposed in this paper can be used for EMI predication in the ignition system.

Steady-state Inductive Coupling to the Underground Pipeline Parallel to Overhead Transmission Line above Two-layer Soil

Lei Qi, Yan Wu, and Xiang Cui

Beijing Key Laboratory of High Voltage & EMC, North China Electric Power University

Abstract— As China's economy continued to grow, the electromagnetic influence on oil/gas pipeline near alternating current transmission line becomes increasingly prominent. Based on the transmission line model of pipeline-earth circuit, the analytic expressions of induced voltage generated by the normally operating ac transmission line are obtained for different terminal loads of the underground pipeline in this paper. The conception of critical length is put forward when the pipeline is terminated by the matched loads at both ends. The two-layer soil model is used for the simulation and the quasi-Monte Carlo integration method is applied to the computation of the Pollaczek integrals in the expressions of the self ground return impedance of the underground pipeline and mutual impedance between the overhead transmission line and underground pipeline.

I. INTRODUCTION

As China's economy continued to grow, the power transmission lines and oil/gas pipelines are in the construction of rapid development for more and more energy demand. Ultra High Voltage (UHV) and West-East gas projects are the national key projects in recent years. Because of the similarity of transmission path selectivity of the power industry and oil/gas industry, the situation of parallelism, oblique approach and crossing between the transmission lines and pipelines has frequently happened. Therefore, the electromagnetic influence on oil/gas pipelines near alternating current (ac) transmission lines becomes increasingly prominent.

The pipelines are subject to interference arising from three parts, i.e. capacitive, resistive and inductive coupling. Capacitive coupling only affects the aboveground pipeline since it has both a capacitance to the transmission line and to earth. And the pipeline buried below ground is shielded by the ground and cannot be affected by capacitive coupling. Resistive coupling between the transmission line and pipeline is only relevant during the grounding fault and lightning strike when significant level of current flows into the earth. And this will result in the potential rise of the tower base and of the neighboring soil with regard to the remote earth. In this situation, the inductive coupling will also take place and put the pipeline at severe risk. Inductive coupling is caused by the time-varying magnetic field produced by the transmission line currents. The induced voltage at the pipeline ends will vary as a function of length of parallelism, soil resistivity, distance between the pipeline and transmission line, and so on. Aerial and underground pipelines are both affected by inductive coupling. When the transmission line is running in a normal condition, the electromagnetic fields dependent on the three

overhead line phases generally balance each other and significantly reduce the net field seen by the pipeline. However, the induced voltage on underground pipeline parallel to normally operating overhead transmission line is very important for being concerned with personal safety, ac corrosion of pipeline and normally operating of pipeline cathodic protection system.

Some research has been carried out and the limits of electromagnetic influence are released in [1]-[4]. These studies mainly focus on the inductive and resistive coupling modeling during the ground fault, switching and lightning surge in power system. The earth is assumed to be semi-infinite and homogeneous in all of these literatures.

In this paper, based on the transmission line model of pipeline-earth circuit, the analytic expressions of induced voltage generated by the normally operating ac transmission line are obtained for different terminal loads of the underground pipeline. The conception of critical length is put forward when the pipeline is terminated by the matched loads at both ends. The two-layer soil model [5] is used for the simulation and the quasi-Monte Carlo integration method is applied to the computation of the Pollaczek integral [6].

II. TRANSMISSION LINE MODEL OF PIPELINE-EARTH CIRCUIT

Considering the location at infinity below the earth as the zero-voltage reference point, the equivalent circuit of the pipeline-earth circuit is shown in Fig.1. The telegrapher's equations are given in frequency domain

$$\frac{dV(x)}{dx} + ZI(x) - E(x) = 0 \quad (1)$$

$$\frac{dI(x)}{dx} + YV(x) = 0 \quad (2)$$

where $V(x)$ and $I(x)$ are respectively the voltage and current along the pipeline; Z and Y are respectively the per-unit-length (PUL) series impedance and shunt admittance; $E(x)$ is the induced electromotive force (EMF) on the PUL pipeline produced by the transmission line. Assuming $E(x)$ along the pipeline to be a constant E , the general solutions to (1) and (2) are as follows

$$V(x) = Ae^{\gamma x} + Be^{-\gamma x} \quad (3)$$

$$I(x) = \frac{E}{Z} - \frac{1}{Z_c} (Ae^{\gamma x} - Be^{-\gamma x}) \quad (4)$$

here

$$\gamma = \sqrt{ZY} = |\gamma| \angle \theta = \alpha + j\beta \quad (5)$$

$$Z_c = \sqrt{\frac{Z}{Y}} \quad (6)$$

where Z_c , γ , α and β are the characteristic impedance, propagation constant, attenuation constant and phase constant of the pipeline-earth transmission line model, respectively. The undetermined constants A and B in (3) and (4) depend on the terminal constraints

$$V(0) = -Z_1 I(0) \quad (7)$$

$$V(L) = Z_2 I(L) \quad (8)$$

Substituting (7) and (8) into (3) and (4) gives

$$A = \frac{E[(1 + \rho_1)\rho_2 - (1 + \rho_2)e^{\gamma L}]}{2\gamma(\rho_1\rho_2 - e^{2\gamma L})} \quad (9)$$

$$B = \frac{E[(1 + \rho_1)e^{2\gamma L} - \rho_1(1 + \rho_2)e^{\gamma L}]}{2\gamma(\rho_1\rho_2 - e^{2\gamma L})} \quad (10)$$

here

$$\rho_1 = \frac{Z_1 - Z_c}{Z_1 + Z_c} \quad (11)$$

$$\rho_2 = \frac{Z_2 - Z_c}{Z_2 + Z_c} \quad (12)$$

where Z_1 and Z_2 are the terminal loads of the pipeline illustrated in Fig.1; ρ_1 and ρ_2 are respectively the reflection coefficients at the beginning and end of the pipeline. Typical values of Z_1 and Z_2 are listed in Table I and corresponding voltage and current solutions to (3) and (4) can be achieved by the above formulas.

Fig. 1. Equivalent circuit of the pipeline-earth circuit

When the pipeline extends for a few kilometres beyond the parallel routing without earthing, the corresponding reflection coefficients ρ_1 and ρ_2 are zero. The investigation shows that the maximum coating stress voltage appears at the ends of the parallel routing and can be evaluated by

$$V_{\max} = \left| \frac{E(1 - e^{-\gamma L})Y_2}{2\gamma(Y_1 + Y_2)} \right| \quad (13)$$

where V_{\max} is the maximum coating stress voltage, which equals to the difference between the metal pipeline potential and coating potential with regard to the remote earth. Y_1 is the PUL shunt admittance including two parts, the leakage conductance and capacitive reactance of the coating. Y_2 is the PUL ground return admittance.

It can be proved that V_{\max} in (13) firstly increases, then slightly decreases, finally tends to some constant with the increase of parallelism length of the pipeline. In other words, V_{\max} in (13) can achieve some maximum V_m when the parallelism length of the pipeline equals to some critical length L_m . L_m and V_m can be solved by the following equations

$$\begin{cases} \cos(\beta L_m - \theta) = \cos \theta e^{-\alpha L_m} \\ V_m = \left| \frac{E}{2\gamma} \right| \sqrt{1 + e^{-2\alpha L_m} - 2e^{-\alpha L_m} \cos(\beta L_m)} \end{cases} \quad (14)$$

TABLE I
TYPICAL VALUES OF Z_1 AND Z_2

Item	Z_1	Z_2	ρ_1	ρ_2
1	Z_c	Z_c	0	0
2	Z_c	∞	0	1
3	0	Z_c	-1	0
4	∞	∞	1	1
5	0	0	-1	-1
6	0	∞	-1	1

III. COMPUTATION OF POLLACZEK INTEGRAL

Apparently, it is necessary to determine the self ground return impedance of the underground pipeline and mutual impedance between the overhead transmission line and underground pipeline in order to evaluate V_{\max} in (13). The two-layer soil model is used for the simulation and the quasi-Monte Carlo integration method is applied to the computation of the Pollaczek integral in this section.

IV. VALIDATION AND APPLICATION

In this section, the proposed method is validated and applied to the evaluation of power frequency induced voltage on the West-East gas pipeline in parallel with 1000kV UHVAC transmission line.

A New Stochastic LPP Model for studying ELF Bioelectromagnetic Interaction

Viale A. Doria 6, 95125, Catania, Italy
coco@diees.unict.it

Abstract—In this paper we present a stochastic 3D Langevin-Lorentz-Poisson (LLP) coupled model in order to investigate the ion transport across ionic channels situated on the cell membrane in the presence of external ELF magnetic fields. An iterative scheme is adopted, which alternates the solution of a Poisson problem with the time domain integration of a modified kind of Langevin-Lorentz equations. A Fokker-Planck analysis of the latter equations is performed to compute the statistical parameters of ion motion. An example of application to the analysis of a Ca⁺⁺ membrane ionic channel is also given.

I. INTRODUCTION

In the last years the study of Extremely Low Frequency (ELF) magnetic fields effects on living cells has been a growing interest. Since the activation of signaling among cells depends on ion concentrations, the most plausible mechanism by which ELF magnetic fields are thought to interact with a biological system is an alteration of the signal transduction within the biological system, involving the gating of ionic channels and changes of intracellular ionic concentrations, affecting various critical cellular functions (differentiation, apoptosis, etc) [1][2].

In this paper we present a stochastic 3D Langevin-Lorentz-Poisson (LLP) coupled model in order to investigate the ion transport across ionic channels situated on the cell membrane in the presence of external ELF magnetic fields. In particular a correction function, which takes into account in a probabilistic way the effect of external ELF magnetic fields, has been used in the model following an analogous approach adopted for modeling the gating of voltage-dependent channels. The numerical solution of the coupled problem is performed by integrating the dynamical equations of ions subject to electromagnetic forces inside the ionic channels, assuming a stationary flux of ions. In this case we make use of an iterative scheme, which alternates the solution of a Poisson problem with the time domain integration of Langevin-Lorentz equations which govern the ion motion. A Fokker-Planck analysis of the latter equation is performed to compute the statistical parameters of ion motion. The solution of the coupled problem is achieved by exploiting an appropriate stationary representation of the 3D ion spatial distribution. The developed model also uses a stochastic mechanism of ion injection in membrane channels (describing the fluctuation in time of the total number of particles inside the simulation region), allowing us to carry out more realistic simulations. In order to remarkably reduce the simulation time needed for launching several simulations and managing a huge quantity of data, we used a distributed computing based approach in a

grid infrastructure, in the framework of the PI2S2 project [3].

II. THE STOCHASTICAL LPP MODEL OF ION MOTION

The behaviour of ions inside cellular membrane ionic channels is governed by a system of coupled equations consisting of a Langevin-Lorentz equation for the motion of ions and a Poisson problem for the electrical scalar potential ϕ

$$m \frac{d\mathbf{v}}{dt} = -h\mathbf{v} + q(\mathbf{E}_T + \mathbf{v} \times \mathbf{B}_T) + \mathbf{N}(t) \quad (1)$$

$$\nabla^2 \phi + q \iiint_{\Omega} f(P) d\Omega = 0$$

where m is the generic ion mass, v is its velocity, h is a viscous friction coefficient, modeling the ion interactions with water molecules, q is the ion charge, \mathbf{E}_T and \mathbf{B}_T (if any) are the total electric and magnetic field respectively, $\mathbf{N}(t)$ is a force taking into account the thermal noise; in the Poisson equation (1) Ω indicates the domain of analysis for the ionic channel and $f(P)$ is the space charge distribution function. The total electric field \mathbf{E}_T consists of two terms: the first is due to the scalar potential $-\nabla\phi$, the second, \mathbf{E}_{ESO} , takes into account exogenous electric forces, if any, influencing the ion in the cell environment and summarizing the contributions of the environment to the total electric field. The numerical solution of this coupled electromechanical problem is iteratively carried out by using a self-consistent scheme, which at each step alternates the solution of a Poisson problem with the time-domain integration of the Langevin equation. In particular for each time step the solution of a Poisson problem is calculated by using a point to point method, that is the electric field is computed by adding the contributions due to each ion, assuming a stationary ion flow.

The ion displacements are computed by adding to the deterministic ion displacement component obtained by a time-integration of the Langevin-Lorentz equation in the absence of thermal noise; a stochastic component computed by a Fokker-Planck analysis of the dynamical equation. Assuming that the typical transit time of an ion is of the order of 1 ns, the simulation time interval was chosen greater than this typical transit time. In order to make the analysis compatible with the hypothesized stationary conditions the integration time step was chosen of the order of 1 fs.

This model in this form is not suitable to describe the ELF magnetic field effects for two main reasons: first the simulation time should be about 0.1 s and consequently about 1E+14 steps should be executed (this is beyond currently available computing resources); secondly the model is not

able to take into account the influence of ELF magnetic fields on ionic channel gating. Thus in order to overcome these problems a modified version of the model has been set up, including explicitly ELF magnetic fields effects on channel gating. For this purpose we changed the first equation of (1) with the following equation, taking into account experimental results, which indicate that in the presence of external ELF magnetic fields, for some frequency and intensity windows, the flux of ions in ionic channel increases:

$$m \frac{dv}{dt} = -h\nu + \mathbf{N}(t) + Z(B)(q\mathbf{E}_T)$$

where $Z(B)$ is an expression giving the probability of opening/closing of a single membrane channel as a function of the external ELF magnetic field intensity. This expression is analogous to that describing the probability of opening/closing of the channel as a function of the transmembrane applied voltage

$$Z(B) = \{1 + \exp(-(B - B_0)/\Delta B)\}^{-1}$$

$$B = B_{\max} \sin \omega t$$

Where ΔB , B_0 are parameters derived from experimental measurements [4]. In our simulations we use $B_{\max} = 0.1$ T and $\omega = 2\pi 50$ rad/s. According to this new approach the gating is ruled by the ELF sinusoidal magnetic field. In this way we translate the external ELF magnetic fields effect on the amount of channels which open at the same time.

III. ANALYSIS OF A Ca^{++} CHANNEL

The analysis of a typical ionic flow across a Ca^{++} channel is performed hereafter in order to show the application of the proposed model to a realistic case. For the description of the Ca^{++} channel, we assume a commonly used schematization, in which only the channel region is considered; it consists of a cylinder, with a height of 10 Å and a radius of 5 Å and the cylinder axis coincident with the z axis. A schematic representation of the Ca^{++} channel is shown in figure 1. The aim is to investigate the influence of an external ELF magnetic field on the relation between applied membrane voltage and the number of the ion escapes from the Ca^{++} channel, for an assigned value of the viscous coefficient $\beta = h/m$.

Under these assumptions, thanks to the GRID infrastructure, several hundreds of runs with the original and the modified models have been performed in a very short time. In figure 1 the number of the Ca^{++} ions crossing the channel versus the transmembrane voltage coming out from the original model are shown, for a value of the viscous coefficient equal to $2E+12$; for this configuration it is worth noticing, the quasi-linear increase of the average number of ions crossing the channel as the membrane voltage increases. This result is in good agreement with results coming from other models and with experimental data [5], for analogous configurations. In fig. 2 the number of the Ca^{++} ions crossing the channel versus the transmembrane voltage coming out from modified model are shown. It is worth noticing that the differences between the two models are negligible, and apparently the introduction of probability function $Z(B)$ does not seem to affect the motion

of ions across membrane channels. But if we repeat the same simulation by using a longer simulation time (10 or 100 times) an interesting result is obtained: in the longer time analysis case the modified model gives as result a current crossing the channel of 10% higher than original model. This is clearly due to the influence of the external magnetic field on gating as expected. Further details about results will be given in the full version of the paper.

Fig. 1 - Number of ions exiting the channel versus transmembrane voltage ($\beta=2E+12$) by using original model.

Fig. 2 - Number of ions exiting the channel versus transmembrane voltage ($\beta=2E+12$) by using new model.

An Enhanced Ellipsoid Method for Electromagnetic Devices Optimisation and Design

D. A. G. Vieira, A. C. Lisboa and R. R. Saldanha

Department of Electrical Engineering, Federal University of Minas Gerais, Brazil
 {douglas,adriano,rodney}@cpdee.ufmg.br

Abstract—This paper proposes a novel ellipsoid method for the optimisation of sub-differentiable electromagnetic constrained problems. Unlike the classical method, which can apply only one cut per iteration, this novel algorithm can employ multiple cuts simultaneously. This improves the convergence rate while preserving all the method original theoretical guarantees. The design of a modelled reflector antenna is presented and it asserts the efficiency of the introduced technique.

Index Terms—Optimisation, sub-differentiability, ellipsoid method, reflector antenna.

I. INTRODUCTION

Optimising electromagnetic devices is known as a hard task, since it relies on the evaluation of numerical methods, which implies a huge computational effort. Additionally to improving accuracy and decreasing computational burden of numerical methods, it is also important to develop the optimisation procedures themselves.

Nowadays there are several classes of optimisation algorithms, each of them having their own advantages and disadvantages. Stochastic methods, such as genetic algorithm (GA), immune system (IS) and particle swarm optimisation (PSO), are very popular, as they require little knowledge about the function properties [1], [2]. They are very suitable in situations where continuity and differentiability cannot be assured. Furthermore, they can also be applied to generate an initial design point to deterministic methods. However, they are known to be slow, since they require a considerable amount of function evaluations [3].

Deterministic methods, usually divided into search direction and cutting-plane methods, typically require some kind of function differentiability. Search direction methods typically requires function differentiability, but can make an efficient local search, even in very sensitive problems, as does an extended gradient method when optimising antennas [3], [4]. When sub-differentiability is considered, cutting-plane methods are more suitable than deterministic methods. The ellipsoid algorithm [5] is one of the most popular cutting-plane methods. It can handle constraints directly, without any kind of transformation into unconstrained problems by penalty functions or barrier functions. Deterministic techniques can also be coupled with stochastic methods in a hybrid configuration [6], [7]. Therefore, improving these techniques are useful in many aspects.

Notwithstanding its robustness, the ellipsoid method lacks good performance in practice, specially as dimension in-

creases. To overcome this drawback, this work proposes to apply multiple cuts, instead of the single cut considered in the classical method, inside an inner loop. In the classical method, only one sub-gradient is considered per iteration. There are also closed-form solutions when two cuts (one-sided, parallel and wedge-shaped cuts) are considered, see [8] and references therein.

In the new multiple cuts ellipsoid method (MCEM), several cuts defined in the current evaluation point can be considered at once (e.g. when there are more than one active/violated constraint), as well as cuts memorised from previous iterations. The MCEM relies in a theoretically correct deep cut, instead of heuristic deep cuts [9].

The MCEM will be briefly described and then applied to design a reflector antenna for satellite communication. This problem has 38 control variables and was formulated considering 13 constraints. Hence, the results must test the claim that using multiple cuts improves the convergence rate, and decreases the computational effort entailed by the optimisation process of electromagnetic devices.

II. MULTIPLE CUTS ELLIPSOID METHOD

Consider the single objective optimisation problem

$$\begin{aligned} \min \quad & f(x) \\ \text{s.t.} \quad & g_j(x) \leq 0, \quad j = 1, \dots, n_g \end{aligned} \quad (1)$$

where $f(x)$ and $g_j(x)$ are real valued quasi-convex continuous sub-differentiable functions and $x \in \mathbb{R}^n$ is the vector of parameters. The set of n_i violated constraints is defined as $\mathbb{I} = \{j : g_j(x) > 0\}$. Given an ellipsoid $\mathbb{E}_k = \{x \in \mathbb{R}^n : (x - x_k)^T Q_k (x - x_k) < 1\}$ and an open half space $\mathbb{H}_k(x_k, d_k) = \{x \in \mathbb{R}^n : d_k^T x < d_k^T x_k\}$ the Shor's algorithm makes $\mathbb{E}_{k+1} \supseteq \mathbb{E}_k \cap \mathbb{H}_k$. His main achievement was to find a closed-form solution such that \mathbb{E}_{k+1} has minimal content. The direction d_k is $-\nabla f(x_k)$ if x_k is feasible, or $-\nabla g_j(x_k)$, for some $j \in \mathbb{I}$, otherwise. For quasi-convex functions, an optimal solution $x^* \in \mathbb{E}_k$ implies $x^* \in \mathbb{E}_{k+1}$.

Shor's algorithm only uses of one of the violated constraints. If more than one constraint are violated, it is better to calculate the intersection between the ellipsoid \mathbb{E}_k and the cone $\mathbb{C}_k = \bigcap_j \mathbb{H}_k^-(x_k, \nabla g_j(x_k))$, $\forall j \in \mathbb{I}$, composed by the intersection of cutting halfspaces, instead of a single halfspace.

The existence of a closed-form solution for the minimal content ellipsoid containing $\mathbb{E}_k \cap \mathbb{C}_k$ is unlikely. This paper proposes solving $\mathbb{E}_{k+1} \supseteq \mathbb{E}_k \cap \mathbb{C}_k$ iteratively. Let $\mathbb{E}_{k0} = \mathbb{E}_k$,

$\mathbb{E}_{k(i+1)} \supseteq \mathbb{E}_{ki} \cap \mathbb{H}_i$ for $i = 0, \dots, m-1$, and $\mathbb{E}_{k+1} = \mathbb{E}_{km}$. The MCEM relies on the cut depth

$$\alpha_{ki} = \frac{(x_{k0} - x_{ki})^T d_i}{\sqrt{d_i^T Q_{ki}^{-1} d_i}}, \quad (2)$$

where x_{ki} is the centre of \mathbb{E}_{ki} , $d_i = -\nabla g_j$ for some $j \in \mathbb{I}$. The convergence rate of the classical method improves by using (2) iteratively until α_{ki} becomes enough close to $-1/n$ for any $j \in \mathbb{I}$.

III. THE REFLECTOR ANTENNA PROBLEM

The proposed algorithm was applied in a satellite broadcast communication problem, which is described by Lisboa et al. [4]. In this problem, a reflector antenna in geosynchronous orbit must illuminate a target - the Brazilian territory for instance - on the earth surface. The optimisation problem is to maximise the average gain at n_s sample points \mathbb{P} , constrained to lower bounds of gain at certain sample points $\mathbb{S} \subseteq \mathbb{P}$. Hence, there is one constraint for each sample point in \mathbb{S} . The sample points \mathbb{P} are spread out all over the target. Specifying the minimum of 35dB in 13 points on the southeast region, the most populated in the country, the problem can be written as

$$\begin{aligned} \min_x \quad & f(x) = -\frac{1}{n_s} \sum_{i=1}^{n_s} G(x, p_i), \quad p_i \in \mathbb{P} \\ \text{s.t.} \quad & g_j(x) = 35 - G(x, p_j) \leq 0, \quad p_j \in \mathbb{S}, \quad j = 1, \dots, 13 \end{aligned} \quad (3)$$

In the original formulation these constraints were not considered [4]. The calculation of the gain at each sample point uses numerical techniques that are computationally expensive. The reflector surface was parameterised with 38 control variables. Therefore, it is a complex black box problem.

IV. RESULTS

The initial configuration x_0 was a reference classical paraboloid reflector. The respective radiation pattern is shown in Fig. 1 together with the optimal solution achieved after 19,500 function evaluations using the MCEM.

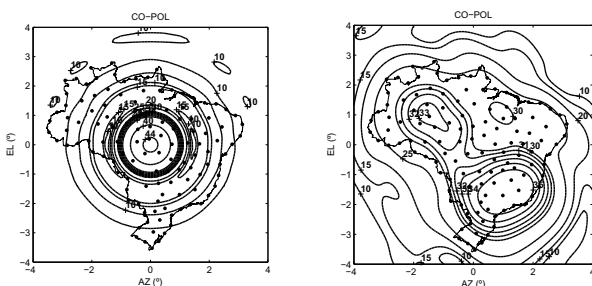

Fig. 1. Initial (left) and optimal (right) radiation pattern.

The convergence of the MCEM is contrasted with Shor's classical algorithm in Fig. 2. The convergence of the MCEM was faster and smoother. The MCEM converged to 30.97dB while the classical method converged to 30.69dB. The classical

method found 62% of infeasible points during the convergence, while the MCEM found 46%, as it discards infeasible points more efficiently by using more than one constraint at each iteration.

Fig. 2. Convergence curves of the MCEM and Shor's classical algorithm.

V. CONCLUSION

This paper has introduced a novel ellipsoid optimisation method that considers simultaneous multiple cuts. Its formulation takes advantage of the constraint structure to shrink the ellipsoid and, hence, to increase the convergence rate. The results of the application of MCEM to a optimisation problem with 38 variables support this claim. The proposed technique is a robust tool with a simple formulation to handle constraints.

Abstract — This paper presents an effective methodology for robust optimization of electromagnetic devices. To achieve the goal, the method improves the robustness of the objective function by minimizing the second-order sensitivity information, called a gradient index and defined by a function of gradients of performance functions with respect to uncertain variables. The constraint feasibility is also enhanced by adding a gradient index corresponding to the constraint value. The validity of the proposed method is tested with the TEAM Workshop Problem 22.

I. INTRODUCTION

Due to a growing demand for high-performance and high-reliability electromagnetic devices or equipment, attention has recently been focused on the robust optimization of products with the aim of minimizing the variation of the performance as a result of uncontrollable factors such as manufacturing errors, operating conditions, material properties, etc. Until now, most of the attempts which have been made used the Taguchi's robust design concept or Monte Carlo simulation based on the assumption that design parameters are random variables with a probability distribution [1]. However, implementation difficulties usually arise because it is not easy to acquire probability data of uncertain variables and also information about which parameter is dominant may not be available.

To overcome the aforementioned drawbacks, this paper proposes an effective methodology utilizing the second-order sensitivity information, defined as a 'gradient index' (GI), for the robust optimization of electromagnetic systems [2]. The basic concept of the method is to obtain robustness of the objective function by minimizing a GI value calculated from the gradients of performance functions with respect to uncertain variables. Simultaneously, the constraint feasibility is also considered by adding a term determined with a constraint value and a gradient index corresponding to the constraint. Consequently, the method needs neither statistical information on design variations nor calculation of the performance reliability while it is searching for a robust optimal solution.

II. ROBUST OPTIMAL DESIGN USING A GRADIENT INDEX

The TEAM benchmark problem 22 is concerned with the design optimization of a superconducting magnetic energy storage system (SMES) as depicted in Fig. 1. In order to simplify the design problem, a constraint of the current quench condition on the superconductivity magnet is not considered here. A typical optimization problem for minimizing an objective function subject to a set of constraints is expressed as

Fig. 1. Configuration of the SMES device with 8 design variables

$$\begin{aligned} \text{Minimize} \quad & f(\mathbf{x}) = \sum_{i=1}^{21} |B_{stray,i}(\mathbf{x})|^2 \\ \text{subject to} \quad & g_1(\mathbf{x}) = \left(\frac{E(\mathbf{x}) - E_o}{0.05 \times E_o} \right)^2 - 1 \leq 0 \\ & g_2 = (R_1 - R_2) + \frac{1}{2}(D_1 + D_2) \leq 0 \\ & \mathbf{x}_L \leq \mathbf{x} \leq \mathbf{x}_U \end{aligned} \quad (1)$$

where \mathbf{x} is a design variable vector, $B_{stray,i}$ the stray field values calculated at the i th design iteration, E the stored magnetic energy and E_o the energy target value of 180 MJ. The values \mathbf{x}_L and \mathbf{x}_U denote the lower and upper bounds of the design variables, respectively.

To complement the above expressions, the proposed robust optimization for improving the robustness of the objective and the constraint functions is formulated as follows:

$$\begin{aligned} \text{Minimize} \quad & GI_f = \max_i |df(\mathbf{x})/du_i| \quad i = 1, 2, \dots, 8 \\ \text{subject to} \quad & g_j(\mathbf{x}) + \Psi_j(g_j(\mathbf{x})) \leq 0 \quad j = 1, 2 \\ & f(\mathbf{x}) \cong M \end{aligned} \quad (2)$$

where GI_f is a gradient function of the objective function with respect to the uncertain variables u_i and M denotes the target value of the objective function. In order to enhance the robustness of the constraint feasibility, the term $\Psi_j(g_j)$ in (2) is added to each constraint

$$\Psi_j(g_j) = \begin{cases} 0 & g_j < CT \\ \frac{\kappa_j GI_{g_j}}{CTMIN - CT} & CT < g_j < CTMIN \\ \frac{\kappa_j GI_{g_j}}{CTMIN - CT} & g_j > CTMIN \end{cases} \quad (3)$$

$$GI_{g_j} = \max_i |dg_j(\mathbf{x})/du_i| \quad i = 1, 2, \dots, 8$$

where GI_{g_j} is a gradient function of the j th constraint function with respect to the uncertain variables. If the constraint is numerically critical ($CT \leq g_j \leq CTMIN$) or violated ($g_j > CTMIN$), a term proportional to GI_{g_j} multiplied by a proper constant κ is added according to the value of the robustness of the constraint feasibility.

III. NUMERICAL IMPLEMENTATION

The proposed method has been implemented by combining the commercial finite element code MagNet [3] with a DOT optimizer [4] as shown in Fig. 2, where a modified feasible direction algorithm with the second-order sensitivity information by finite differencing is used. To obtain the GI values, the first-order sensitivity values are computed by the continuum design sensitivity analysis (CDSA).

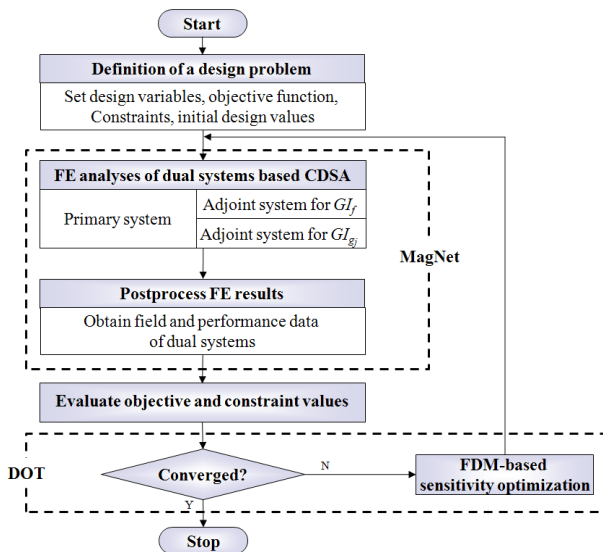

Fig. 2. Flow chart of the proposed robust optimization method

IV. RESULTS

The optimization problem for minimizing the stray fields of the SMES device of Fig. 1 is solved using two methods. The first is a deterministic method based on CDSA that does not take into account the effects of uncertain parameters; the second approach is the proposed robust optimization method. In this paper, all of the 8 design variables used in the deterministic method are selected to be the uncertain variables for the purpose of comparison between the two methods.

Starting with an initial design, the deterministic and the robust optima are presented in Table I. The stored energy values obtained from the two methods almost reach the target value of 180 MJ, but the robust optimum produces a better mean value of the stray fields than the deterministic algorithm. It is inferred that the deterministic optimal solution is trapped in one of the local minima near the constraint boundaries, while a better optimal solution is found by the robust optimization as the feasibility robustness of the constraints is improved. In Figs 3 and 4, the variations of the sensitivity values and the stray fields are compared between the deterministic and the robust optima, respectively.

TABLE I
DESIGN VARIABLES AND PERFORMANCE INDICATORS

Adapted Output Space-Mapping Technique for a Bi-Objective Optimization

T. V. Tran, F. Moussouni, S. Brisset, and P. Brochet

L2EP, Ecole Centrale de Lille, Cité Scientifique, BP 48, 59651, Villeneuve d'Ascq Cedex, France

Abstract—Multi-objective optimizations by means of 3D finite element models result in very high computation burden. To have an affordable computation cost, the output space-mapping technique is applied with a new method where the scalar correction of the model outputs is replaced by a set of corrective functions. This method is used for the bi-objective optimization of a transformer and allows finding the complete Pareto optimal set in less than two days on a laptop.

Index Terms—Space-mapping, Multi-objective optimization, 3D finite element model, Transformer.

I. INTRODUCTION

THE OPTIMAL design of electromagnetic devices is a complex and complicated task. A way to formulate the problem is to find the trade-off between conflicting goals. Solving this problem requires building the Pareto optimal set with accuracy. With two objectives, the Pareto optimal set can be easily drawn and helps the designer to find a good solution. Many methods are able to find the solutions of a bi-objective optimization: scalar methods such as the well-known weighted sum (WS), ϵ -constraint methods, etc. [1]; and stochastic methods such as non-dominated sorting genetic algorithm II (NSGA II), niched Pareto genetic algorithm (NPGA), etc. [2]. Unfortunately, those methods require a very high number of model evaluations. This is not compatible with the use of a 3D FE magneto-thermal model that requires 2 hours [3].

The purpose of space-mapping (SM) [4]-[7] is to align a coarse model and a fine model to reduce the computation time. In electromagnetic, the fine model is a 2D or 3D FEM and the coarse model is often a lumped mass or analytical model. The Manifold-Mapping [6] and Output Space-Mapping (OSM) [7] techniques are the most recent and effective methods. Unfortunately, no SM algorithm has been developed or adapted to multi-objective optimization problem. The aim of this paper is to adapt the OSM to bi-objective optimization problems.

First, the bi-objective optimization of a safety transformer [3] is presented and the designer's dilemma is raised. Section III proposes a new method to solve this problem that is applied in section IV to the bi-objective optimization of the safety transformer. Finally, some concluding remarks are given.

II. OPTIMIZATION PROBLEM

The safety isolating transformer is a one-phase step-down transformer. It uses grain-oriented E-I laminations. The primary and secondary windings are both wound around the

frame surrounding the central core.

The bi-objective optimization problem of a safety isolating transformer contains 7 design variables. There are three parameters a , b , c for the shape of the lamination, one for the frame d , two for the section of conductors S_1 , S_2 , and one for the number of primary turns n_1 . There are 6 non-linear inequality constraints in this problem. The copper and iron temperatures T_{co} , T_{ir} should be less than 120°C and 100°C, respectively. The magnetizing current I_μ/I_1 and drop voltage $\Delta V_2/V_2$ should both be less than 10%. Finally, the filling factors of both coils f_1 and f_2 should both be lower than 0.5. The objective functions are to maximize the efficiency η and to minimize the total mass M_{tot} of iron and copper materials.

A. Coarse and fine models

The multi-physical phenomena within the transformer are electric, magnetic and thermal. They are modeled by a lumped-mass (coarse) model (LM) and a 3D finite element (fine) model (3D FE) [3].

The LM model is built with the assumption that the voltage drop due to the magnetizing current is neglected. Therefore the maximal induction depends on the primary voltage. The computational time of the coarse model is very short (50 ms on an Intel Pentium M 2.13 GHz machine).

The 3D FE magneto-thermal model is built with the assumption that all magnetic and electric quantities are sinusoidal. The iron loss is computed with Steinmetz formula described in [3] and the leakage inductances are calculated with the magnetic energy. Full-load and no-load simulations are used to compute all characteristics of the safety isolating transformer. The 3D FE model with magneto-thermal coupling requires a very expensive computational time (about 2 hours on an Intel Pentium M 2.13 GHz laptop).

B. Designer's dilemma

Generating 100 optimal solutions of the Pareto optimal set by means of the 3D FE model requires 10 000 hours while 5 minutes only are needed with the LM model. In fact, as solving 3D FE model is very expensive only six points are computed and considered as a reference set (Fig. 1). The points are found by using the classical OSM technique. The LM model is used to build an extended Pareto optimal set in a short time. It is obvious that this last optimal set is far from the reference set.

A first solution to this dilemma is to interpolate the reference set. Unfortunately, no information on the design parameters can be obtained because the interpolation can only be made in the objective space.

Therefore, the authors propose to adapt OSM technique for bi-objective optimization problems in order to generate an extended and accurate Pareto optimal set in less than 100 hours.

III. ADAPTED SPACE-MAPPING TECHNIQUE

A. Bi-objective optimization algorithm

According to the state of the art, the ε -constraint method is a useful approach to build a Pareto optimal set [1]. Moreover, this method may reach Pareto optimal solutions in the non-convex region. The ε -constraint method consists to transform the multi-objective problem in a single-objective problem. Among the objectives, one is kept and the others are transformed in inequality constraints.

B. Space-mapping techniques

Space mapping techniques aim to use both coarse and fine models to reduce the computational time and increase the accuracy of the obtained solution [4]-[7].

One approach of SM techniques, called Output Space-Mapping (OSM) [7] consists to modify the coarse model by adding some corrective coefficients computed with the fine model, in order to align the results of both models.

C. Corrective spline functions

In the case of a mono-objective optimization only a set of scalar coefficients is searched. In the case of a multi-objective optimization, the corrective coefficients' values must be changed for each solution from the Pareto set. So that these coefficients are replaced by corrective functions.

IV. APPLICATION CASE

The bi-objective optimization problem of the safety isolating transformer presented in section II is solved with the proposed algorithm. Fig. 2 shows the Pareto optimal set obtained by using the corrective functions. 30 points are given at each iteration. At the end of the optimization, a Pareto optimal set very close to the reference set is found.

Finally, only 17 3D FE simulations are needed to obtain an accurate Pareto optimal set. The computational time of the

proposed algorithm is approximately 34 hours (1.4 day) on an Intel Pentium M 2.13 GHz laptop. The reference Pareto optimal set requires 60 hours (2.5 days) on the same machine. To have an accurate Pareto optimal set by using the 3D FE model only, approximately 10,000 hours (14 months) are required.

V. CONCLUSION

The output space-mapping technique is adapted to provide a practical way to build an accurate Pareto optimal set in bi-objective optimization using full 3D coupled finite element model and keeping the computational time in an acceptable limit. Cubic spline interpolation functions are used to predict the values of the corrective coefficients. By using these corrective functions, the ε -constraints bi-objective optimization algorithm gives an extended and accurate Pareto optimal set in less than 2 days.

Abstract—Many real world optimization problems turn out to be multi-objective optimization problems revealing a remarkable number of locally optimal solutions corresponding to the chosen objective function. Therefore, it seems desirable to detect as many of those solutions with as few objective function calls as possible. A Niching Higher Order Evolution Strategy (NES) can successfully be applied to locate a remarkable number of local solutions during a single optimization run. Additionally, it turns out that all of these solutions can be found next to the front of non-dominated solutions. Therefore, evaluating more than one objective function (in parallel or in series) yields a good approximation of the Pareto-optimal front. The proposed method will be tested against several test functions and then applied to the solution of a magnetic shunting/shielding problem.

Index Terms—Stochastic Optimization, Niching Evolution Strategies, Multi-Objective Problems.

I. INTRODUCTION

Applying optimization algorithms to technical design problems has become a standard procedure within the last decades. Stochastic methods like Evolution Strategies among many others have become frequently used tools for this task. Besides their major advantages like high convergence stability, these methods still suffer from an inherent high number of function calls. Even if CPU power has risen incredibly since the introduction of these methods for optimizing electromagnetic fields, in dealing with complex real world applications one must still economize computational effort. This calls for an optimization strategy which supplies the user with as much information as possible from as few runs as necessary. Niching Higher Order Evolution Strategies (NES) take advantage of a modified recombination operator. In contrast to the classical version [1], NES group the population into clusters and perform recombination within a cluster with a higher probability than among different clusters [2]. It turns out that over the course of the optimization process several sub-populations start to flock together temporarily in the vicinity of different local solutions and give them up again on their way to the final solution. The entity of these local solutions corresponding to a single objective function form a part of the front of the non-dominated solutions [3]. Taking multiple objective functions into account in parallel or in series, more than one part of the front of the non-dominated solutions can be found. Moreover,

in a predominant number of optimization runs, NES finally converges to the global solutions among the detected local ones. The optimization strategy must be able to report on all solutions to the user. It is obvious that the population size has to be related to the number of local solutions. To keep the numerical effort still reasonable, it is very important to estimate the number of these solutions reasonably well and to adapt it continuously during the optimization run. The proposed strategy is applied to several test functions for comparison of the number of function calls or global behaviour and finally to a 2D real world shape optimization problem, namely a magnetic shielding and shunting problem for industrial devices.

II. THE MAGNETIC SHUNT/SHIELDING PROBLEM

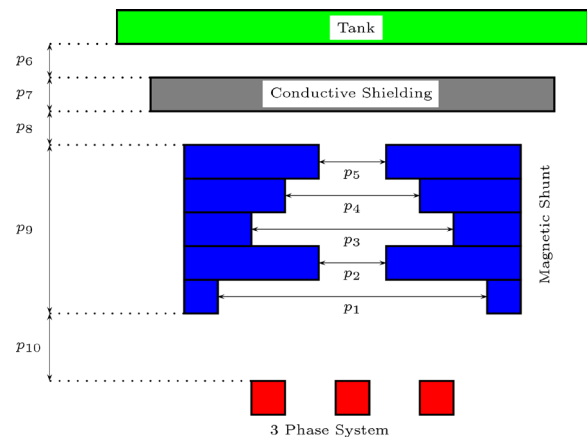

Fig. 1. Topology of the Shunt Problem with Trial Variables p_1 to p_{10}

Figure 1 shows the magnetic shunt/shield problem [4]. Eddy currents can flow in the tank (made of steel) only. The magnetic shunt is made up from a certain number of slices. They all have the same thickness but different widths. A layer of copper acting as a magnetic shield can additionally be inserted between the shunt and the tank. The magnetic field is produced by a three phase system. The goal is to minimize the power losses in the tank while keeping the volume of the magnetic shunts (and later also of the conductive shielding) as low as possible.

III. OPTIMIZATION STRATEGY: NICHING HIGHER ORDER $[\kappa(\mu/\rho, \lambda)]$ EVOLUTION STRATEGY

A higher order $[\kappa(\mu/\rho, \lambda)]$ Evolution Strategy (NES) [1] relies on the application of features of biological evolution, like population, mating and environmental selection, recombination, reproduction and mutation [5]. Recombination is usually done by arithmetic crossover, taking the fitness of all parents under consideration into account. Prior to this step the whole generation is clustered using a complete linkage clustering method [2]. Then, recombination within a cluster is performed with a higher probability than recombination between different clusters. This leads, even after a few generations, to a certain number of sub-populations gathering around local solutions. The best solution of each cluster is stored in order to remember all individual local solutions. Since the population is adjusted depending on the number of clusters under investigation, it is very important to estimate this number as accurately as possible in order to spend CPU resources economically. This can be done by monitoring the cluster radii, both in a static way (comparing the radii of the individual clusters of one generation) and dynamically (tracing the behaviour of the radius of the largest clusters). Then, over the course of the optimization process, one local solution after another is given up, which leads to a continuously decreasing population. At last, all individuals can be found next to the final solution only, which more often than not turns out to be the global of all distinguished solutions.

IV. FRONT OF NON DOMINATED SOLUTIONS

To detect a major part of the front of non-dominated solutions [3], more than only the main objective function is taken into account. Using a fuzzy scheme [6] to supply the NES with a scalar value characterizing the quality of the current configuration, this can be done by selecting appropriate sets of weighting factors as indicated in (1).

$$\mu(\mathbf{p}) = (w_1 + w_2) - w_1\mu_{losses}(\mathbf{p}) - w_2\mu_{volume}(\mathbf{p}). \quad (1)$$

Putting more emphasis on one or the other objective (in parallel or in series), a large part of the pareto front can be detected.

V. RESULTS

A $[\kappa(\mu/\rho, \lambda)]$ NES with $\kappa = 10$ clusters, $\mu = 4$ parents with $\rho = 2$ of them performing recombination leading to $\lambda = 10$ children is used to solve the above magnetic shunt/shielding problem. The electromagnetic field problems are solved using the 2D Finite Element code ELEFANT2D [7]. In the first stage only magnetic shunts are taken into account. Ten trial variables (Fig. 1) can be adjusted to minimize both the losses and the volume of the shunts. In a sequential way, four different objective functions (1) with different weights are used (Fig. 2). Each problem was run once, leading to a single optimal solution for each objective function, respectively. The best result - obtained with $w_1=1$ and $w_2=1$ - was able to decrease the volume by 53% and the eddy current losses by

40% compared with a massive shunt of the same dimensions. Additionally, the best solutions of each of the ten clusters were stored and evaluated. The non dominated ones of each problem were selected and are plotted in Fig. 2 together with a vast number of solutions obtained in the different optimization runs and the respective front of non-dominated solutions. It can be seen that the cluster solutions are quite close to the front of pareto optimal solutions.

Fig. 2. Front of Non-Dominated Solutions.

VI. CONCLUSION

A Niching Higher Order Evolution Strategy was applied to determine the optimal design and location of five layers of magnetic material in order to shield as much magnetic field from the tank wall of a transformer as possible. Estimating the number of clusters (and hence the number of local solutions) fairly well, the population size can be kept to a minimum, saving CPU time. Running this strategy several times sequentially with different objective functions (stressing one or another objective), it turned out that additionally to the respective optimal designs, several solutions along or close to the pareto front can be detected.

Abstract — This paper presents a new methodology for design optimization of dielectric waveguide filters based on continuum design sensitivity analysis in conjunction with standard electromagnetic software. To achieve this, an analytical sensitivity formula and unified program architecture applicable to optimal design of high-frequency devices are proposed. A three-dimensional dielectric resonator used in waveguide filters has been tested to illustrate the validity of the method.

I. INTRODUCTION

In recent years, a few attempts at optimizing waveguide filters based on the design sensitivity analysis (DAS) have been made. Depending on the technique used to compute the derivative of an objective function, DAS can be categorized as the discrete DSA (DDSA) [1] or the continuum DSA (CDSA) [2]. However, from the practical viewpoint of combing with general-purpose electromagnetic (EM) software packages, DDSA has a critical drawback as it requires some amendments to the software code to perform sensitivity calculation. In the meantime, Yang *et al* [2] proposed the analytical sensitivity formulas by using the bilinear mapping obtained from the weak form of wave equations. Even though CDSA could overcome the aforementioned problem of DDSA, no in-depth work on CDSA concerning high-frequency device design has been carried out to date. It is believed that the complication of the sensitivity derivation based on the bilinear mapping may lead researchers to the ambiguity of the adjoint system.

In this paper, an analytical sensitivity formula for shape optimization in frequency domain is newly derived from a fairly routine procedure, where the augmented Lagrangian method (ALM), the material derivative concept and the adjoint variable method (AVM) are exploited [3]. During the mathematical expansions, the adjoint system equation is systematically deduced and compared to the wave equation referred to as the primary system equation. It is well known that the analytical formula facilitates calculating the first-order gradient information of an objective function with respect to shape design variables and saves a lot of computing time in finding an optimal solution especially as the number of design variables increases. To utilize the advantages of CDSA, a unified program architecture, where engineering software packages are integrated into a design tool, is proposed.

II. SHAPE DESIGN SENSITIVITY FORMULA

In order to deduce the design sensitivity and the adjoint system equation systematically, the variational form of source-free wave equation in time-harmonic case, referred to as the

primary system, is added to objective function g based on the augmented Lagrangian method:

$$\begin{aligned} \bar{F} = & \int_{\Gamma} g(\mathbf{E}(\mathbf{p})) d\Gamma \\ & + \int_{\Omega} [-\mu_r^{-1} \nabla \times \mathbf{E} \cdot \nabla \times \boldsymbol{\lambda} + k_o^2 \epsilon_r \mathbf{E} \cdot \boldsymbol{\lambda}] d\Omega \\ & - \int_{\gamma} [\gamma_e (\mathbf{n} \times \mathbf{E}) \cdot (\mathbf{n} \times \boldsymbol{\lambda}) + \mathbf{V} \cdot \boldsymbol{\lambda}] d\Gamma \end{aligned} \quad (1)$$

where g is scalar functions differentiable with respect to the electric field \mathbf{E} , which is itself an implicit function of design variable vector \mathbf{p} , Γ the boundary of analysis region Ω , $k_o = \omega(\epsilon_o \mu_o)^{1/2}$, $\boldsymbol{\lambda}$ the Lagrange multiplier vector interpreted as the adjoint variable, γ_e a known parameter and \mathbf{V} a known vector. To obtain an explicit expression for the deformation of the interface boundary γ between different materials, Ω_1 and Ω_2 , the second integral on the right-hand side of (1) is split into the two regions. After taking the material derivative on both sides of (1), the adjoint system equation is defined as:

$$\begin{aligned} & \int_{\Omega} [-\mu_r^{-1} \nabla \times \boldsymbol{\lambda} \cdot \nabla \times \mathbf{E}' + k_o^2 \epsilon_r \boldsymbol{\lambda} \cdot \mathbf{E}'] d\Omega \\ & - \int_{\gamma} [\gamma_e (\mathbf{n} \times \boldsymbol{\lambda}) \cdot (\mathbf{n} \times \mathbf{E}') - \mathbf{g}_E \cdot \mathbf{E}'] d\Gamma = 0 \end{aligned} \quad (2)$$

where \mathbf{E}' denotes an arbitrary variable vector and the pseudo-source, $\mathbf{g}_E = \partial g / \partial \mathbf{E}$, plays the role of incident field imposing on the boundary Γ . It is noted that only the boundary value used is different in the dual system consisting of the primary and the adjoint systems.

Finally, the design sensitivity formula applicable to design optimization of high-frequency devices is given by

$$\begin{aligned} \dot{\bar{F}} = & \int_{\gamma} [\omega^2 \mu_o (\mu_2 - \mu_1) (\mathbf{H}_{1n} \cdot \mathbf{H}_{2n}(\boldsymbol{\lambda}) - \mathbf{H}_{1t} \cdot \mathbf{H}_{2t}(\boldsymbol{\lambda})) \\ & - k_o^2 (\epsilon_{r2} - \epsilon_{r1}) (\mathbf{E}_{1n} \cdot \boldsymbol{\lambda}_{2n} - \mathbf{E}_{1t} \cdot \boldsymbol{\lambda}_{2t})] V_n d\gamma \end{aligned} \quad (3)$$

where the subscripts, n and t , are the normal and tangential vectors to the interface boundary, respectively.

III. NUMERICAL IMPLEMENTATION

Using the analytical formula (3), the first-order gradient information of an objective function with respect to the design variables can be easily calculated from the field values obtained in the dual system. To implement this, a unified program architecture applicable to high-frequency device design is presented in Fig. 1. The program consists of three independent modules that are distinguished by the dotted boxes shown in Fig. 1. The optimization module outside the two boxes controls the overall design procedure and evaluates crucial quantities such as the objective functions, adjoint source terms, and design sensitivity. On the other hand, the analysis module inside the upper box estimates the performance of the dual system whenever the design variables

change. The optimization toolbox module provides efficient searching techniques for seeking out an optimal solution in infinite design space and returns optimal displacement values to design variables. The proposed method has been executed by combining the commercial EM code HFSS with the general optimizer DOT, where a modified feasible direction algorithm with the first-order sensitivity information is used.

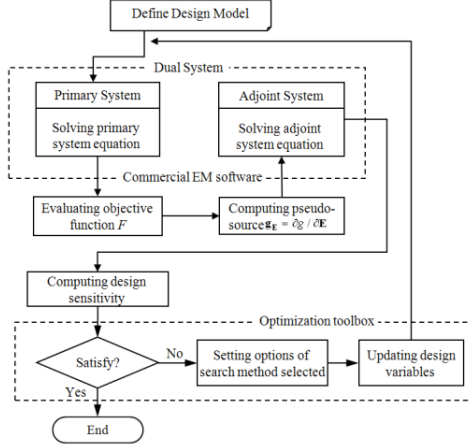

Fig. 1. Flowchart of the proposed method

IV. RESULTS

The proposed program architecture has been successfully applied to optimization of a dielectric waveguide filter in conjunction with the two different commercial software packages without the need to modify the source code. For analyzing the 3-D design model depicted in Fig. 2, the frequency domain solver with the second-order tetrahedral elements is used. The objective function is defined as (4) to achieve a second-order Chebyshev Type I lowpass transfer function from 1.4 GHz to 3.4 GHz, where the cutoff frequency is 2.4 GHz with passband ripple of 0.5 dB.

$$\text{Minimize } F = \sum_{i=1}^n \frac{1}{n} (|T_{ri}| - |T_{ro}|)^2 \quad (4)$$

$$\text{subject to } g_j(\mathbf{p}) = (\mathbf{p}_j - \mathbf{p}_{j+1}) + \varepsilon_j \leq 0 \quad j = 1, \dots, 5$$

where n is total frequency points of 21 selected at 0.1 GHz intervals, T_{ri} the transmission coefficient calculated at the i th frequency, T_{ro} the desired value at the same frequency, g_j the j th constraint function imposed on the design variables. The optimization problem is solved using two different searching techniques. The first adopts finite differencing method (FDM) for calculating the sensitivity information; the second approach is based on CDSA. In this paper, 6 design variables as shown in Fig. 2 are selected for the purpose of comparison between the two methods.

Starting with an initial design, the CDSA-based and the FDM-based optima are presented in Table I. The objective function values obtained from the two methods almost reach the same value of -38.40 dB but total iteration number and computing time required by the CDSA-based method is smaller by nearly 60% compared to the FDM-based method. In Fig. 3, the amplitude of the transfer functions is compared with each other before and after optimization. Even though some discrepancy in the target and optimized values is

observed, it is inferred that the current optimum is the best optimal solution provided by the real 3-D structure.

V. CONCLUSION

An analytical sensitivity formula and a unified program architecture applicable to high-frequency device design have been introduced in this paper. The results reveal that the proposed method offers high performance compared to FDM-based optimization method.

Abstract — The inspection of the hardened depth of surface hardening spheroidal graphite cast iron is important in maintenance of various mechanical parts etc. There is a difference of the electromagnetic property in the layer with and without hardening. Therefore, the evaluation of the hardened depth is possible by detecting the difference of the electromagnetic characteristic.

In this paper, the electromagnetic method for measuring the depth of a hardened layer using an alternating magnetic field is proposed. The flux density in the surface hardening spheroidal graphite cast iron is estimated by 3-D nonlinear FEM taking into account of interpolation of the electromagnetic property of the layer with and without hardening. In addition, the experimental verification is also carried out.

I. INTRODUCTION

The surface hardening spheroidal graphite cast iron is used for various mechanical parts etc. It is necessary to inspect the depth of hardened layer in keeping the quality of machine parts etc. The ultrasonic wave testing, or the four-point probe method [1] using the change of resistivity in hardened material are generally used. However, the non-contacting inspection is difficult in these techniques.

The permeability and conductivities of hardened layer is decreased rather than the layer without hardening. Therefore, the evaluation of the hardened depth is possible by detecting the difference of the electromagnetic characteristics [2].

In this paper, the non-contacting inspection method of the hardened depth of surface hardening spheroidal graphite cast iron by applying the alternating magnetic field is investigated. The B-H curves and conductivities of the layer with and without hardening are measured. Then, the evaluation of the flux density between the layer with and without hardening inside the surface hardening spheroidal graphite cast iron is estimated by the 3-D nonlinear FEM taken into consideration of alignment interpolation of these electromagnetic property. In addition, the experimental verification of this method is carried out.

II. INSPECTION METHOD AND MODELING OF MAGNETIC PROPERTY OF SURFACE HARDENING SPHEROIDAL GRAPHITE CAST IRON

Fig.1 shows the 1/2 domain of the proposed non-contacting inspection model for evaluating hardened depth in

the surface hardening spheroidal cast iron. The lift-off between the spheroidal graphite cast iron and the ferrite yoke was set to 0.1mm. Fig.2 shows the initial magnetization curves of the layer with and without hardening of the spheroidal graphite cast iron. Table I shows the conductivities, respectively. The permeability and conductivity are decreased with the increase of the hardness.

Fig. 3 shows the example of a measurement result of the hardness using the Vickers hardness meter when the effective hardening depth is 2.5mm. The figure denotes that the

TABLE I
CONDUCTIVITIES OF LAYER WITH AND WITHOUT HARDENING OF THE SPHEROIDAL GRAPHITE CAST IRON

	Conductivity (S/m)
without hardening (275HV)	6.59×10^5
with hardening (775HV)	4.62×10^5

Fig. 1. Initial magnetization curves of the spheroidal graphite cast irons with and without hardening.

Fig.2 Inspection model of surface hardening spheroidal graphite cast iron (1/2 domain).

hardness in 2.5mm depth from the surface is about 775HV,

7. Material Modeling

the hardness of 2.5mm to 3.5mm depth is decreased rapidly, and that of more than 3.5mm depth becomes about 275HV. The B-H curve of the domain of the depth of 2.5mm to 3.5mm is obtained by the linear interpolation using the B-H curves of the layer with (0mm-2.5mm depth) and without hardening (more than 3.5mm depth). Fig.4 shows the method of linear interpolation of B-H curve using the B-H curves of the layer with (μ_H) and without hardening (μ_A). The angles θ_A and θ_H of the interpolated permeability μ_I at the point of which the depth is equal to D_x shown in Fig.3 is obtained so that the following relationship is satisfied:

$$\frac{\theta_A}{\theta_H} = \frac{D_A - D_x}{D_x - D_H} \quad (1)$$

The conductivity σ is also interpolated similarly.

III. INVESTIGATION OF INSPECTION OF HARDENED DEPTH

Fig.5 shows the effect of the hardened depth on the change of flux density $|Bz|$ of a search coil. Several specimens with 0mm-10mm hardened depth are prepared, and $|Bz|$ is measured and calculated. The frequency and the flux density B_E inside the exciting coil are 100Hz and 0.166T, respectively. The figure denotes that $|Bz|$ is decreased when the hardened depth is increased. Fig.6 shows the distribution of flux density inside the surface of hardening spheroidal graphite cast iron when the hardened depth D_1 is 2.5mm. The figure illustrates that the flux is more distributed in the layer without hardening, since the permeability of hardened domain is lower than that of the layer without hardening.

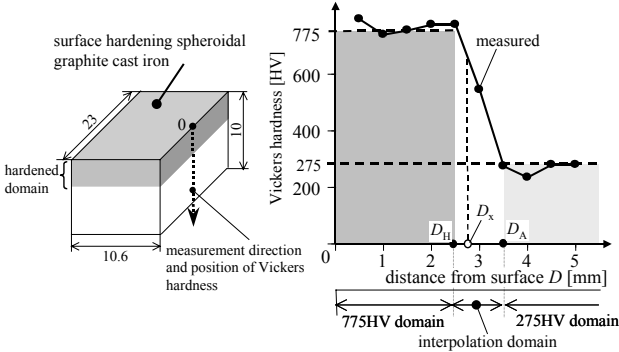

Fig.3. Example of a measurement result of the hardness using the Vickers hardness meter when the effective hardening depth is 2.5mm.

Fig.4. Interpolation of B-H curves.

Fig.5. Effect of hardened depth on change of flux density $|Bz|$ in a search coil (100Hz, $B_E = 0.166T$).

Fig.6. Distribution of flux density in the surface hardening spheroidal graphite cast iron (100Hz, $B_E = 0.166T$, 1/4 domain).

In the full paper, the optimal magnetization condition for the inspection is examined using the 3-D edge-based hexahedral FEM. In addition, the experimental verification is also carried out.

IV. CONCLUSIONS

The results obtained are summarized as follows:

- (1) The permeability and conductivity of the layer with hardening in the surface hardened spheroidal graphite cast iron are lower than that of the layer without hardening.
- (2) The flux density in a search coil of the proposed inspection method is decreased when the hardened depth is increased, because the permeability and conductivity are decreased in the hardened layer. Therefore, the non-contacting inspection of the hardened depth is possible by detecting the change of flux density of search coil.

Abstract—The magnetic modeling of Si-Fe magnetic steels is presented in this paper. The modeling is based on a class of vector Hysteresis operators recently introduced. The vector approach works without the additional manipulations and corrections of the scalar case. Some preliminary experimental verifications are also reported.

I. INTRODUCTION

This paper discusses the modelling of vector Hysteresis in Si-Fe magnetic steels. The modelling applied has been recently introduced, and it is based on a vector hysteresis operators, hysterons, defined in the applied field space. The model is rate independent, so that the applied field variation when comparing with experiment must be sufficiently slow so that no dynamic effects are excited. The vector hysterons each of which obey certain behavior rules that depend upon its critical surface, defined in the applied field plane for that hysteron. This critical surface is a closed convex surface so that the model is consistent with the laws of thermodynamics. The magnitude of the magnetization of the hysteron is constant for all fields. Thus, we can normalize it, and we will refer to the magnetization of the hysteron as unit magnitude hysteron. The rules for computing the magnetization of the unit magnitude hysteron are:

- When the applied field lies outside the critical surface, the unit magnitude hysteron magnetization is a conservative function of the applied field.
- When the applied field lies inside the critical surface, the unit magnitude hysteron magnetization is constant.
- When the applied field enters the critical surface, the unit magnitude hysteron magnetization is frozen to the value that it had just before entering the critical surface.
- When the applied field exits the critical surface the unit magnitude hysteron magnetization experiences a Barkhausen Jump to a direction that it is normal to the critical surface.

It is under this last rule that there is a dissipation of energy in the material. Further explanation about the modelling above mentioned can be found in [1], [2], [3]. The resulting model is the extension in 2-d and 3-d of the classical Preisach model in that it obeys the vector generalizations of the congruency and the deletion properties [4]. To obtain realistic behavior for magnetic materials, such as Si-Fe magnetic steels, the classical scalar Preisach model has to be modified introducing

correction and additional terms [5], [6], [7]. The model here presented has intrinsically a reversible component of the magnetization, and the distribution function is intrinsically magnetization dependent, as will be discussed in the full paper. Therefore it can be implemented to the numerical analysis of hysteresis in magnetic materials without the additional manipulations and corrections of the scalar case. This fact is discussed in the paper, where we show the implementation of the model for the case of Si-Fe magnetic steels, and the experimental verification of the material behaviour predicted by the model.

II. NUMERICAL IMPLEMENTATION OF THE MODEL TO THE CASE OF 2-D SI-FE STEELS

The numerical approximation of the model for the Si-Fe Steels has been made following these points:

- 1) It is defined a suitable memory allocations grid defined on the space (H_x, H_y, u) . This structure contains $n_x \times n_y \times n_u$ allocations, where $n_x \times n_y$ is the number of the hysterons for a given value of u , and n_u is the number of the u values taken into account. On each allocation there are stored two parameters: the probability density $P_{i,j,k}$ and the magnetization state $Q_{i,j,k}$ of the corresponding hysteron.
- 2) It is defined the zero magnetization state (virgin state) when the applied field is zero, and the previous history has been deleted. The virgin state is obtained imposing all the $Q_{i,j,k}$ unitary vector to be aligned in the direction that links the center of the hysteron (i, j, k) to the H-plane origin for each location of the memory grid.
- 3) The magnetization state $Q_{i,j,k}$ for a given hysteron is computed through the value v of the orientation of the magnetization calculated by

$$\frac{H_x - H_{lx}}{\cos(v)} - \frac{H_y - H_{ly}}{\sin(v)} = 1 \quad (1)$$

- 4) The probability density values $P_{i,j,k}$ in the memory allocations grid are defined a priori using a suitable identification procedure of the model. These values are constant for the entire magnetization process. When the magnetic field changes, the memory allocations grid also changes in term of hysteron magnetization state. We used her a “Least-Squares” approach with a “Tikhonov regularization” scheme. Defining the following error functional

$$\varepsilon(\mathbf{p}) = \|\mathbf{M}^* - \mathbf{m} \cdot \mathbf{p}\|^2 + \alpha^2 \cdot \|\mathbf{R} \cdot \mathbf{p}\|^2 \quad (2)$$

we find the estimated solution \mathbf{p}_{est} that minimizes ε

$$\mathbf{p}_{est} = (\mathbf{m}^T \cdot \mathbf{m} + \alpha^2 \cdot \mathbf{R}^T \cdot \mathbf{R})^{-1} \cdot \mathbf{m}^T \cdot \mathbf{M}^* \quad (3)$$

The term $\|\mathbf{M}^* - \mathbf{m} \cdot \mathbf{p}\|^2$ represents the quadratic error on the data space (“discrepancy”), whereas α and \mathbf{R} are the regularization parameter and matrix respectively. The probability of the k -th hysteron must be in the range $(0, 1)$. So it has been introduced a projection operator “ \mathbf{F} ” defined as

$$(\mathbf{F}\mathbf{p})_k = \begin{cases} 0 & \text{if } p_k < 0 \\ p_k & \text{if } 0 \leq p_k \leq 1 \\ 1 & \text{if } p_k > 1 \end{cases} \quad (4)$$

The value of α it is chosen in order to have a local minimum of the functional ε . The total magnetization components M_x and M_y are computed for each step using the data stored in the memory allocations grid. For a given index k the products $P_{i,j} \cdot Q_{x,i,j}$ and $P_{i,j} \cdot Q_{y,i,j}$ define two piece-wise values of the surfaces on the $n_x \times n_y$ grid. The volumes defined by these surfaces are calculated and represent a part of the magnetization M_x and M_y . In particular they are the magnetization created by the family of the hysteron with the value of u corresponding to the index k . The sum of these partial magnetizations for k from 1 to n_u gives the total magnetization.

III. NUMERICAL CALCULATION AND EXPERIMENTAL VERIFICATION

In this section we report some preliminary calculations made and the experimental verification of the computational accuracy attained. We used a “single disk tester” [8] to characterize the magnetic behaviour of disks of 3.2% wg Si-Fe steel. The experimental system is driven by a programmable board which generates and records arbitrary waveforms. The signals generated are amplified by a set of linear amplifiers operating in four quadrants in the frequency range DC - 5 kHz. The amplifiers feed the stator of an induction motor with two poles, which generates on the sample of magnetic material a magnetic field driven in modulus and direction. The probes for the detection of the magnetic field and the magnetization components x and y are placed on the sample and connected to the driver board. The applied field frequency is less than 5 Hz, so we can neglect the effect of eddy currents.

In Figure 1 we show the magnetization path predicted and measured when an increasing rotating field is applied starting from the virgin state. In figure 2 rotational and scalar static losses, either computed and measured are shown, for different values of the magnetization.

Fig. 1. Comparison between measured and computed rotational magnetization.

Fig. 2 – Rotational and scalar static losses vs the amplitude of applied magnetic field.

flavio.calvano@unina.it

Abstract—The paper presents a technique to compute magneto-quasi-static non-destructive testing problems with parameterized defect geometry. A single mesh is used for computations within a range of parameters, and the metric variations due to parameter variations are compensated for in the numerical values of the material parameters.

I. INTRODUCTION

A typical problem in non-destructive testing (NDT) is to specify the defect that generates a certain signal into a probe. This is an indirect problem –the geometry of the defect that causes the signal is not known– and consequently, a number of computations is required to sketch the defect. Moreover, finite element-type NDT computations are known to be rather sensitive to numerical errors and all this makes NDT problems burdensome. This paper suggests exploitation of metric properties of space in solving NDT problems. The dimensions of a defect *depend on the metric chosen for a space*. At first this may sound preposterous, as obviously the defect is what it is and cannot be changed by some modeling choice. This is indeed the case, but the issue is *how we as the modelers observe the defect*.

The change of metric is like viewing the defect through eyeglasses that magnify locally the view, making the defect appear large. This alleviates the FE-mesh generation problems caused by narrow defects. Moreover, *the magnification can be made adjustable, and a family of defect widths can then be modeled with a single (topological) mesh*. This reduces the errors sensitive to the mesh. [1]

Practically, the change of eyeglasses in this sense is done by a transformation between different systems that reflect the choices of metric one makes. Pre-processors use hardwired Euclidean metric to measure distances of coordinates. *Standard parameterizations* [1] assign coordinates to points such that their distance equals the measured distance of the points. Reparameterization changes the points' coordinate distances (as we cannot redefine the hardwired coordinate metric) and this induces a new metric into the space. The change of metric affects the constitutive laws' material parameters, whose numerical values depend on the particular metric. Another view to the matter: Each finite element stiffness matrix corresponds to some field problem. If one changes locally the metric, altering the numeric values of distances, one can counterbalance

this by adjusting the material parameters such that the entries of the stiffness matrix remain the same.

II. TRANSFORMATIONS

In most NDT applications, the probe must be placed into the immediate vicinity of the defect in order to detect it reliably, and because the geometry of the probe is independent of the defect width, it is not practical to extend the transformation into the probe. We shall consequently restrict the transformations into the immediate vicinity V of the defect. V may be tessellated into subdomains if practical. The feasible transformations

- must not displace any points at the boundary of V , and
- be continuous and piecewise differentiable with piecewise differentiable inverse.

It is usually practical to tessellate the vicinity into polyhedra [1]. Despite the high number of different transformation types required, the model can be created and the transformations derived with moderate effort. The Jacobians of the transformations must be reasonably well-behaved: Their condition numbers must not be excessive, and their determinants must not be extreme. A rectangular defect example and its boundary regions are shown in figure 1.

Fig. 1. Defect (shaded) and its vicinity regions

The defect model is drawn to be w wide. The original width of the defect is αw , and the transformation is produced by displacement of points of V in y -direction only. α is a parameter for the computation of a family of defects with different widths. We denote the coordinates as seen in the pre-processor by x, y, z , and the coordinates related to the original metric by ξ, v, ζ . We derive a piece-wise transformation that maps from x -positions to ξ -positions, and denote it by $h = \xi \circ x^{-1}$. The Jacobian J of the transformation h is

Work supported by the Academy of Finland, project 5211066, and ERASMUS exchange program.

needed when the material parameters –readily available in the original metric– are adjusted to the modified metric. The new parameters are [1]:

$$\sigma_x = J^{-1} \sigma_\xi J^{-T} \det(J), \quad \nu_x = \frac{1}{\mu_x} = \frac{J^T \nu_\xi J}{\det(J)}. \quad (1)$$

These expressions are convenient, because the Jacobian is expressed in terms of x -coordinates, and σ_ξ and μ_ξ expressed in ξ -coordinates are constant for the media. The transformations from x to ξ and z to ζ are identities, and the only interesting component of each transformation is y to v , expressed in figures 2 and 3, and equations (2)–(6).

Fig. 2. Regions 1 to 3

Fig. 3. Regions 4 and 5

$$v_1 = \alpha y, \quad v_1 = y + (1 - \alpha)(w/2) \frac{y - y_e}{y_e - w/2}. \quad (2)$$

$$v_2 = y - y(1 - \alpha) \left(1 - \frac{z - z_c}{z_v - z_c}\right) \quad (3)$$

$$v_3 = y - (1 - \alpha)(w/2) \left(1 - \frac{x - x_c}{x_v - x_c} - \frac{y - w/2}{y_e - w/2}\right) \quad (4)$$

$$v_4 = y - y(1 - \alpha) \left(1 - \frac{x - x_c}{x_v - x_c} - \frac{z - z_c}{z_v - z_c}\right) \quad (5)$$

$$v_5 = y - (1 - \alpha)(w/2) \left(1 - \frac{x - x_c}{x_v - x_c} - \frac{y - w/2}{y_e - w/2} - \frac{z - z_c}{z_v - z_c}\right) \quad (6)$$

III. COMPUTATIONAL EXAMPLE

TEAM test problem number 8 [2] is used as the computational example. The problem features a $40 \times 10 \times 0.5$ mm

rectangular defect at the surface of an austenitic 18-10MO steel plate with relative permeability $\mu_r = 1$ and conductivity $\sigma = 0.14 \times 10^7$ S/m. We used 1A current with 100 turns in the active coil, and calculate the average differential flux in the receptive coils.

This problem demonstrates two strengths of the proposed technique: The high aspect ratio of the defect can be reduced somewhat to ease the meshing, and defects of different width can be computed with a single mesh. Compared to different meshes generated from scratch, the use of a single mesh provides a better idea of the development of the flux estimate when the defect width is altered.

We used the symmetrized version of $A, V - A$ formulation [3] with the tree-co-tree gauge [4]. The models were constructed with gmsh [5], and the computations were carried out with GetDP [6].

Fig. 4. Real and imaginary part of the magnetic flux in the receptive coils

Figure 4 shows the real and imaginary part of the computed magnetic flux in the receptive coils, for a parallel scan of the active probe [2], with values 1, 1/2, 1/3 for α . The results with different values of α show reasonable mutual agreement. It is to be noted that generation of high quality mesh was easiest when the defect scale-up was greatest.

An Improved Jacobi-Davidson Method for the Computation of Selected Eigenmodes in Waveguides

Bastian Bandlow, Denis Sievers, and Rolf Schuhmann
 FG Theoretische Elektrotechnik, EIM-E, University of Paderborn
 Warburger Str. 100, D-33098 Paderborn, Germany
 bandlow@tet.upb.de

Abstract — The numerical simulation of open structures requires the truncation of the computational domain and the definition of appropriate boundary conditions. However, this artificial boundary at finite distance causes additional non-physical modes in the eigenanalysis of waveguides which must be excluded from the computed spectrum. We propose an extension of the Jacobi-Davidson method by introducing a special weighting function that enables a reliable suppression of undesired eigenmodes already during the solution process. Moreover, the number of iteration steps as well as the computation time can be drastically reduced by this process. We show the improvement of efficiency by means of an eigenmode computation in a photonic crystal fiber discretized by the finite integration technique.

I. INTRODUCTION

The computation of eigenvalues in two- and three-dimensional electromagnetic structures is a challenging task in engineering. Since dielectric waveguides for optical applications (fibers) can be highly multi-modal, the corresponding 2D-eigenvalue problem may include a high number of guided modes, with only little differences in their propagation constants. For such modes, the power is confined within the core of the fiber, and the field strength in the cross section decays exponentially with increasing radius. With this a-priori knowledge, one may wish to apply an adequate transversal boundary condition, which allows truncating the mesh close to the core of the fiber. Such an 'open boundary' can be modeled, for example, by a perfectly matched layer (PML), which absorbs the evanescent wave parts by real-coordinate stretching [1]. However, the application of any boundary condition changes the discrete eigenvalue problem, and an ideal boundary condition as well as the staggered material layers of the PML themselves can act as a waveguiding structure. This leads to a spoiled spectrum, which consists not only of the desired guided modes within the core, but we observe a lot of additional, non-physical modes, which are guided inside the PML. In order to get rid of these spurious modes, we propose a new variant of the Jacobi-Davidson eigenvalue solver [2, 3] which allows to distinguish between the two classes of eigenvectors *within the solution process* and to produce only the desired core-modes in an efficient way.

II. WEIGHTED JACOBI-DAVIDSON ALGORITHM

The Jacobi-Davidson (JD) algorithm [2, 3] is feasible for the computation of a few interior or exterior eigenvalues of the spectrum. Within the algorithm, the original eigenvalue problem is projected onto (and solved in) a low-dimensional

subspace, which is gradually refined by solving a correction equation. We use a Matlab implementation of the JD-algorithm from its original authors which is available from [3]. As so-called target value, an end of the spectrum or an arbitrary value within the spectrum can be specified. According to this target value, the approximated eigenvalues are sorted in different sophisticated ways during the solution process. The solution of the low-dimensional, projected eigenvalue problem, however, does not only yield approximations of the eigenvalues, but of course we also obtain approximations of the corresponding eigenvectors. If we map them back in the original space, we can interpret these vectors as approximations of field solutions of the discrete formulation. To establish a new criterion for the choice of the desired modes, we test these field distributions against a weighting vector \mathbf{f} , which describes a scalar spatial distribution for each field component with its maximum at the core and an evanescent decay towards the boundaries. We choose a Gaussian profile as components of these vectors, since it is easy to define and it fulfills the requirements of a strong decay toward the boundaries. Now, we can measure the quality of our approximate eigenvectors \mathbf{u}_i within the JD-algorithm very easily. The standard scalar product

$$\Psi = \langle \mathbf{f}, |\mathbf{u}_i| \rangle \quad \text{with } \|\mathbf{u}_i\|_2 = 1, \|\mathbf{f}\|_\infty = 1 \quad (1)$$

can be used to decide, whether the field strength is concentrated around the core ($\Psi > 1$) or whether it is concentrated inside the boundary ($\Psi \ll 1$).

III. NUMERICAL RESULTS

A. Photonic Crystal Fiber

We choose a hollow-core photonic crystal fiber (PCF) [4] as an example, which is operated at $2\mu\text{m}$ wavelength (Fig. 1). It consists of a glass core ($n_G = 1.45$) with a surrounding hexagonal lattice of air holes. Each hole has a radius of $2.9\mu\text{m}$ and the lattice constant is $9.4\mu\text{m}$. The discrete model is truncated by a PML boundary condition and has the dimensions $74\mu\text{m} \times 84\mu\text{m}$. The cross section of the fiber is discretized by the finite integration technique (FIT, [5]), using CST Microwave Studio [6] for all preprocessing steps. The resulting two-dimensional model has 155×193 grid points, and we add 4 grid lines in each transversal direction for the PML boundary condition. The eigenvalue problem [7] for the squared propagation constants β^2 is linear, of the type

$$\mathbf{A}\mathbf{u}_i + \beta_i^2\mathbf{u}_i = 0, \quad (2)$$

and has 64438 degrees of freedom. We are interested in the first two guided modes of the PCF. Fig. 2 shows the part of the spectrum with the smallest real part of the propagation constants β_i . The first 36 modes are guided within the PML region. Modes 37 and 38 are the ones we are looking for and which fulfill our weighting criterion in (1).

Fig. 1. Electric field strength of a core mode (left) and a spurious mode (right) caused by a transversal truncation of the computational domain.

Fig. 2. Propagation modes of the PCF.

B. Performance Comparison

We used the unmodified Jacobi-Davidson solver as well as the weighted JD solver to compute the first two guided modes of the PCF from the previous subsection. For all eigenmodes computations, the system matrix is shifted and scaled before the solver starts, which significantly improves the condition number of the problem. The target is chosen to be the smallest real part. The initial subspace is generated randomly and is fed in each of both solvers in order to have equal starting conditions. The correction equation within the JD algorithm is solved exactly in both solvers. This is time-consuming, but we can expect at least a second order convergence. The results are given in Table 1. We look for two core guided modes, which are found by both solvers. The weighted JD outperforms the standard JD by a factor of 15 in time. The number of iterations, which are needed to gradually refine the subspace, is reduced by a factor larger than two. The reason for the disagreement of these two factors can be seen in the convergence history in Fig. 3. A lot of iterations are needed at the beginning of both algorithms, in order to improve the quality of the subspace. Once refined, the subspace allows the quick computation of the consecutive eigenvalues.

Fig. 3. Convergence history of the standard and the weighted JD method.

TABLE I

RESULTS OF THE STANDARD AND THE WEIGHTED JD METHOD

JD	Core Modes	Total Modes	CPU Time	Iterations
Standard	2	38	2687 s	108
Weighted	2	2	165 s	46

IV. CONCLUSION AND OUTLOOK

We have shown that a simple extension of the selection process of the approximate eigenpairs within a Jacobi-Davidson algorithm leads to a superior convergence behavior for waveguide models which are surrounded by a PML boundary condition. The number of eigenvalues which have to be computed until we arrive at the desired ones is drastically reduced.

The final paper will discuss a couple of improvements concerning the performance, the computationally efficiency, and the range of application of the modified eigensolver: At first, other weighting functions can be used, e.g. it should be possible to find only modes with a specific polarization, modes with an energy transport in specific regions of the cross section, etc. In the current implementation only the values of the electrical grid voltage are taken into account by the weighting function. However, it may also be applied to Poynting's vector or other secondary quantities. Secondly, the performance of the modified Jacobi-Davidson algorithm itself can be significantly improved. An important issue is the solution of the correction equation: An only approximate solution here typically deteriorates the convergence rate in terms of the number of iterations, but increases the overall computationally efficiency. Besides, the number of iterations can be further reduced by re-using the weighting function as start solution of the eigensolver.

Finally, the weighting could also be implemented into other eigensolvers such as the implicitly restarted Arnoldi algorithm, where it should also be possible to eliminate the undesired eigenvectors from the approximate subspace. Of course, this kind of solver can also be applied to other types of waveguides such as microstrip lines with PML boundary conditions.

Abstract—A multirate Adams-Bashforth (AB) scheme for simulation of electromagnetic wave propagation using the discontinuous Galerkin finite element method (DG-FEM) is presented. The algorithm is adapted such that Single Instruction Multiple Thread (SIMT) characteristic for the implementation on a Graphics Processing Unit (GPU) is preserved. Accuracy and performance is analyzed with help of suitable benchmarks.

I. INTRODUCTION

Increasing complexity of modern electromagnetic devices is challenging current simulation tools. When large structures should be considered, small parts within these structures are leading to large aspect ratios of the mesh size. These aspect ratios have severe performance effects on explicit time integration schemes in use, since the smallest element is determining the maximum stable timestep for the entire mesh in a global scheme.

One way of coping with these restrictions is the use of multirate timestepping schemes, which integrate elements of different sizes with different timesteps. In this work, a multirate scheme using AB time integration is adapted such that it can be implemented on a GPU. This combines the performance gain of the multirate algorithm with the highly parallel computing power of GPUs. Multirate schemes using AB methods have been presented first in [1]. Relevant results in local timestepping for solving Maxwell's equations with DG-FEM was published by Piperno [2], Hesthaven & Warburton [3] for 2D domains and Montseny et. al. [4] in 3D on hexahedral meshes.

II. DG-FEM DISCRETIZATION

Electromagnetic wave propagation in lossless medium can be described with help of Maxwell's curl equations. A nodal variational form of Maxwell's equations is derived in [3], where the unknown fields are approximated using local high-order multi-dimensional Lagrange polynomials. This leads to a system of ordinary differential equations, reading

$$\frac{d}{dt} \varepsilon \mathbf{E} = \mathbf{M}^{-1} \mathbf{S} \mathbf{H} + \mathbf{M}^{-1} \mathbf{F} (\hat{\mathbf{n}} \times (\mathbf{H}^* - \mathbf{H}^-)), \quad (1)$$

$$\frac{d}{dt} \mu \mathbf{H} = -\mathbf{M}^{-1} \mathbf{S} \mathbf{E} - \mathbf{M}^{-1} \mathbf{F} (\hat{\mathbf{n}} \times (\mathbf{E}^* - \mathbf{E}^-)). \quad (2)$$

Here, \mathbf{E} and \mathbf{H} denote the electric and magnetic field strength, respectively. Regarding elementwise computations, the index $-$ refers to the value in the element, the index $*$ to a combination of field values of neighboring elements. A special characteristic of DG-FEM is that the DG-operators \mathbf{M} , \mathbf{S} and \mathbf{F} yield mass-, stiffness and flux-matrices that have compact support only within each element's boundary. As a consequence, \mathbf{M} is locally defined on the reference element and can be inverted without much numerical effort providing the opportunity of using explicit time integration schemes. Furthermore, this formulation includes good parallelization characteristics [5].

III. MULTIRATE GPU IMPLEMENTATION

A. Timestep Selection

Explicit time integration is not unconditionally stable since the timestep has to comply with the Courant-Friedrichs-Lewy criterion

$$\Delta t_{\min} = \min \left\{ \frac{\Delta x}{v} C \right\}. \quad (3)$$

Here, Δx denotes the characteristic size of the element, v the wave speed and C the Courant number which depends on the time integration scheme and on the spatial approximation order. Regarding multirate timestepping, the use of arbitrary numbers of levels as presented in [6] results in complex code design when all inter-level dependencies are considered. Consequently, a direct transition of the multirate CPU code is not appropriate. Multiple inter-level dependencies would introduce a complexity breaking with the NVIDIA SIMT approach associated to high performance GPU computing.

B. Level Classification

In order to respect the parallelization design aspects, a 2-level multirate scheme with selectable temporal separation is proposed. In this case, temporal separation describes the way fine and coarse elements are classified and also how the fine-coarse boundary is defined. Starting with the timestep Δt_{\min} of the smallest element, all elements with a stable timestep $\Delta t < 2^s \cdot \Delta t_{\min}$ with s being a positive integer greater than zero belong to the fine level. The timestep ratio 2^s is computed adaptively with respect to the mesh, minimizing computational costs. Eqn. (4) highlights the splitting configuration for the

discretized Ampère’s law.

$$\frac{d}{dt} \begin{pmatrix} E_F \\ E_C \end{pmatrix} = \begin{pmatrix} \mathcal{L}_{FF} & \mathcal{L}_{FC} \\ \mathcal{L}_{CF} & \mathcal{L}_{CC} \end{pmatrix} \begin{pmatrix} H_F \\ H_C \end{pmatrix} \quad (4)$$

The linear operator \mathcal{L} represents the right hand side computation in (1). The indices C and F denote coarse and fine elements, CF and FC coarse-fine interactions, respectively.

Fig. 1. Multirate scheme for a timestep ratio 4.

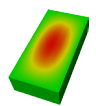

This behaviour has already been reported in [7] and will be investigated in the full paper in detail.

IV. FIRST NUMERICAL RESULTS

As a first numerical benchmark, a cavity discretized with 398 tetrahedra was excited with its fundamental mode. Regarding the different element sizes of the mesh, a level separation with a timestep ratio 4 was chosen. This corresponds to 182 fine elements having an individual stable timestep lower than $4 \cdot \Delta t_{\min}$ and 216 coarse elements having a larger stable timestep. Computations were carried out on a AMD Opteron 8356 CPU at 2.3 GHz and on one of the four NVIDIA TESLA S 1070 GPUs. Table I is listing computation time and speedup

TABLE I

COMPARISON OF GLOBAL CPU, GLOBAL GPU AND MULTIRATE GPU

Example	Implementation	Computation time	Speedup compared to CPU global
	CPU global	4 h 56 min 54 s	1.0
	GPU global	10 min 51 s	27.4
	GPU multirate	8 min 6 s	36.7
	CPU global	29 h 6 min 46 s	1.0
	GPU global	39 min 1 s	44.8
	GPU multirate	11 min 50 s	147.6

for CPU-GPU acceleration and in a second step with enabled multirate. Although this academic example is not providing large aspect ratios, the efficiency can benefit from the multirate scheme. Regarding accuracy, Fig. 2 highlights the maximum error of the electric field during several computations, each evaluating 200 periods of the cavity mode with a maximum of 1 577 781 micro-timesteps. The error of the computation with DG-FEM of order 4 is below 10^{-3} for all computations. In detail, there is almost no difference in accuracy between the GPU multirate and the GPU global scheme.

Regarding efficiency of the multirate scheme, a scattering object as presented in Fig. 3 is discretized with 130 413 tetrahedra, as shown in Fig. 4. The adapted timestep ratio

The benefit of this multirate approach is that all evaluations of the \mathcal{L}_{CC} operator have to be executed only every 2st timestep, as highlighted in Fig.1 for $s = 2$. Regarding stability, the intermediate zones are of special interest. With this configuration, the Courant number has to be chosen slightly smaller than in the global scheme.

Fig. 2. Maximum relative error of the electric field computed in a 3D cavity with multirate and global schemes on GPU and CPU.

Fig. 3. Scattering object - CAD model.

Fig. 4. Scattering object - mesh with 130 413 tetrahedra.

is 4, separating the mesh into 127 676 coarse and 2737 fine elements. The global GPU computation was accelerated by a factor of 44.8 compared to the CPU implementation and could be further accelerated by a factor of 3.3 using the multirate scheme as presented in Table I. The electric field at the surface of the scattering object (y-component) is presented in Fig. 5.

Fig. 5. Electric field of a scatterer hit by a TEM wave, computed with $15.6 \cdot 10^6$ unknowns at 52 043 microsteps.

V. CONCLUSION

A multirate GPU accelerated DG-FEM algorithm was presented. The multirate timestepping scheme can further accelerate GPU computations, especially when high aspect ratios of multiscale problems are of concern. The full paper will provide more detailed information about the theory as well as the stability and accuracy of the timestepping scheme.

Abstract— In this paper, two methods for calculating induction motor (IM) end-winding leakage inductances are presented. The 3-D geometry of the winding ends, the motor cross-section and the motor housing is very complex and difficult to model using a conforming finite element (FE) mesh. Both presented methods propose an alternative to this standard procedure. The first method is based on the numerical calculation of the Biot-Savart field using a non-conforming FE mesh. The Biot-Savart field is used to obtain an edge element representation of the rotational part of the magnetic field. In the second method, the source current distribution of the winding ends is described by spline functions and the rotational part of the magnetic field is defined by identifying the loops generated by co-tree edges within a simple graph associated with only one single finite element at a time. All elements are treated in defined succession using just one sweep. Applying either method, the eddy current analysis is carried out, thus the induced currents in the housing and in the front-end steel plate of the machine are calculated and their influence on the field distribution and on the leakage inductances is taken into account.

I. INTRODUCTION

The end-winding leakage inductance is a very important parameter whose influence is most significant during the starting behavior of the IM. In [1], a strong dependence between the end-winding leakage inductance and the acceleration time of the IM motor has been proven. In order to enable the accurate dynamic simulation of the IM starting procedure, the end-winding leakage inductance should be precisely defined and incorporated in the 2-D FE model as an additional lumped parameter [1]. In order to extract IM equivalent circuit parameters, like stator and rotor leakage inductances, a magnetizing inductance and a rotor resistance, the 2-D finite element method (FEM) is usually used. 3-D leakage fields present in the end region of the machine are, therefore, neglected. These inductances are usually estimated using design formulas that combine approximate analytical results with measurement statistics. In [2], different semi-empirical equations first presented by Alger and Gray are compared with measurement results. The improved analytical approach based on multiple solutions of the Neumann integral and on the method of images is presented in [3]. Owing to the complex geometry of the end-winding and due to the complicated boundary conditions of the problem, these analytical expressions are able to give only a rough

estimation of the leakage inductances. On the other hand, numerical methods can contribute to the accuracy of these calculations. In order to calculate the leakage reactance of the end-winding, a static 3-D FEM simulation has been applied in [4] and [5]. A problem associated with the FEM simulations of the motor end-regions is the modeling process of the end-winding itself. To obtain a conforming FE mesh of the two layered windings and the surrounding air, an enormous number of FE is required which results in a huge computation time. Therefore, the production units only rarely use 3-D FEM computations for defining the leakage inductance. Furthermore, the static FEM analysis of end-region effects is not sufficient. Namely, the induced eddy currents in the front-end steel plate of the machine and in the machine housing have significant influence on the magnetic field distribution and, therefore, on the inductance values. The aim of this paper is to present methods to overcome these problems, hence to propose a numerical procedure that would simplify the modeling of the end-winding, the machine and the surrounding end-region. The influence of the eddy currents on the magnetic field distribution and, consequently, on the leakage inductance is also taken into consideration by performing the FEM analysis in the frequency domain.

II. NUMERICAL ANALYSIS

A. Method 1 – Non-conforming FE mesh

Nowadays, companies commonly use the support of CAD modeling in the manufacturing process, thus drawings of the end-winding are often already available. It is relatively simple to mesh the winding ends without the surrounding air. In the present method, such a FE mesh has been used in order to perform a static current flow analysis and to obtain the current distribution in the winding. Knowing the current distribution, the Biot-Savart field has been calculated in the integration points of another FE mesh representing the motor, its housing and the surrounding air. The two meshes are non-conforming (Fig. 1). The eddy current problem is solved in the frequency domain using the \mathbf{T}, Φ - Φ formulation [6]. Thus, the given current density \mathbf{J}_0 is represented by an arbitrary function \mathbf{T}_0 , which satisfies the following condition:

$$\text{curl}(\mathbf{T}_0) = \mathbf{J}_0 . \quad (1)$$

Knowing the numerically calculated Biot-Savart field \mathbf{H}_s , the rotational part \mathbf{T}_0 of the magnetic field is represented with the aid of the edge element shape functions in order to avoid cancellation errors:

$$t_i = \int_{\text{Edge } i} \mathbf{H}_s dl; \quad \mathbf{T}_0 = \sum_{\text{Edge } i} t_i N_i, \quad (2)$$

where N_i stands for the vectorial edge element shape functions associated with the i -th edge and n_e for number of FE edges.

Fig. 1. 3-D FE model of the induction motor, its end-winding and housing

B. Method 2 – Generating \mathbf{T}_0 by a procedure based on element graphs

Since only an edge-element representation of \mathbf{T}_0 is required, it is sufficient to compute the coefficient t_i in (2) in a way that the integral form of (1),

$$\oint_{C_i} \mathbf{T}_0 dl = \int_{\Gamma_i} \mathbf{J}_0 d\mathbf{S} \quad (3)$$

holds for any closed path C_i in a fundamental set of loops in the graph with Γ_i being a surface bounded by the curve C_i . Following the idea first presented in [6], a general algorithm for the generation of \mathbf{T}_0 has been developed. The coefficients t_i in (2) are computed by evaluating the surface integrals of the current density \mathbf{J}_0 over a surface bounded by the loop defined by the co-tree edge in a simple element graph (Fig. 2). The advantage of this method is that the surface integrals are defined equally for each finite element by one fixed co-tree (Fig. 2a), hence it is not necessary to define global loops in the FE mesh.

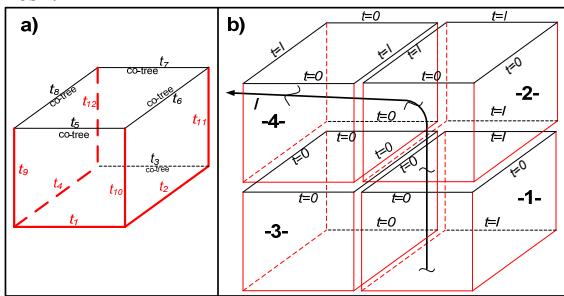

Fig. 2. a) Tree and co-tree definition within FE, b) A simple 3-D mesh

All elements are treated in defined succession which ensures that no element is arrived at after all its neighbors have been treated. The coefficients t_i on tree branches of the treated element are set to zero if no value has been assigned to these edges in previous steps, and the t_i values of the co-tree edges are calculated by numerical surface integration of the current density over the surface generated by the co-tree edge.

A simple example of four elements and one current filament is shown in Fig. 2b. Using this approach, the FE mesh of the end-winding is not required. Additional details of this method with emphasis on the numerical description of the end-winding geometry and the numerical integration procedure will be presented in the full paper.

III. PRELIMINARY RESULTS AND CONCLUSION

Using the first presented method, the magnetic field in a 3-D model of a 2.2 MW IM (Fig. 1) has been calculated. As presented in the Fig. 3 also the eddy currents in the surrounding metal parts were taken into consideration. By calculating the magnetic energy in the motor end-region the leakage inductance of 74 μH has been determined (the leakage inductance of 44.5 μH has been calculated using semi-empirical formulas). A very important influence of the eddy currents on the inductance values has been established, showing that static FEM analyses are not sufficient to calculate the leakage inductance. In the final paper results of both methods are going to be presented, mutually compared and, additionally, advantages and disadvantages of the two procedures are going to be discussed in detail.

Abstract — A combination of computational techniques for analyzing unbounded magnetic field problems involving ferromagnetic materials is presented. The proposed approach is mainly based on a synergy between a Neural Network (NN) and the Finite Element Method. In particular, the unbounded problem is solved by using an iterative scheme based on a fictitious boundary that encloses all the hysteretic regions. The boundary conditions on the fictitious boundary are initially guessed and successively updated according to the solution obtained in the previous iteration step. The hysteretic nature of the material is taken into account by an original NN able to perform the modelling of any kind of quasi-static loop (saturated and non-saturated, symmetric or asymmetric). An application to a simple 2.5-D geometry is presented in order to illustrate the whole procedure.

I. INTRODUCTION

In this paper the authors present a Finite Element code for the analysis of magnetic problems in unbounded domains combined with a Neural Network (NN) approach for the characterization of magnetic hysteresis. By starting from a small set of measured loops, the NN manages the values of the magnetic field, H , and the flux density, B , as inputs while the differential permeability is the output. In particular, the proposed NN is capable to perform the modelling of saturated and non-saturated, symmetric or asymmetric hysteresis loops. In order to treat boundlessness in the system of coupled equations that must be used for solving the magnetic problem, we adopt an iterative scheme based on a fictitious boundary that encloses all the field sources and the material hysteretic regions with the aim to define a bounded domain. In this way the unbounded coupled problem solution is converted into the iterative solution of a sequence of bounded Dirichlet magnetic hysteresis problems. The boundary conditions on the fictitious boundary are initially guessed and successively updated according to the solution obtained in the previous iteration step. This treatment of boundlessness closely follows an analogous approach, successfully used for the solution of uncoupled electromagnetic problems in unbounded domains [1]. An application to a 2.5-D geometry is presented in order to illustrate the whole procedure.

II. FE SOLUTION OF THE MAGNETIC PROBLEM IN UNBOUNDED DOMAINS

Starting from Maxwell's equation for the stationary magnetic field and considering the constitutive law for magnetic hysteretic materials

$$\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M}) \quad (1)$$

where \mathbf{M} is the nonlinear magnetization function and μ_0 is the vacuum permeability, it is possible to obtain the following equation in terms of the magnetic potential vector \mathbf{A} :

$$\nabla \times \left(\frac{1}{\mu_0} \nabla \times \mathbf{A} \right) = \mathbf{J} + \nabla \times \mathbf{M} \quad (2)$$

By introducing a fictitious boundary $\partial\Omega$ this equation is considered in a bounded domain Ω_M enclosing all the density current sources \mathbf{J} and all the magnetic materials. In this way the unbounded problem solution is converted into the iterative solution of a sequence of bounded Dirichlet magnetic problems. The boundary conditions on the fictitious boundary are initially guessed and successively updated according to the magnetic vector potential and current density distributions obtained in the preceding iteration step. In particular, the boundary values of magnetic potential vector can be derived by exploiting its Laplacian behaviour in a region which does not contain sources by means of the Green's function. In fact, for a generic harmonic function, Φ , in the external homogeneous unbounded source free region one has:

$$\Phi(\mathbf{r}_F) = - \int_{\Gamma} \left[\frac{\partial \Phi(\mathbf{r})}{\partial \mathbf{n}} G(\mathbf{r}, \mathbf{r}_F) - \frac{\partial G(\mathbf{r}, \mathbf{r}_F)}{\partial \mathbf{n}} \Phi(\mathbf{r}) \right] ds \quad (3)$$

where: Γ is an arbitrary surface contained in Ω_M enclosing all the sources and magnetic materials; \mathbf{n} is the unit vector normal to Γ , oriented toward Ω_M ; \mathbf{r} and \mathbf{r}_F are point vectors relative to Γ and $\partial\Omega_M$, respectively and G is the Green's function for free space. Since in the FEM approximation, the surface curve Γ is conveniently selected as constituted by finite element sides, the (3) can be rewritten for each boundary "unknown" \mathbf{A}_F in the form: $\mathbf{A}_F = \mathbf{R}_M \mathbf{A}$ where \mathbf{R}_M is a rectangular matrix of purely geometrical coefficients. The solution of the coupled problem from equations (2) and (3) are well suited to be solved iteratively, arbitrarily guessing at the beginning the magnetic vector potential on boundary $\partial\Omega_M$. On the other hand even the solution of the discretized equation (2) requires an iterative scheme. Consequently several choices for the hierarchical relationships between the two kinds of iterations are possible; in the full paper the performance of the different schemes will be discussed in details.

III. THE NEURAL NETWORK HYSTERESIS MODEL

The possibility of using Neural Networks to model magnetic hysteresis has been largely verified in literature [2]; and it is a valid alternative to classical models such as the Preisach or Jiles-Atherton ones. In fact, any hysteresis model requires the experimental characterization of the material by

using measured loops. Moreover, as shown in [2], the characterization performed by using the saturated major loop is often not suitable for accurately simulating minor loops. Then the identification of hysteresis models is an open problem as it is testified by the huge production available in literature about this task. Thus, the aim of the presented NN approach is to provide a computational tool able to predict the quasi-static magnetic hysteretic behaviour of a ferromagnetic material by the direct exploitation of few simple measurements. They consist of the generation of an asymmetric loop obtained by following a path involving a portion of the major-saturated-loop branch and an ascending non-symmetric branch as in Fig. 1.

Fig. 1. Example of the Saturated loop used for NN training (M indicates the Major Loop Branch while A indicates the Asymmetric Branch).

In this way the NN is able to simulate any possible kind of loop (symmetrical or asymmetrical, saturated or non-saturated) by exploiting the transplantation technique [4]. In particular, the implemented NN is a simple feedforward net trained by using the Levenberg-Marquardt backpropagation algorithm. The NN consists of two input neurons, representing the magnetic field, H , and the flux density, B , one hidden layer with 9 neurons and one output neuron that gives as a result the value of the differential permeability, $\mu_d(H, B) = dB/dH$. The training set exploits 100 H - B sampled points for each asymmetric saturated hysteresis loop (see Fig.1) obtained by measurements. Altogether, 20 measured loops are used. Moreover, the NN is able to reproduce symmetric loops even if it is trained on asymmetric ones because a symmetric loop can be obtained by the superposition of mirror asymmetric branches (see Fig. 2). Finally, the reconstructions of minor loops are performed in two subsequent steps: while the NN predict the first ascending (or descending) branch of the minor loop, the second descending (or ascending) branch is obtained by the transplantation technique proposed in [4]. Thus, the present approach can be easily and usefully embedded into a set of field equations since it does not require a preliminary knowledge of the H (or B) waveform. More in detail, let us consider the NN input $[H(k), B(k)]$ and the returned NN output $\mu_d(H(k), B(k)) = dB(k)/dH(k)$ at the k -th step of an iterative procedure. Let us assume dH (or dB) the imposed increment of the magnetic field (or flux density). Thus, at the $k+1$ -th step we can input the NN with $[H(k+1) = H(k) + dH(k+1), B(k+1) = \mu_d(H(k), B(k))dH]$ (similarly for an imposed dB). In Fig. 3, an example of validation is shown.

Fig. 2. Symmetric loop obtained by the superposition of mirror asymmetric branches.

Fig. 3. Example of NN approach validation

IV. EXAMPLE OF APPLICATION

Hereafter a test of the proposed method is applied to a magnetic problem involving a simple geometry: a ferromagnetic cylinder is considered having a length of 8 cm and a radius 1 cm, surrounded by a coil solenoid of inner radius 2 cm, outer radius 2.5 cm and length 10 cm, carrying a uniform current of 1 A. Since the problem is axisymmetric it is possible to analyze only $1/4$ of the whole geometry, as shown in fig. 4, where the domain considered for the problem is represented together with the results expressed in terms of magnetic potential vector intensity.

Fig. 4. Magnetic potential vector intensity for the considered example.

Abstract—The paper presents an innovative computational methodology dedicated to establishing equivalent characteristics of anisotropic laminated structures. The method is based on the homogenization technique. The influence of eddy currents on the equivalent characteristic is also counted.

Key words—anisotropic laminations, equivalent magnetic characteristics, homogenization, eddy currents, lamination stack

I. INTRODUCTION

Iron cores in electrical machines and transformers are usually made of lamination stacks in order to reduce eddy current losses. It is impossible to model with finite element software the eddy currents in each lamination. Indeed, full 3D numerical modeling of such structures is time consuming and it requires large memory. That is why the main idea is to replace the complex three-dimensional structure by a homogenized 'equivalent' material. This material, magnetically equivalent, allows the real 3D structure made of thin sheets to be treated computationally as a 2D problem. It requires to establish a family of equivalent characteristics. For instance, joints in power transformers are made of internal air gaps and thin anisotropic laminations (0.17-0.5mm) of varied rolling directions. Such a structure may be replaced by an equivalent homogenized material [1]. In the first stage, it has been assumed that the normal flux density component B_z is negligible compared to the components B_x and B_y in the lamination surface. As a consequence, the effects of eddy currents have been neglected too and such an approximation inevitably causes some inaccuracies. Although the component perpendicular to the sheets is typically only a few percent of the tangential components, it is distributed on large areas. This paper describes the second stage of the investigation: objective is to replace the 3D region by an equivalent 2D structure taking into account the eddy currents induced by the longitudinal flux. The complete influence of the flux normal to the lamination plane [2-4] will be introduced in a further paper.

II. ANALYSIS OF THE 3-D SIMULATION RESULTS

In order to set out in detail the possible simplifications, several 3D simulations have been made. The influence of the eddy currents created by longitudinal and normal fields are analyzed for the following structures:

1. Several superposed sheets with different lamination directions
2. Corner of Epstein frame
3. Step-lap joint with internal air-gaps.

The main purpose of these 3D simulations is to estimate the effect of the eddy currents induced by the normal flux on the field distribution. For each structure, two simulations were made: with and without the eddy currents.

Conclusions from the 3-D simulation are the following:

- 1) The perpendicular flux is non negligible only in the air gaps and in the non conducting regions because of the continuity of \vec{B}_z between the non conducting and conducting layer, but also because B_z is very low comparing with the longitudinal component).
- 2) The longitudinal flux density component in the air is negligible (the eddy current flowing on the sheet surface are too low to disturb H_x and H_y , so due to the field continuity on the lamination surface, the field and the flux density in the air are very low)
- 3) The surface eddy current in the lamination generated by the normal field causes the adequately losses, but it does not intervene on the flux penetration from one lamination to another.
- 4) It is only necessary only to take into account in the mathematical model the dependence between the longitudinal flux in the lamination and the normal flux penetrating from non conducting layers.

Fig.1 Flux density components for the penetration of flux from one to another lamination by non conducting layer.

a) Longitudinal component in the lamination (max. 1.22T)

b) Normal component in the air-gap between laminations (max. 0.076T)

III. DESCRIPTION OF THE METHOD

The macrostructure in the homogenization technique is a complete stack, while the microstructure is a repeatable set of several layers. It is customary, when describing a family of $B(H)$ curves for different angles, to assume that 0° is in the rolling direction for one lamination and x the direction for the equivalent structure. For every layer i , of the

thickness d_i it has been assumed that the flux density \vec{B}_i and the time derivative of flux density $\frac{\partial \vec{B}}{\partial t}$ is spatial average

$$\left\langle \frac{\partial \vec{B}_i}{\partial t} \right\rangle = \frac{1}{d_i} \int_{-d_i/2}^{d_i/2} \frac{\partial \vec{B}(z, t)}{\partial t} dz \quad (1)$$

The flux density components in a sample of dimensions $\delta x \times \delta y \times \delta z$ may be found as:

$$B_{ix} = \frac{1}{2} \frac{\phi'_{ix} + \phi''_{ix}}{\delta y \delta z}; \quad B_{iy} = \frac{1}{2} \frac{\phi'_{iy} + \phi''_{iy}}{\delta x \delta z}; \quad B_{iz} = \frac{1}{2} \frac{\phi'_{iz} + \phi''_{iz}}{\delta y \delta x}; \quad (2)$$

where $i=1, 2, \dots, n$ denotes the structure's layer, ϕ'_{ix} is the flux 'in' through the surface yz , ϕ''_{ix} is the flux 'out', ϕ'_{iy} , ϕ''_{iy} , ϕ'_{iz} and ϕ''_{iz} are similar fluxes respectively through the surface xz and xy . The field distribution results of the system's tendency to achieve a minimum of magnetic energy. Unknowns in the minimization task are the flux density components in every layer. The starting values for B_{1x} , B_{1y} , B_{2x} , B_{2y} , B_{1z} and B_{2z} follow an initial assumption that magnetic flux goes entirely through the laminations avoiding the gaps. The model is established with the following simplifications:

a) For the non-conducting layers, the three components of the flux density exist. The total energy of the layer is the magnetic field energy $W_{\mu 0} = \frac{(B_{ix}^2 + B_{iy}^2 + B_{iz}^2)}{2} \delta x \delta y \delta z \nu_0$

where ν_0 is the vacuum reluctivity.

b) For each lamination of thickness d_i and electric conductivity σ the analytical solution is established. As they are in every sheet two main magnetic fluxes (one parallel to the lamination surface and the second perpendicular to the lamination surface), two eddy currents densities are considered. The total current density results from the vector superposition of eddy current densities.

Fig.2 Fluxes in three consecutive layers

When reaching the boundary between non-conducting and conducting layers, the normal component of the flux density turns and became tangential (fig.2). The magnetic flux is harmonic function of time. Compliance of these phenomena is established by the boundary conditions on the surface of the lamination.

The energy W_{μ} per time unit into the i^{th} lamination equals the integral of Poynting's vector along the lamination surface. The current density in the isolating layer is function of all flux density components in the layer and of the normal component in the neighboring isolating layer.

The steady-state eddy current loss density P (W/m³), averaged over a time period and over the lamination thickness, for the

flux parallel to the lamination surface is given by the following expression:

$$P_J = \frac{1}{T} \int_0^T \vec{H}_i \frac{\partial \vec{B}_i}{\partial t} dt = f(\sigma_i, d_i^2, f^2, \langle B_{xi} \rangle^2, \langle B_{yi} \rangle^2, B_{s(i-1)}, B_{s(i+1)}) \quad (3)$$

where $B_{s(i-1)}, B_{s(i+1)}$ are the flux density on the boundaries of the i -th lamination.

For the whole structure, the following argument exploits the system natural tendency to achieve the minimum of the field energy which may be expressed as:

$$W_{\mu \min} = \sum_{i=1}^n W_{\mu i}(\mu_i, \vec{B}_i) \quad (4)$$

where μ_i is the permeability, and \vec{B}_i the induction in individual laminations, n is number of laminations in the microstructure. The equivalent permeability at any point of the core is a function of the resultant flux density and the minimal field energy $\mu(\vec{B}_{eq}, W_{\mu \min})$. A standard Hooke and Jeeves Direct Search Method has been used as it is known to be robust and insensitive to the starting point. The equivalent reluctivity ν_{eq} of the homogenized replacement material may be found by equaling the energies of the real and equivalent structures. In the following, a numerical procedure and the eddy currents generated by the perpendicular flux will be described in detail. The material modeling and its implementation inside the procedure will be discussed. The equivalent characteristics for different anisotropy directions have been computed by varying the equivalent flux density from 0.01T up to saturation for 3D structures presented in advance.

IV. CONCLUSIONS

In order to provide independent verification of the proposed approximations and gain more insight into the behavior of the magnetic field in the laminated structures, and in particular to study the effects of the eddy currents induced by the transverse flux, an attempt was made to model the systems studied using full 3D and homogenized 2D finite element code. The results will be presented in the full paper.

An Anisotropic Vector Hysteresis Model Using Isotropic Vector Play Model

Tetsuji Matsuo

Graduate School of Engineering, Kyoto University

tmatsuo@kuee.kyoto-u.ac.jp

Abstract— A simple anisotropic vector hysteresis model is developed for representation of 2D weakly anisotropic vector hysteretic property. An isotropic vector play model is identified from azimuthally averaged vector property of anisotropic material. An anisotropic matrix is multiplied to the isotropic vector play model to represent anisotropy. Vector properties of a non-oriented steel sheet are represented by the proposed model.

I. INTRODUCTION

The play model is an efficient and precise hysteresis model, which has several vector versions [1]-[3]. However, the representation of anisotropic vector hysteretic properties of silicon steel sheets is still an open problem for the play model and other hysteresis models. This article proposes a simple generalization of vector play model for representation of two-dimensional (2D) weakly anisotropic vector hysteretic property, which is observed in non-oriented steel sheets.

II. ISOTROPIC VECTOR PLAY MODEL

An isotropic vector play model is given as

$$\mathbf{H} = \mathbf{P}(\mathbf{B}) = \int_0^{B_s} f(\zeta, \mathbf{p}_\zeta(\mathbf{B})) d\zeta \quad (1)$$

$$f(\zeta, \mathbf{p}) = f(\zeta, |\mathbf{p}|) \frac{\mathbf{p}}{|\mathbf{p}|} \quad (2)$$

where $f(\zeta, \mathbf{p})$ is a shape function, B_s is the saturation magnetic flux density, and \mathbf{p}_ζ is a vector play hysteron having a radius ζ . The hysteron \mathbf{p}_ζ [4] is given as

$$\mathbf{p}_\zeta(\mathbf{B}) = \mathbf{B} - \frac{\zeta(\mathbf{B} - \mathbf{p}_\zeta^0)}{\max(\zeta, |\mathbf{B} - \mathbf{p}_\zeta^0|)} \quad (3)$$

$$\mathbf{p}_\zeta^{0*} = \frac{(B_s - \zeta)\mathbf{p}_\zeta^0}{\max(B_s - \zeta, |\mathbf{p}_\zeta^0|)} \quad (4)$$

where \mathbf{p}_ζ^0 is the vector \mathbf{p}_ζ at the previous time-point.

The play model (1) is a 3D vector model. However, this article discusses its 2D property for the representation of rotational and alternating hysteretic properties of silicon steel sheets.

Anisotropic properties of non-oriented silicon steel sheet (JIS: 50A1300) are averaged along the azimuthal direction to obtain isotropic properties for simulations. An averaged alternating property is used to identify the shape function f . The dashed line in Fig. 1 shows the simulated rotational hysteresis loss of the steel sheet, which is larger than the measured one.

To adjust the rotational hysteresis loss, the vector play model is modified similarly to a vector stop model [5] as

$$\mathbf{P}^*(\mathbf{B}) = (\mathbf{P}(\mathbf{B}) \cdot \mathbf{e}_\parallel) \mathbf{e}_\parallel + r(|\mathbf{B}|) (\mathbf{P}(\mathbf{B}) \cdot \mathbf{e}_\perp) \mathbf{e}_\perp \quad (5)$$

where \mathbf{e}_\parallel and \mathbf{e}_\perp are parallel and perpendicular unit vectors to \mathbf{B} , respectively, and $r(|\mathbf{B}|)$ is the ratio of the measured rotational hysteresis loss to the simulated loss given by \mathbf{P} . The solid line in Fig. 1 shows the rotational hysteresis loss given by \mathbf{P}^* , which agrees with the measured one.

Fig. 1. Rotational hysteresis losses given by isotropic vector play models

III. ANISOTROPIC VECTOR HYSTERESIS MODEL

A simple 2D anisotropic version of the vector play model is given as

$$\mathbf{P}_B(\mathbf{B}) = \mathbf{W}_B(\mathbf{B}) \mathbf{P}^*(\mathbf{B}) \quad (6)$$

where $\mathbf{W}_B(\mathbf{B})$ is a matrix of which components are single-valued function of \mathbf{B} . For example, \mathbf{W}_B is determined so as to reconstruct anisotropic alternating property from averaged alternating property as

$$\mathbf{W}_B(\mathbf{B}) = \begin{pmatrix} w_{B_x}(B, \varphi_B) & 0 \\ 0 & w_{B_y}(B, \varphi_B) \end{pmatrix} \quad (7)$$

$$w_{B_x}(B, \varphi_B) = \frac{H_x(B, \varphi_B)}{H_{\text{ave}}(B) \cos \varphi_B},$$

$$w_{B_y}(B, \varphi_B) = \frac{H_y(B, \varphi_B)}{H_{\text{ave}}(B) \sin \varphi_B} \quad (8)$$

where $\mathbf{B} = |\mathbf{B}|$ and $\varphi_B = \tan^{-1}(B_y/B_x)$; $(H_x(B, \varphi_B), H_y(B, \varphi_B))$ is the measured initial magnetization property for unidirectional input of \mathbf{B} along the φ_B -direction; $H_{\text{ave}}(B)$ is the azimuthally averaged initial magnetization property for unidirectional input, which is accurately represented by the isotropic vector play model \mathbf{P}^* .

Another anisotropic vector play model is given as

$$\mathbf{P}_H(\mathbf{B}) = \mathbf{W}_H(\mathbf{P}^*) \mathbf{P}^*(\mathbf{B}) \quad (9)$$

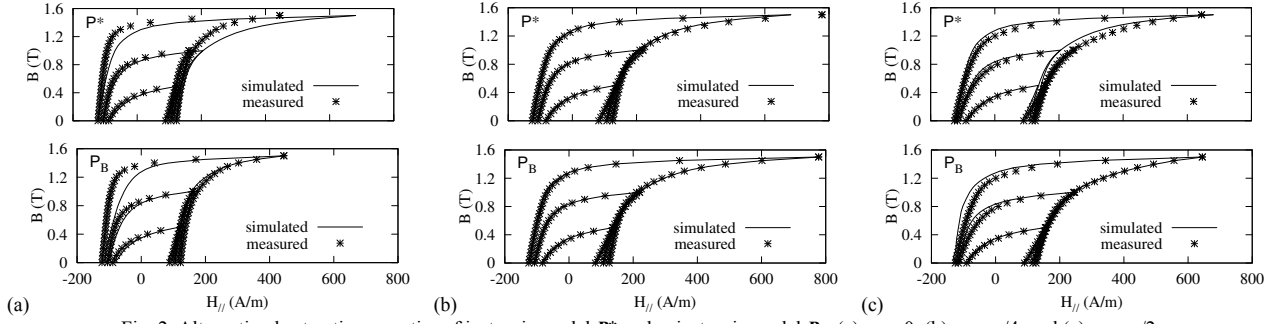

Fig. 2. Alternating hysteretic properties of isotropic model P^* and anisotropic model P_B : (a) $\varphi_B = 0$, (b) $\varphi_B = \pi/4$, and (c) $\varphi_B = \pi/2$.

where W_H is a matrix of which components are single-valued function of P^* . W_H is determined similarly to W_B as

$$W_H(P^*) = \begin{pmatrix} w_{Hx}(P^*, \varphi_H) & 0 \\ 0 & w_{Hy}(P^*, \varphi_H) \end{pmatrix} \quad (10)$$

where $P^* = |P^*|$ and $\varphi_H = \tan^{-1}(P^*_y/P^*_x)$. Functions w_{Hx} and w_{Hy} are given as

$$\begin{aligned} w_{Hx}(H_{ave}(B), \varphi_B) &= \frac{H_x(B, \varphi_B)}{H_{ave}(B) \cos \varphi_B}, \\ w_{Hy}(H_{ave}(B), \varphi_B) &= \frac{H_y(B, \varphi_B)}{H_{ave}(B) \sin \varphi_B} \end{aligned} \quad (11)$$

because $\varphi_H = \varphi_B$ for alternating input.

IV. SIMULATION RESULTS

Vector hysteretic properties of non-oriented silicon steel sheet, JIS: 50A1300, are simulated.

Fig. 2 depicts alternating hysteretic properties of isotropic model P^* and anisotropic model P_B for $\varphi_B = 0, \pi/4, \pi/2$, where $H_{ij} = \mathbf{H} \cdot \mathbf{e}_{ij}$. The anisotropic model gives accurate amplitudes of H_{ij} . The alternating hysteretic property of P_H is not shown because it is similar to P_B .

Figs. 3(a), (b) and (c) portray the loci of \mathbf{H} for counterclockwise rotational inputs of \mathbf{B} with $|\mathbf{B}| = 0.5, 1.0, 1.5$ T, which are simulated by P^* , P_B and P_H , respectively. The isotropic model P^* yields circular loci of \mathbf{H} . The loci obtained by P_B are directly affected by the phase lag of \mathbf{B} to P^* because of $W_B(\mathbf{B})$. The loci obtained by P_H are not affected by the rotational direction because $W_H(P^*)$ does not depend on the phase lag of \mathbf{B} to P^* . Fig. 3(d) shows the loci of \mathbf{H} given by $(P_B + P_H)/2$, which approximately agree with the measured loci.

Abstract— In electromagnetic applications, hysteresis phenomena in magnetic materials are responsible of considerable causes of losses especially in transformer modelling cases. In specific case, such as current sensor, the output signal can be modified because of this loss. The paper presents the implementation proceeding used for some hysteresis material models and how they are applied in a sensor study case. A priori loss computation, simultaneously carried out with the simulation is one of the main advantages of this implementation. A transformer application is performed with the dynamic hysteresis characteristic taken into account and compared with experimental measurements.

I. INTRODUCTION

Nowadays, electrical engineering is concerned with energy efficiency. In addition, in the case of electromagnetic devices, such as current sensors, the energy losses change the output signals; so, to approach an ideal sensor, losses have to be minimized. Thus, to improve electrical device design, loss computation has to be carried out with a maximal accuracy. Many works allow a posteriori loss estimation [1], however, "Real time" approach, meaning a priori computation is furthermore interesting as it allows more accuracy in simulation.

Generally, in such devices, the total losses come from different sources as resistances and magnetic cores. The first one, copper losses are practically calculable by resistance and current measurements. However, the last one, magnetic losses or iron losses is more complicate to identify. In soft magnetic materials, experimental results show that they can be evaluated in two terms: hysteresis static losses, and dynamic losses. By adding these two terms, we obtain the so called iron losses. The static part corresponds to the $B(H)$ loop area in quasi-static mode, i.e. at low frequency. The dynamic one depends on the variation speed of the excitation source which is more important at high frequency.

II. MATERIAL MODEL WITH HYSTERESIS

A. Hysteresis model

Studies have shown that the mechanism that causes magnetization phenomena depend on many factors [2]: the material, the excitation field, the external environment, etc.

From an experimental point of view, two operating conditions can be distinguished: the quasi-static and the dynamic one. In quasi-static condition, the $B(H)$ loop representing the material behavior does not depend on the excitation frequency. Following the predefined criteria such as induction response and losses computation, some compatible models are identified. Among them, the chemical model [3] provides a good accuracy for soft magnetic materials by a description of two main microscopic mechanisms of the static magnetization: Bloch wall displacement and domain rotation. Furthermore, based on the balance of chemical equation analogies, this model has the advantage of a fast implementation and a quick computation. Another model, with a different approach, is called Derivative Static Hysteresis Model (DSHM). It focuses in the knowledge of memorization effect in the material during the magnetization. DSHM uses a matrix representation. Its accuracy depends only on the matrix size.

In dynamic operating conditions, the loop $B(H)$ expands according to the increasing frequencies (Fig.1).

Fig. 1. $B(H)$ loop in static mode measurement (narrow cycle) and dynamic mode by measurements (large cycle in continuous line) and by simulation (large cycle in dotted line)

The area of this loop represents the energy of the material losses during a period. This energy loss is higher in dynamic state (the area is bigger). The flux tube model using a single dynamic parameter has been studied [4] to represent the additional dynamic losses:

$$H_{exc} = H_{stat}(B) + \gamma \frac{dB}{dt} \quad (1)$$

with H_{exc} the excitation field, H_{stat} virtual static excitation field for a given flux density and γ a coefficient depending of the electrical and magnetic properties (resistivity, permeability, etc.) of the material.

B. Model identification on soft magnetic material

A test bench able to automate material characterization proceedings was carried out in Ampère laboratory (Lyon). The output is given in the form of $B(H)$ loops.

For each sample/material, a numerous of measurements corresponding to a variation of excitation field and of frequency are realized. Optimization algorithms allow an automatic identification of models parameters.

III. ELECTROMAGNETIC DEVICE SIMULATION

Once the magnetic material model parameters have been identified, the relation between the excitation current and the flux in the magnetic circuit is established. Magnetic equation system is so obtained. By a coupling with electrical equation system, all the system is completely described.

For the coupling equation solving, some numerical techniques as Newton-Raphson are applied at each time step. A numerical ODE solver is used to give the system behavior in transient mode.

All these algorithms are implemented inside a new tool called RelucTool [5], dedicated for the modelling of low voltage electromagnetic devices.

IV. APPLICATION AND RESULTS

A. Simulation of a current sensor

To illustrate that hysteresis causes considerable losses in electromagnetic devices, a simple current sensor is simulated. The primary coil is supplied by a pseudo-sinusoidal current source, 50Hz with a variable primary current I_p ; the secondary coil is connected to a load, flowed by a current I_s . The magnetic core is made of a grain oriented silicon iron (SiFe) used in industrial production that provides a good characteristic in saturation induction and magnetic losses. In the ideal case, without loss, the I_s/I_p ratio is equivalent to N_p/N_s , the ratio of the number of wire turns respectively in the primary and secondary. Here the ideal ratio I_s/I_p is 0.1.

B. Result

Simulations with a chemical model have been carried out. The comparison with experimental results is taken via the secondary currents and the core losses found out, in two cases, according to the introduced primary current value (fig.2). A very good match between our model and the measures is observed. The non-ideal characteristic of the transformer that is represented by the variation of the quotient I_s/I_p is correctly modeled. The iron losses in the magnetic core, obtained by modelling, are very close to the experimental value.

These losses contribute to the system total losses so the energy balance that is established during the simulation process, not a posteriori.

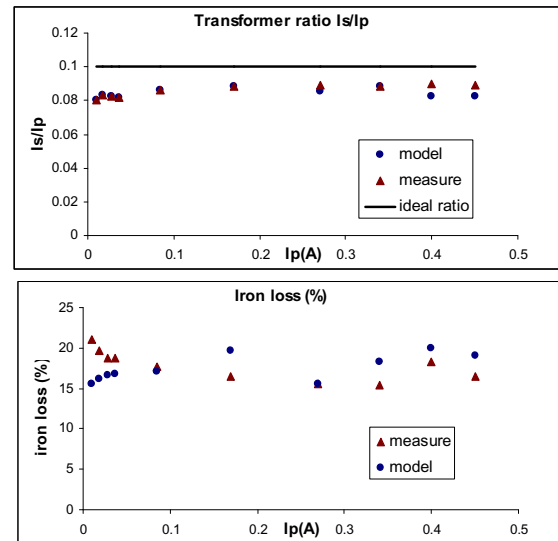

Fig. 2. Comparison of simulation and measurements results. On the top: losses make the ratio I_s/I_p lower than the ideal one. On the bottom: iron losses in percentage of input coil energy.

V. CONCLUSIONS AND INCOMING WORK

Simulations with variable frequency have been carried out. They allow confirming the model performance in dynamic mode.

From these results, the same proceedings can be applied to other hysteresis models. A comparison between different models can be thus performed to aid in the choice of an adapted model according to the application needs. The authors are carrying out a material model library of soft magnetic materials, useful for designers. Additional results will be presented in the full paper.

For sensor applications, further interesting studies can be developed such as amplitude and frequency range limits research thanks to the simulation with dynamic hysteresis models. In the future, a complete electronic component library will allow simulating more complex systems.

Abstract—In large transformer cores, burr-induced short circuits can cause hot spots which may locally damage the core. This paper presents a Finite Element (FE) analysis of this problem for Grain Oriented (GO) sheets; results are confirmed by measurements. The equivalent circuit derived from both measurements and FE simulation allows the power dissipated in a hot spot to be determined for the worst case.

I. INTRODUCTION

GO magnetic sheets in transformer cores are insulated on both sides with a thin inorganic coating on the glass film layer that forms during annealing. Before core assembly, the sheets are cut by mechanical shears; although great care is bestowed on this process, burrs may remain which can cause interlaminar shorts on edges of columns and yokes. Such shorts are known to increase eddy current loss [1]. In some cases, the currents circulating in the contact points cause small hot spots which may spread and locally damage the core through melting.

Considering the stochastic nature of a cutting burr, the contact is assumed to have an unknown resistance. The power dissipated in the contact point depends thus on this unknown value, but also on the characteristics of the equivalent electrical circuit in which the current flows. The purpose is to model this equivalent circuit and derive the power dissipation in the contact point in the worst case. A first model is based on experimental results. It is then extended to more general cases using a 3D FE simulation taking into account the strong anisotropy and the non-linearity of GO sheets.

II. MODEL BASED ON EXPERIMENTAL RESULTS

A current may flow in a cutting burr only if a closed path embracing a magnetic flux exists, so at least two contact points are needed. Considering the simplest case, it is possible to model an interlamination short by an equivalent circuit defined through two quantities: the electromotive force (e. m. f.) and the internal impedance. This kind of model is typically linear, therefore, it is important to identify the limits of validity using an experimental test bench built with GO sheets. The e. m. f. is the voltage measured in open circuit condition and the internal impedance is deduced from the short circuit current.

In order to determine these elements experimentally, the random aspect of burr-induced contacts is eliminated. Two low-resistance contacts are created by depositing solder on locally skinned GO sheets. Four thin wires are included in order to measure e. m. f. and voltage drop over the contacts. Fig. 1 shows the two instrumented sheets before stacking. The

short-circuit current is measured by means of a miniaturised Rogowski coil having 350 turns at a thickness of 600 μm and an internal diameter of 5 mm. Since its output voltage is in the range of microvolts, a low-noise differential amplification system and filtering circuitry is used. The phase shift of the filters and the transversal flux density gradient in the Rogowski coil are compensated [2].

Fig. 1. Instrumented magnetic sheets.

After stacking, the instrumented sheets are placed in a square magnetic circuit with excitation coils, so as to form one of its legs. The main flux is measured with a 10-turn coil directly wound around the instrumented sheets.

The quantities e. m. f. and short circuit current have been recorded for various flux density levels. Fig. 2 presents data for 1,8 T; the plotted curves are normalized with respect to their peak values in order to allow an easy comparison of the waveforms.

Fig. 2. Short circuit current and e. m. f. under saturation.

Measurement results show that the short circuit current has almost the same waveform as the e. m. f. and that there is no

phase lag. The congruence of the two curves is even better for lower flux densities. A detailed analysis of experimental results has been performed for different flux density levels and sheet widths. The equivalent circuit impedance is determined dividing the e. m. f. by the short circuit current and taking into account the small voltage drop over the artificial contacts. Analysis shows that, admitting an accuracy of 10%, the impedance of the equivalent circuit can be seen as a pure resistance which depends on sheet width and thickness for constant frequency. The e. m. f. is proportional to the cross section of the sheets and can be calculated analytically [3].

III. NUMERICAL MODEL

The FE model is designed to determine the parameters of the equivalent circuit for interlaminar shorts with more complex geometries. Numeric modelling of the short circuit in 3D is challenging since both anisotropy and nonlinearity of the GO material have to be taken into account. Furthermore, the very thin sheets have to yet be meshed with a number of layers to allow eddy currents to be represented correctly. The magnetisation curves $B(H)$ used in simulation were previously measured with Epstein strips cut in rolling direction and in transverse direction. These measurements were done at 1Hz and up to strong saturation; an extrapolation formula yielding points up to 2T and $\mu = \mu_0$ was applied in order to achieve computation convergence with Opera 3D. Fig. 3 presents an example of the simulation results, showing a detail of the mesh and the convergence of the current lines towards a contact point.

Fig. 3. Mesh and convergence of current lines towards a short-circuit

Short circuit current and e. m. f. are determined in post processing. Calculated quantities are compared to the experimental results for several flux densities and sheet widths. The differences found between simulation results and measurement were 5% for the e. m. f. and 4% for the short circuit current, respectively.

The FE simulation is used to determine e. m. f. and internal resistance of the equivalent circuit for the case when the contacts are not located exactly opposite to each other, as well as for configurations such as non-punctual contacts due to long burrs. Fig. 4 presents results for two shifted punctual contacts.

As predicted by the analytical analysis, the e. m. f. does not depend on the shift s . It can be seen that the short circuit current decreases more slowly than the inverse of the distance between the contacts. Analysis reveals that this phenomenon is due to the spreading of the current in the sheet plane and

amplified by the anisotropy of the material. Fig. 4 also shows that for large shifts of the burr-induced contacts ($s \gg b$), the short circuit current can be neglected.

Fig. 4. Influence of a shift between the contacts on the current

For a given transformer core width, it is possible to define the equivalent circuit but not the current, because the burr resistance remains unknown. However, assuming a local contact, the worst case can be defined: it is obtained when the burr resistance is equal to the resistance of the internal circuit. Therefore, the power dissipation in the hot spot can be estimated. For example, assuming a large core ($b = 500$ mm) made of 0,3 mm GO sheets, magnetized at 1,7T, 50 Hz and containing a burr-induced short with zero shift, the equivalent circuit resistance estimation is 10 m Ω and the e. m. f. 85 mV peak. For a perfect contact, the short circuit current is 8,6 A peak. For the worst case, the estimation of the peak power in the hot spot is 0,10 W. This small power can correspond to a very high power density when it is concentrated in a burr of small section.

IV. CONCLUSION

FE simulation of short circuits between GO magnetic sheets has been performed and verified by experimental measurements. Power dissipation in a microscopic short circuit can be estimated for the worst case. Associated with a capacitive test method [4], this model can be used to estimate the extra core loss due to a multitude of microscopic burrs.

Abstract—Homogenization techniques are efficient tools to determine macroscopic properties of heterogeneous materials. These techniques, mainly developed in the framework of uncoupled behavior, have been recently applied to coupled behavior. Finite Element Method is a classical approach for such heterogeneous problems. We propose to compare these two approaches in the case of magnetoelectric composite materials made of the assembly of piezomagnetic and piezoelectric constituents. The two approaches are shown to be in good agreement in the case of matrix-inclusions microstructures, with a much lower computational cost for homogenization technique.

Index Terms—Magnetoelectric effect, homogenization, finite element method.

I. INTRODUCTION

The study of coupling effects is a long-standing domain of interest in physics. The possibility of applications such as sensors or actuators have made materials with strong coupled properties receive more and more attention in the past years. In the case of magnetoelectric (ME) materials, composite materials made of the assembly of piezomagnetic and piezoelectric constituents have shown to exhibit a much stronger (extrinsic) ME effect than homogeneous materials [1].

In order to design properly corresponding applications, the material microstructure (essential in the definition of the macroscopic properties) has to be accounted for. This is the reason why advanced modeling tools are needed. Finite Element modeling is a classical approach and can provide a full description of the fields in the composite [2]. But its main disadvantage is the computational cost. Another approach is the use of homogenization techniques, that can be adapted to coupled behavior [3], with a very low computational cost (especially in the case of linear behavior for which analytical solutions can be provided).

The purpose of homogenization is the deduction of the effective properties of heterogeneous materials [4], meaning the properties of a (fictive) homogeneous material with the same macroscopic properties than the heterogeneous material. Homogenization techniques only use a few pieces of information about the microstructure and can provide bounds or estimates on the effective properties.

In this paper Finite Element and homogenization approaches are compared in the case of a magneto-electric composite with

matrix-inclusion type microstructure.

II. PIEZOMAGNETIC/PIEZOELECTRIC COMPOSITE

For the composites studied in this paper, the magnetoelectric effect is extrinsic: none of the phases exhibits such an effect. The coupling effect appears through mechanics (see Fig. 1): the piezomagnetic phase deforms when a magnetic field is applied to the composite, then the strain spreads to the piezoelectric phase, leading to an electric polarization (the converse phenomenon also appears: an applied electric field leads to a magnetic polarization).

Fig. 1. ME effect in piezomagnetic/piezoelectric composites.

The constitutive laws for the phases are (the subscript m stands for the piezomagnetic phase, e for the piezoelectric phase):

$$\begin{pmatrix} \mathbb{T}_m \\ \mathbb{B}_m \\ \mathbb{D}_m \end{pmatrix} = \begin{pmatrix} \mathbf{C}_m & -{}^t\mathbf{q} & \mathbf{0} \\ \mathbf{q} & \boldsymbol{\mu}_m & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \boldsymbol{\epsilon}_m \end{pmatrix} \cdot \begin{pmatrix} \mathbb{S}_m \\ \mathbb{H}_m \\ \mathbb{E}_m \end{pmatrix} \quad (1)$$

$$\begin{pmatrix} \mathbb{T}_e \\ \mathbb{B}_e \\ \mathbb{D}_e \end{pmatrix} = \begin{pmatrix} \mathbf{C}_e & \mathbf{0} & -{}^t\mathbf{e} \\ \mathbf{0} & \boldsymbol{\mu}_e & \mathbf{0} \\ \mathbf{e} & \mathbf{0} & \boldsymbol{\epsilon}_e \end{pmatrix} \cdot \begin{pmatrix} \mathbb{S}_e \\ \mathbb{H}_e \\ \mathbb{E}_e \end{pmatrix} \quad (2)$$

where \mathbb{T} and \mathbb{S} are the stress and strain tensors, \mathbb{B} and \mathbb{H} are the magnetic induction and the magnetic field, \mathbb{D} and \mathbb{E} are

the electric induction and the electric field. \mathbf{C} , $\boldsymbol{\mu}$ and $\boldsymbol{\epsilon}$ are respectively the stiffness tensor, the permeability tensor and the permittivity tensor. The tensors \mathbf{q} and \mathbf{e} are respectively the piezomagnetic and piezoelectric coupling tensors.

III. HOMOGENIZATION

The homogenization technique used to model these composites is based on inclusion problems [5]. The method developed in the framework of uncoupled behavior has been extended to coupled behavior thanks to an appropriate decomposition of the fields [3]. The classical homogenization tools still apply and the uncoupled constitutive laws can be extracted. The coupling effects appear through additional relations. The obtained effective properties of the composite are written:

$$\begin{pmatrix} \overline{\mathbb{T}} \\ \overline{\mathbb{B}} \\ \overline{\mathbb{D}} \end{pmatrix} = \begin{pmatrix} \tilde{\mathbb{C}} & -\tilde{\mathbf{q}} & -\tilde{\mathbf{e}} \\ \tilde{\mathbf{q}} & \tilde{\boldsymbol{\mu}} & \tilde{\boldsymbol{\alpha}} \\ \tilde{\mathbf{e}} & \tilde{\boldsymbol{\alpha}} & \tilde{\boldsymbol{\epsilon}} \end{pmatrix} \cdot \begin{pmatrix} \overline{\mathbb{S}} \\ \overline{\mathbb{H}} \\ \overline{\mathbb{E}} \end{pmatrix} \quad (3)$$

where the notation $\overline{\mathbb{X}}$ stands for the average value of \mathbb{X} over the volume. It has to be noticed that the macroscopic constitutive law exhibits a magnetoelectric coupling tensor $\tilde{\boldsymbol{\alpha}}$ whereas none of the phases exhibits such an effect. This coupling tensor links the macroscopic magnetic induction $\overline{\mathbb{B}}$ to the macroscopic electric field $\overline{\mathbb{E}}$ ($\overline{\mathbb{B}} = \tilde{\boldsymbol{\alpha}} \cdot \overline{\mathbb{E}}$) when the macroscopic strain $\overline{\mathbb{S}}$ and the macroscopic magnetic field $\overline{\mathbb{H}}$ are null. It can also be defined as the link between the macroscopic electric induction $\overline{\mathbb{D}}$ and the macroscopic magnetic field $\overline{\mathbb{H}}$ ($\overline{\mathbb{D}} = \tilde{\boldsymbol{\alpha}} \cdot \overline{\mathbb{H}}$) when the macroscopic strain $\overline{\mathbb{S}}$ and the macroscopic electric field $\overline{\mathbb{E}}$ are null.

IV. RESULTS

The example of application is the study of the magneto-electric effect in composites made of $BaTiO_3$ (piezoelectric) and $CoFe_2O_4$ (piezomagnetic). The material properties can be found in [6]. The studied microstructures are random distributions of $CoFe_2O_4$ cylinders in a $BaTiO_3$ matrix (see Fig. 2). Both phases have their poling directions along the y -axis.

Fig. 2. Matrix-inclusions microstructure (in 2-D).

For this kind of microstructure, a satisfying estimate of the effective properties in homogenization can be obtained with the Hashin & Shtrikman estimate [3]. In this application, the 2-D coupling tensor $\tilde{\boldsymbol{\alpha}}$ has the following shape:

$$\tilde{\boldsymbol{\alpha}} = \begin{pmatrix} \alpha_{11} & 0 \\ 0 & \alpha_{22} \end{pmatrix} \quad (4)$$

The homogenization results (presented in Fig. IV) are compared to the corresponding results obtained from a Finite Element computation using COMSOL software for random 2-D microstructures.

Fig. 3. ME coupling coefficients as a function of the volumetric fraction f of the piezomagnetic phase (homogenization and FE results).

The ME coefficients are shown to depend on the volumetric fraction f of the piezomagnetic phase. The results obtained from homogenization and Finite Element method are very similar. The corresponding computational time is more than a thousand times lower when using the homogenization technique.

V. CONCLUSION

Homogenization approach is able to catch structure effects such as the ME effect exhibited in piezomagnetic/piezoelectric composites. The interest of this modeling approach is its very light computational cost compared to the Finite Element method. The comparison with the results obtained from a Finite Element model shows a very satisfying agreement in the case of matrix-inclusion microstructures. More comparisons with Finite Element computations will be proposed in the full paper.

Abstract — To reduce the loss of reactor driven by inverter power supply using magnetic field analysis, the eddy currents generated in laminated steel plates should be taken into account. To calculate the eddy currents in steel plates accurately, the anomalous eddy current induced by domain wall motion should be considered. In this paper, a simple numeric modelling of anomalous eddy current taking account of domain wall motion is proposed. The proposed method is compared with the ordinary modelling of modifying the conductivity of steel plate in the loss calculation of one sheet of steel plate. It is shown that the eddy current losses obtained from the proposed method can agree with the measured data in lower frequencies, however, error occurs in high frequencies as skin effect is neglected at present.

I. INTRODUCTION

We have developed the method of magnetic field analysis which models a laminated core as a solid one taking account of eddy currents in the steel plate by using the finite element method [1]. In this method, the 1D eddy current sub-analysis of steel plate is carried out for each element in main-analysis of the solid core model and the classical eddy current loss can be obtained directly. However, in the iron loss calculation of reactor under inverter power supply, the calculated iron loss are much smaller than the measured one [2] because the anomalous eddy current loss [3] generated by domain wall motion was neglected. In order to taking account of the anomalous eddy current loss, the numeric modelling of modifying the conductivity of steel plate has already been proposed [3] but the physical phenomena of domain wall motion can not be expressed by this method [4].

In this paper, a simple numeric modelling of anomalous eddy current taking account of domain wall motion, which should be simple for introducing it into the sub-analysis, is proposed. The proposed method is applied to the loss calculation of one sheet of steel plate and compared with the measured data and the ordinary numeric modelling mentioned above.

II. METHODS OF MODELLING

First, the ordinary numeric modelling for considering the loss increase by modifying the conductivity σ of steel plate is described. In this modelling, the classical eddy current in the steel plate with the modified conductivity σ^* is calculated. The

modified conductivity σ^* of steel plate is determined by fitting the calculated eddy current loss of one sheet of steel plate with the measured data. The eddy current is calculated by using the 1D nonlinear eddy current finite element analysis (FEA).

Next, a simple modelling of anomalous eddy current loss taking account of domain wall motion using a 1D domain model shown in Fig. 1 is described. In this model, the steel plate is assumed to be infinity in x and y directions and composed of domains with uniform magnetization M which have y component only and are 180 deg different in turns periodically lining in x direction as shown in Fig. 1. The position of domain wall can be determined by making the average value of magnetization M equal to the applied average flux density B . In this modelling, not only the classical eddy current but also the anomalous eddy current due to domain wall motion can be taken account of as shown in Fig. 1. The eddy currents due to the domain wall motion is calculated by using the 2D linear eddy current FEA in x - z plane only in the region R shown in Fig. 1 due to periodic and symmetric phenomena of the domain model. The length L_x of region R is determined by fitting the calculated eddy current loss with the measured data.

Fig. 1. A simple 1D magnetic domain model (proposed method).

III. VERIFICATION MODEL

Both methods are applied to the eddy current loss calculation of one sheet of steel plate. The magnetic material used for the steel plate is AISI: M-36 (thickness 0.35 mm, $\sigma = 1.852 \times 10^6$ S/m) and the steel plate is assumed to be infinity in x and y directions. In this case, the ordinary and proposed methods become 1D and 2D eddy current analyses, respectively. The saturated magnetization M for the proposed modelling is set to be 2.1T. The applied average flux density B is the sinusoidal waveform with amplitude B_{max} . By fitting the

7. Material Modelling

eddy current loss calculated when the maximum average flux density B_{max} is 0.5 T and the frequency f is 100 Hz with the measured data in catalogue, the modified conductivity σ^* in the ordinary modelling and L_x in the proposed modelling are determined to be 3.0×10^6 S/m and 0.3 mm, respectively.

IV. RESULTS AND DISCUSSION

Fig. 2 shows the flux and eddy current distributions of half region of the steel plate obtained by using the classical 1D eddy current analysis with the real and modified conductivities at the instant when the average flux density in the steel plate is the maximum. It is seen that the eddy current obtained from the modified conductivity is greater than that obtained from the real conductivity, so the eddy current loss increase due to the anomalous eddy current loss can be considered by the modification of the conductivity of steel plate. However, the skin effect is greater when the modified larger conductivity is used than that when the real conductivity is used. This is not the same with the real phenomenon resulted from the domain wall motion and it seems to cause error in the hysteresis loss calculation.

Fig. 3 shows the flux and eddy current distributions of half region of the steel plate obtained by using the proposed modelling at the same instant. It can be seen that the classical eddy current loop and the anomalous eddy current loop due to domain wall motion are represented. However, the skin effect cannot be observed in the flux distribution because the magnetization \mathbf{M} is assumed to be uniform in z direction at present.

Fig. 2. Flux and eddy current distributions obtained from the ordinary modelling ($B_{max} = 0.5$ T and $f = 1$ kHz).

Fig. 3. Flux and eddy current distributions obtained from the proposed modelling ($B_{max} = 0.5$ T and $f = 1$ kHz).

Fig. 4 shows the eddy current losses at different maximum

average flux densities B_{max} s and frequencies f s obtained from the ordinary modelling with the modified conductivity $\sigma^* = 3.0 \times 10^6$ S/m and the measured data. To show the anomalous eddy current loss, the eddy current loss with original conductivity σ at $B_{max} = 0.5$ T is also shown in Fig. 4. The measured eddy current losses are obtained from the iron loss curves at different frequencies f s in catalogue. The eddy current losses of one sheet of steel plate obtained from the ordinary modelling are in good agreement with the measured data in a wide range of frequencies. However, it is not physical modelling.

Fig. 5 shows the eddy current losses obtained from the proposed modelling with $L_x = 0.3$ mm and the measured data. In lower frequencies, the eddy current losses obtained from the proposed modelling are in good agreement with the measured data, however, error occurs in high frequencies due to neglect of the skin effect. The method of considering the skin effect in the proposed modelling will be discussed in the full paper.

Fig. 4. Comparison of eddy current losses between the ordinary modelling and measured data.

Fig. 5. Comparison of eddy current losses between the proposed modelling and measured data.

Inclusion of Eddy Currents in Laminations in Two-Dimensional Finite Element Analysis

J. Pippuri, A. Belahcen, E. Dlala, and A. Arkkio

Department of Electrical Engineering, Helsinki University of Technology

P.O. Box 3000, FI-02015 TKK, Finland

jenni.pippuri@tkk.fi

Abstract — The inclusion of eddy currents in electrical steel sheets in a two-dimensional (2D) finite-element analysis is studied. For the eddy-current modeling a so-called one-dimensional (1D) approach is applied. Two different techniques for the eddy currents within the 2D field equations are investigated and shown. According to the computation results a suggestion for a proper coupling method is made.

I. INTRODUCTION

A two-dimensional (2D) field analysis is commonly applied to analyze electromechanical applications. Although such an approach is sufficient in many cases, from it certain phenomena such as eddy currents flowing in electrical steel sheets are by definition excluded. For modeling the eddy currents within the 2D analysis, for instance a so-called one-dimensional (1D) approach has been proposed [1], [2]. In this work, this approach is adopted. The novelty of this work lies in the careful analysis of the coupling, i.e. how the eddy-current solution can reliably be included in the 2D equations. The results show the scale of errors to which an improper coupling might lead thus emphasizing the importance of the topic.

II. COMBINED 2D-1D METHOD

In this work, a simple geometry consisting of a stack of electrical steel sheets and a voltage source i.e. a coil is applied. The volume of the stack is 1 m^3 and the volume of the coil side is 0.2 m^3 .

In the 2D scheme the magnetic vector potential and current density are given as

$$\mathbf{A} = A(x, y, t) \mathbf{e}_z \quad (1)$$

$$\mathbf{J} = J(x, y, t) \mathbf{e}_z. \quad (2)$$

in which x and y denote Cartesian spatial coordinates, t denotes time, and \mathbf{e}_z denotes the unit vector of the z -axis.

The magnetic flux density in the studied geometry fulfills

$$\nabla \times (\nu \nabla \times \mathbf{A} + \mathbf{H}_{\text{ec}}) = \frac{N\mathbf{i}}{S}. \quad (3)$$

ν is the reluctivity given as a spline function of the second power of the magnetic flux density, \mathbf{B}^2 , \mathbf{H}_{ec} is the component due to the eddy currents, N is the number of turns in series, \mathbf{i} is the current in the coil, and S is the cross sectional area of the coil.

The voltage in the coil satisfies

$$\mathbf{u} = \frac{IN}{S} \int_S \frac{\partial \mathbf{A}}{\partial t} \cdot d\mathbf{S} \mathbf{e}_z + R\mathbf{i}. \quad (4)$$

in which l denotes the length of the coil and R the DC resistance of the coil.

The 1D eddy-current model of the electrical steel sheets is developed in the lamination depth. The magnetic vector potential and current density are defined as

$$\mathbf{a} = a_x(z, t) \mathbf{e}_x + a_y(z, t) \mathbf{e}_y, \quad (5)$$

$$\mathbf{j} = j_x(z, t) \mathbf{e}_x + j_y(z, t) \mathbf{e}_y. \quad (6)$$

in which z denotes a Cartesian spatial coordinate and \mathbf{e}_x and \mathbf{e}_y are the unit vectors of x - and y -axis, respectively.

The magnetic vector potential in the laminations satisfies

$$\nabla \times (\nu \nabla \times \mathbf{a}) = -\sigma \frac{\partial \mathbf{a}}{\partial t} \quad (7)$$

$$a_x(-d, t) = dB_y \quad a_x(0, t) = 0 \quad (8)$$

$$a_y(-d, t) = -dB_x \quad a_y(0, t) = 0. \quad (9)$$

ν is the reluctivity given as a spline function of the second power of the magnetic flux density, \mathbf{b}^2 , σ and d are the electrical conductivity and half of the thickness of the laminations, respectively, and B_x and B_y are the x - and y -components of the 2D magnetic flux density, respectively.

For the discretization of the coupled problem, the Crank-Nicolson and finite-element method are applied. The nonlinearities of iron are handled by the Newton-Raphson technique. In the 2D scheme, the Newton-Raphson is applied in an incomplete manner. Incomplete, as the terms originating from the \mathbf{H}_{ec} are omitted from the Jacobian matrix. Resulting from this, over-relaxation is required for convergence. For the 1D scheme, a complete Newton-Raphson is applied in a novel manner as discussed in [3].

In the derivations, the eddy-current component, \mathbf{H}_{ec} , is defined as a difference of the 1D magnetic field strength, \mathbf{h} , at the boundary of the sheets ($z = -d$) and the magnetic field strength obtained from the 2D analysis, \mathbf{H}

$$\mathbf{H}_{\text{ec}}(x, y, t) = \mathbf{h}(-d, t) - \mathbf{H}(x, y, t). \quad (10)$$

It will be shown that the accuracy of the coupled method greatly depends on how well the estimation of the magnetic field strength at the boundary of the sheets succeeds. For the estimation, two approaches are proposed. Firstly, one can calculate \mathbf{h} exactly at the boundary (in the point $z = -d$) by the shape functions as a product of magnetic flux density and reluctivity. This option is later referred to as *conventional*. The second option is to use the relation

$$\nabla \times \mathbf{h} = \mathbf{j}. \quad (11)$$

from which following formulae are derivable

$$h_x(-d, t) = \int_{-d}^{z_i} j_y(z, t) \partial z + h_x(z_i, t) \quad (12)$$

$$h_y(-d, t) = -\int_{-d}^{z_i} j_x(z, t) \partial z + h_y(z_i, t). \quad (13)$$

in which z_i is upper value of the integration interval. Term *integration* is used to refer to this approach.

III. RESULTS AND DISCUSSION

The computations were carried out utilizing the example geometry described above. The 1 m² 2D geometry was discretized with eight second-order elements. The thickness and conductivity of the sheets in the stack were 0.65 mm and 2.5 MS/m. For the space discretization of the 1D solution sector (half of the thickness of the sheets, 0.325 mm) three equally sized elements were applied. The input voltage waveform utilized in all the computations is shown in Fig. 1. The time-discretization was done with 400 time steps per period. Altogether 2000 time steps were computed.

Fig. 1. Input voltage used in the computations.

The successiveness of the coupling of the 2D and 1D field solutions was studied in the frame of two criteria: the power balance and computational efficiency. With both the approaches proposed for the evaluation of h at the boundary, three computations were performed varying the number of integration points in the 1D elements.

The BH-loops obtained with the *conventional* method are depicted in Fig. 2. Furthermore, the input powers, losses, and power balances from the computations are shown in Table I. The eddy-current losses presented in Table I were computed from the eddy-current density and the power balance is defined as the difference of the total losses and the input power divided by the input power. Clearly, with the *conventional* method combined with the first-order elements, the eddy-current phenomenon in the sheets is not properly included in the 2D field analysis. The eddy-current losses integrated from the BH-loop are about half of the ones computed from the eddy-current density. A significant improvement in the accuracy is gained by using higher order elements. With the third-order elements the total losses in the example geometry are almost the same as the input power.

In terms of power balance, the *integration* technique performs very well with the first-order and third-order elements. When utilizing the second-order elements the solution of the coupled problem starts to oscillate as depicted in Fig. 3. This results in a rather significant error in the power balance.

— 1. order elements — 2. order elements * 3. order elements

Fig. 2. BH-loops when applying the *conventional* approach.

— 1. order elements — 2. order elements * 3. order elements

Fig. 3. Close-up of the BH-loops when applying the *integration* approach.

TABLE I
COMPARISON OF THE POWERS AND POWER BALANCE

h at the boundary	Order of 1D elements	Eddy-current loss (W)	Resistive loss of the coil (W)	Input power (W)	Power balance (%)
<i>Conventional</i>	1	16593	247	9004	87.04
	2	15643	248	15613	1.78
	3	15663	248	15946	0.22
<i>Integration</i>	1	16502	248	16705	0.27
	2	16196	248	15376	6.94
	3	15637	248	15872	0.08

The computational times of the two approaches were nearly the same with a certain number and degree of elements. The greatest difference was obtained with the first-order elements; computing one period of line voltage took about 3.4 percent more time with the *conventional* approach than with the *integration* one.

Based on the results the *integration* method seems to be the most promising technique for defining the eddy currents in the 2D analysis. With it, a power balance is achieved with the first-order elements that leads to significant savings in computation time.

Electromagnetic Multi-scale Homogenization of Carbon Fiber Composite Materials

G. Wasselynck, D. Trichet, and J. Fouladgar

Institut de Recherche en Electrotechnique et Electronique de Nantes Atlantique
CRTT 37 Bd de l'université BP406, 44602 Saint Nazaire cedex, France
guillaume.wasselynck@univ-nantes.fr

Abstract—A new multi-scale homogenization method is introduced to calculate the field and current distribution inside carbon fiber reinforced polymer composites submitted to an external electromagnetic field. In the microscopic scale, the real structure of the material is taken into account and electromagnetic and electrical equivalent properties are calculated using finite elements method. In macroscopic scale, these properties are introduced in an impedance network or in a shell elements-finite elements method according to the working frequency. The results obtained are in accordance with experimental results.

I. INTRODUCTION

Carbon Fiber Reinforced Polymer (CFRP) composites are used in various industrial applications and more especially in aeronautics. This is due to the fact that CFRP has better mechanical characteristics than aluminum for a lighter weight.

In different periods of their life cycle, the CFRP may interact with electromagnetic fields. This is the case for example, of induction welding of the composite structures or the lightning attacks on flying airplanes. The telecommunication or radar transmission between the plane and the earth station is another example of electromagnetic field interaction with the CFRP. According to the application, the field frequency may vary between several kHz and some GHz.

A perfect comprehension of field propagation inside the CFRP needs a through analysis of the conducting and displacement currents distribution in the carbon fibers and in the resin polymer. In fact, in CFRP composites, the conducting carbon fibers are separated from each other by non conductive resin as shown in Fig. 1. The current circulation in the fibers and in the whole material presents a difficult problem which should be solved. In addition, the composite materials are highly anisotropic and non homogeneous. They present also an important scale factor between the fiber diameter which is around $7\ \mu\text{m}$ and the size of the composite sheet which may be up to several meters. In this paper, we study the case of a unidirectional CFRP where the carbon fibers, parallel to each other, are distributed randomly inside the resin as in Fig. 1. The scale factor is too important to simulate the real structure of CFRP. Homogenization method is then used to overcome this problem. A two scales model is introduced to calculate the eddy current distribution. For this purpose, the CFRP sheet is divided into elementary bricks which are representative of the whole material as shown in Fig. 2.

In microscopic scale, the finite elements method (FEM) is used to calculate the equivalent impedance of the bricks. In macroscopic scale, these properties are incorporated in an

Fig. 1. Section of UD composite

Fig. 2. Elementary brick and Impedance network

impedances network to obtain the current distribution in the whole material.

II. MICROSCOPIC SCALE

The size of the bricks is an important parameter in the homogenization technique. They should contain a reasonable number of fibers to represent statistically the whole material without complicating the local or global solution of the problem. In the full paper we will give more details about the elementary brick size calculation.

To determine the equivalent impedance of each element, it is necessary to find the eddy current circulation in an elementary brick. When an electromagnetic field orthogonal to fibers direction is applied to the material, the current has two possible paths to circulate in the composite as shown in Fig. 3. In the first path (dotted line), the current loop ends in the fiber itself. In the second path (dashed line), the current loop is shared by several fibers passing through the capacities between them. For the two paths, the current has to go through two different impedances. The favorite path is obviously the one with lower impedance. To determine the local impedances of the bricks, one should solve the electromagnetic and electrostatic equations.

Fig. 3. Circulations of currents

A. Electromagnetic formulation

The resistances, the self inductances and the mutual inductances of the fibers are calculated using the following potential vector formulation of the Maxwell equations [1]:

$$\text{curl}\left(\frac{1}{\mu} \text{curl}\mathbf{A}\right) + j\omega[\boldsymbol{\sigma}]\mathbf{A} = \mathbf{J}_0 = \text{curl}(\mathbf{H}_0). \quad (1)$$

Where μ is the permeability, $[\boldsymbol{\sigma}]$ is the conductivity tensor, ω is the field pulsation and \mathbf{H}_0 is the source magnetic field. Figure 4 presents the geometry of a brick with a random distribution of the fibers. Equation (1) is solved by FEM using Whitney's elements to obtain the vector potential \mathbf{A} , the induction \mathbf{B} , the magnetic field \mathbf{H} and the self and mutual inductances.

Fig.4. Random distribution of fibers in elementary brick

If the current loop ends in the fiber itself, it has to flow through an inductance L which is calculated as follows:

$$E = \frac{1}{2} \iiint \mathbf{B} \cdot \mathbf{H} \, dV = \frac{1}{2} L \left(\iint \mathbf{J} \cdot d\mathbf{S} \right)^2. \quad (2)$$

Where E is the electromagnetic energy, \mathbf{J} is the current density, V is the volume and S is the section of the fiber.

B. Electrostatic formulation

The capacities are calculated using the Poisson's equation:

$$\Delta V = -\rho / \varepsilon. \quad (3)$$

Where ρ is the electrical charge density, ε is the permittivity of the matrix and V is the electrical potential. This equation is solved using the floating potential concept to obtain the matrix of capacities between the fibers [2].

$$\mathbf{Q} = [\mathbf{C}]\mathbf{V}. \quad (4)$$

In our case, it is not necessary to calculate the whole matrix \mathbf{C} but only the lines corresponding to the fibers, in black in Fig. 4, at the left, right, top and bottom of the cell. The details of the floating potential calculation will be presented in the final paper.

C. Results and discussion

The impedance calculated from (2) is about $1.15 \times 10^{21} \, \Omega/\text{m}$ for a welding frequency of 150 kHz. This impedance is too high compared to the impedance due to the inter fiber capacities which is about $4.44 \times 10^7 \, \Omega$. The possibility that the current loops ends inside the fiber is practically negligible. For this frequency, the impedances due to self and mutual inductances are less than 1% of the fiber resistances. In this case, the equivalent impedance along the fibers is directly related to the filling rate and the carbon conductivity and each cell is linked only to its neighbors. For high frequencies, however, the self and mutual inductances can not be neglected and each cell is coupled inductively to all other cells.

III. MACROSCOPIC SCALE

For the applications such as welding, the field frequency is relatively low. The impedances obtained from microscopic

calculations can be then incorporated in a 3D impedances network [3]. On each node, the electrical potential is calculated by Kirschhoff's law using the finites differences method. The current along each edge is then calculated by:

$$I = ((V_p - V) - j\omega \int \mathbf{A} \cdot d\mathbf{l}) / Z. \quad (5)$$

Where V_p and V are the end electrical potentials of the segment, Z is its impedance and \mathbf{A} is the source potential vector along the segment.

For high frequencies such as radar transmissions, the self and mutual impedance have to be taken into account. In this case, the impedance network method leads to a full matrix which limits the size of material to be studied. To overcome this difficulty, the microscopic phase is used to obtain a complex equivalent conductivity. This property is then introduced in an anisotropic shell elements - finite elements to calculate the field and current distribution inside the material [4]-[5]. This method will be developed in the full paper.

IV. APPLICATION ON HEATING PROBLEM

To validate the model, a rectangular CFRP plate (120mm x80mm x1.5mm) is heated by a rectangular inductor (40mm x20mm) with a RMS current of 1000A at a frequency of 150 kHz. The fibers are in the direction of the length (120mm) and the filling rate of fibers is equal to 70%.

For this frequency, the equivalent impedances are resistive along fiber axis and capacitive along others axes. The calculated heating power is equal to 814 W which is close to experimental results.

V. CONCLUSION

In this paper, a two scales homogenization method of CFRP composites is introduced. In the microscopic scale, the equivalent impedance of an optimized size elementary brick is calculated using FEM to solve both electromagnetic and electrostatic equations. For low frequencies, the macroscopic scale problem is solved by an impedance network approach. For high frequencies, an anisotropic shell elements-finite elements method is applied. In the full paper we will give the details on the brick size calculations and the different methods to obtain the local impedance, the field and the current distribution inside the composite sheets.

The Effects of Steel Lamination Core Losses on 3D Transient Magnetic Fields

D. Lin, P. Zhou, Q. M. Chen, and Z. J. Cendes
Ansoft LLC, 225 W. Station Square Dr, Pittsburgh 15219 USA
dlin@ansoft.com

Abstract — A 3-dimensional (3D) transient finite element analysis (FEA) approach taking into account the effects of steel lamination core loss is proposed. When using the T-Ω method, the effects of lamination core loss are considered by introducing an additional field component in lamination regions which is derived from the instantaneous core loss in the time domain. The proposed approach is validated by two applications in terms of the power-balance testing, that is, the input power increase due to the core-loss effects must be equal to the total core loss.

I. INTRODUCTION

The steel lamination core loss with sinusoidal excitation is commonly computed based on loss separation, which breaks the total core loss into static hysteresis loss, classical eddy current loss, and excess loss in the frequency domain [1]. In order to apply the method to the time domain, an equivalent elliptical loop (EEL) method was presented to model the hysteresis loop [2], and therefore, the instantaneous core loss at each time step can be predicted in the transient FEA. However, the instantaneous core loss presented in [2] is computed as “post process”, that is, the effects of the core loss on the transient magnetic field are not taken into account.

In this paper, the effects of the lamination core loss on the 3D transient magnetic field are considered by introducing an additional field component in lamination regions when using the T-Ω method. This additional field component is derived from the total instantaneous core loss including the static hysteresis loss, classical eddy current loss and excess loss. The proposed approach is validated by two applications in terms of the power-balance testing, that is, the input power increase due to the core-loss effects must be equal to the total core loss in the device.

II. EFFECTS OF LAMINATION CORE LOSS

A. Basic field equations

The field equation using T-Ω method [3] is

$$\begin{aligned} \nabla \times ([\sigma_a]^{-1} \nabla \times \mathbf{T}) + \frac{\partial}{\partial t} [\mu] (\mathbf{T} + \nabla \Omega) \\ = -\frac{\partial}{\partial t} [\mu] (\mathbf{H}_s + \mathbf{H}_p) \end{aligned} \quad (1)$$

where \mathbf{T} is the vector electric potential in conducting regions, Ω is the scalar magnetic potential, $[\mu]$, the permeability tensor, is anisotropic in lamination regions [4], $[\sigma_a]$ is the anisotropic conductivity tensor to be discussed below, \mathbf{H}_s corresponds to all exciting current sources, and

$$\mathbf{H}_p = \mathbf{H}_{pc} + \mathbf{H}_{ph} + \mathbf{H}_{pe} \quad (2)$$

is an additional field component due to core loss effects.

In (2), \mathbf{H}_{pc} , \mathbf{H}_{ph} and \mathbf{H}_{pe} correspond to the classical eddy current core loss, static hysteresis core loss and excess core loss, respectively.

B. Effects of eddy current loss caused by the normal component of flux density

When a flux density component in z direction B_z changes, an eddy current field distributed in the xy plane will be produced, as shown in Fig. 1.

The equivalent conductivity in lamination regions is anisotropic, and can be expressed by a conductivity tensor

$$[\sigma_a] = \begin{bmatrix} k_{lam} \sigma & 0 & 0 \\ 0 & k_{lam} \sigma & 0 \\ 0 & 0 & \sigma_{min} \end{bmatrix} \quad (3)$$

where k_{lam} is the lamination factor, σ is the conductivity of the laminated steel, and σ_{min} , the minimum conductivity limit, is used to ensure that the system equation is non-singular.

Fig. 1 Eddy current produced by the normal component of flux density

C. Effects of eddy current loss caused by the tangential components of flux density

When the flux density components B_x and/or B_y , tangential to the lamination plane, alternate, the produced eddy current field is bounded in each lamination, as shown in Fig. 2.

Fig. 2 Eddy current produced by the tangential components of flux density

The effects of eddy current produced by the tangential flux components is considered by means of an equivalent magnetic field component \mathbf{H}_{pc} , which can be computed by eddy current core loss. The eddy current core loss per unit volume is normally given in the frequency domain as shown below

$$p_c = k_c (f B_m)^2 \quad (4)$$

where f is the frequency, B_m is the flux density amplitude, and

k_c is the eddy current loss coefficient. In the time domain, the eddy current core loss is computed from

$$p_c(t) = \mathbf{H}_{pc} \cdot \frac{\partial \mathbf{B}}{\partial t} \quad (5)$$

where

$$\mathbf{H}_{pc} = [k] \frac{\partial \mathbf{B}}{\partial t} \quad (6)$$

with

$$[k] = \begin{bmatrix} k_c / (2\pi^2) & 0 & 0 \\ 0 & k_c / (2\pi^2) & 0 \\ 0 & 0 & 0 \end{bmatrix}. \quad (7)$$

D. Effects of hysteresis loss

The hysteresis core loss per unit volume computed in the frequency domain is given below

$$p_h = k_h f (B_m)^2 \quad (8)$$

where k_h is the hysteresis loss coefficient. In the time domain, the hysteresis core loss can be calculated based on the equivalent magnetic field component \mathbf{H}_{ph} , as expressed below

$$p_h(t) = \mathbf{H}_{ph} \cdot \frac{\partial \mathbf{B}}{\partial t}. \quad (9)$$

The equivalent field component \mathbf{H}_{ph} is determined by the equivalent elliptical loop (EEL) method [2]. Each component in the x , y or z direction is computed independently from

$$\begin{cases} B = B_m \sin(\theta) \\ H_{ph} = H_m \cos(\theta) \end{cases} \quad (10)$$

where B is the current flux density, B_m is obtained from a historical record of the maximum and minimum flux densities, and H_m is

$$H_m = \frac{k_h}{\pi} B_m. \quad (11)$$

E. Effects of excess loss

The excess core loss per unit volume is given in the frequency domain as

$$p_e = k_e (f B_m)^{1.5} \quad (12)$$

where k_e is the excess loss coefficient. In the time domain, the excess core loss can be calculated based on the equivalent magnetic field component \mathbf{H}_{pe} , as expressed below

$$p_e(t) = \mathbf{H}_{pe} \cdot \frac{\partial \mathbf{B}}{\partial t}. \quad (13)$$

The equivalent field component \mathbf{H}_{pe} is determined by requiring that the average excess core loss calculated in the time domain must be the same as that obtained in the frequency domain under the same sinusoidal excitation, and it is derived as

$$\mathbf{H}_{pe} = \frac{k_e}{C_e} \left[\left(\frac{\partial B}{\partial t} \right)_m \right]^{-0.5} \frac{\partial \mathbf{B}}{\partial t} \quad (14)$$

where

$$\left(\frac{\partial B}{\partial t} \right)_m = \sqrt{\left(\frac{\partial B_x}{\partial t} \right)^2 + \left(\frac{\partial B_y}{\partial t} \right)^2 + \left(\frac{\partial B_z}{\partial t} \right)^2} \quad (15)$$

and $C_e = 8.763363$.

III. APPLICATIONS

The first application is for the computation of core loss of 250 kVA three-phase amorphous metal power transformer with five legs. The delta-connected three-phase primary windings are energized by three-phase voltage sources, and the secondary windings are open-circuit.

The input power increase due to core loss effects is shown in Fig. 3, compared with the computed core loss. The average input power increase and the computed core loss in the last period (80ms ~ 100ms) are compared with the measured data in Table I.

Fig. 3 The input electrical power increase due to the core loss effects compared with the computed core loss ($k_h=21.08$, $k_e=0$, $k_c=0$)

TABLE I. COMPUTED AND MEASURED CORE LOSS OF THE 250 KVA THREE-PHASE AMORPHOUS METAL POWER TRANSFORMER

	Value	Unit
Input power increase	118	W
Computed core loss	119	W
Measured core loss	126	W

The second application is for the no-load core loss computation of a 165W, 4-pole interior permanent magnet (IPM) brushless DC (BLDC) motor. The mechanical input power increase due to core loss effects is compared with the computed core loss in Fig. 4.

Fig. 4 The input mechanical power increase due to the core loss effects compared with the computed core loss ($k_h=260.4$, $k_e=0.822$, $k_c=40.54$)

Abstract — Analytical calculation of interaction forces between two cylindrical magnets is a difficult problem. Solutions can be obtained by elliptic integrals or by numerical computation. Thanks to the development of the analytical calculation for parallelepiped magnets (interaction energy, force and torque), the calculation of the force component between two cylinders can be obtained in analytical form by decomposition in a finite number of elements.

This type of calculation allows the calculation of many systems that uses the forces of interaction between cylinder magnets. For example it can be used to directly calculate the force exerted in permanent magnet bearings in non-centred position.

I. INTRODUCTION

Recent works on the analytical calculation of forces between permanent magnets allow calculating the interactions between magnets of parallelepiped shapes. The forces, interaction energy and couples can be expressed as analytical expressions, parameterized by the geometrical dimensions and magnetization of the magnets [1 to 4].

However, the problem of rod-shaped magnets has never been analytically solved. The simpler problem of the 3D calculation of the magnetic field is made with elliptic integrals. This field calculation needs two integrations. For the calculation of interaction energy and forces, four successive integrations are necessary.

We will present an innovative analytical method, to calculate the interaction forces between two magnets of cylindrical shapes. The final analytical expression is a series with a limited term number. The accuracy depends on the number of elements.

This method allows calculating the interaction forces in three directions, as well as energy interaction, through a relatively simple analytical expression.

II. CALCULATION PRINCIPLE

Figure 1: Principle of cutting of the cylindrical magnet in parallelepiped elements.

Figure 1 shows the principle of the cutting of the cylinder in parallelepiped elements. The first case corresponds to a cut in 4 parts, the second 10 and third 20. The number of elements is given by the parameter N_{pm} (Number of elementary permanent magnets).

III. INTERACTION ENERGY

We give in the page 2 of this summary only the expression of the energy of interaction. The forces are then obtained by derivation of this energy.

IV. EXAMPLE OF CALCULATION

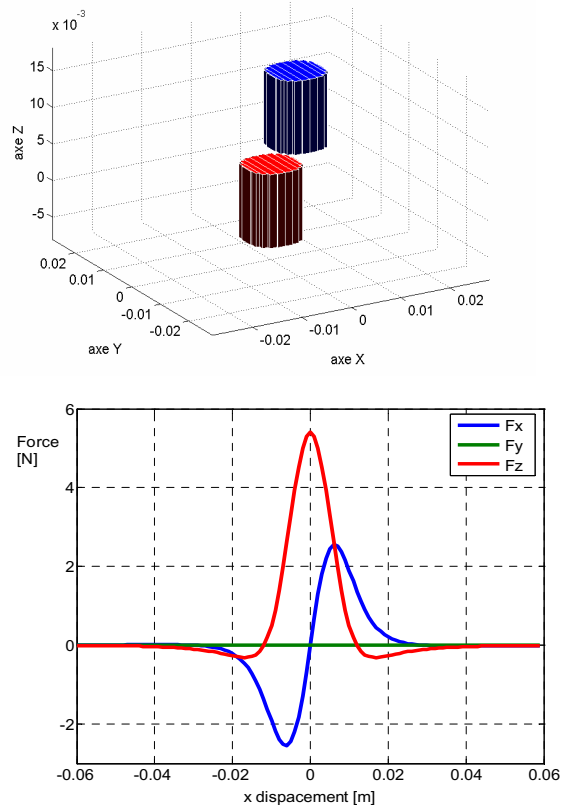

Figure 2: Calculation of the forces components for a magnet moving above a fixed one.

Figure 2 shows a direct example of use of these analytical results. It is the calculation of forces between two cylindrical magnets. The two magnets have a diameter of 10 mm and a height of 10 mm. The second moves horizontally above the first and the distance between the magnets is 5 mm. Polarization J is

Analytical expression of the interaction energy :

$$E = \frac{J \cdot J'}{4\pi\mu_0} \sum_{n=2=1}^{N_{pm} 2} \sum_{n1=1}^{N_{pm} 1} \sum_{i=0}^1 \sum_{j=0}^1 \sum_{k=0}^1 \sum_{l=0}^1 \sum_{p=0}^1 \sum_{q=0}^1 (-1)^{i+j+k+l+p+q} \cdot \psi(U_{ij}, V_{kl}, W_{pq}, r)$$

with:

$$\psi(U, V, W, r) = \frac{U(V^2 - W^2)}{2} \ln(r - U) + \frac{V(U^2 - W^2)}{2} \ln(r - V) + UVW \cdot \operatorname{tg}^{-1}\left(\frac{UV}{rW}\right) + \frac{r}{6}(U^2 + V^2 - 2W^2)$$

The parameters are given by:

$$U_{ij} = (\alpha - \alpha 1(n1) + \alpha 2(n2)) + (-1)^j A(n2) - (-1)^i a(n1)$$

$$V_{kl} = \beta + (-1)^l B - (-1)^k b$$

$$W_{pq} = \gamma + (-1)^q C - (-1)^p c$$

$$r = \sqrt{U_i^2 + V_j^2 + W^2}$$

With:

$$\phi 1(n) = n \cdot pi / N_{pm} 1 \quad xs1(n) = \sqrt{Kc} \cdot \sqrt{R^2 / (1 + \operatorname{tg}^2(\phi 1(n)))} \quad a1(n) = \frac{xs1(n) + xs1(n+1)}{2}$$

$$a1(n) = \frac{|xs1(n) - xs1(n+1)|}{2} \quad b1(n) = |\operatorname{tg}(\phi 1(n)) \cdot xs1(n)| \quad Kc = \frac{\pi \cdot R^2}{4 \sum_{n=1}^{N_{pm}} A(n) \cdot B(n)}$$

normalized to 1 tesla. The results show the values of the three force components, Fx, Fy and Fz.

The accuracy of analytical results is directly related to the number of elementary parallelepiped components used for each of the magnets. The complete study of the accuracy shows that one can easily obtain a relative error less than 1/1000, when the number of elements is sufficient. For this example of two cylindrical magnets, the precision of 1/1000 is achieved when the number of elements is about 20, even for a gap down to 2 mm.

V. APPLICATION TO MAGNETIC BEARING CALCULATION

For example, the calculation of the force exerted in a radial magnetic bearing is a relatively complicated. The permanent magnet magnetic bearings are composed of two rings in magnetic repulsion. Each magnet may be likened to two nested cylinders, representing the external volume, the other representing the internal volume. The problem of calculating the interaction forces between the two rings can be treated as one of four cylinders in interactions. The radial force can be expressed as an analytical expression involving a limited set of sums

. SUMMARY AND CONCLUSION

The calculation of interaction forces between two cylindrical magnets had never been resolved so far as analytical. Following the development of the analytical calculation of parallelepiped magnets, the calculation of these forces between two cylinders can be obtained in analytical form by decomposition to a finite number of elements.

This type of calculation allows the calculation of many systems that uses the forces of interaction between the cylinder magnets. For example it can be used to directly calculate permanent magnet magnetic bearings.

Abstract — This paper deals with two-dimensional modelling of a multifilamentary wire composed of two superconducting filaments in a conducting matrix. In order to avoid the three-dimensional problem solving, a novel technique is proposed to solve the coupled problem in two-dimensions. For that, it is enough to divide the filaments in several sections in the direction of the length of the wire. The difference of the currents in the superconducting filaments between two successive sections is equal to the current which losses in the copper matrix. The relation between the currents crossing the matrix and the electric fields in the filaments obtained by the analytical method is implemented in the finite element program. For a given geometry, the critical length of the wire where the filaments are coupled can be found. The numerical simulation results present the distributions of the current density in the modelled domain. The influence of the wire length on the total magnetization is also considered.

I. INTRODUCTION

A better understanding of the electromagnetic coupling phenomena in the superconducting filaments can be done by numerical simulation. For that, a finite element program has been developed at the LGEP in France for modelling the superconducting materials.

In [1], we proposed new methods for solving the problem of partially coupled superconducting filaments in two-dimensions. In order to approach the three-dimensional problem with better behaviour, we propose in this paper a new technique by dividing the superconducting filaments into several sections and searching the relation between the currents crossing the copper matrix and the electric fields in the filaments.

II. PROBLEM ANALYSIS

In order to solve the problem, it is well to take the problem of several partially coupled filaments in [1], but by treating the problem with the minimum hypothesis. For that, we have considered a multifilamentary wire constituted of two superconducting filaments embedded in a copper matrix. The current density is supposed parallel to the wire axis in each section and invariant along this axis. It only depends on x , y and t . The magnetic induction is thus parallel to the x - y plane and also depends on x , y and t .

To avoid the large number of elements required by three-dimensional modelling, we have then divided the wire into elementary sections of L/n length, where L and n are the wire length and the number of sections respectively. In a simple case, we have taken $n = 8$. The two-dimensional presentation of the currents and voltages of two filaments along a wire length L shows in Fig. 1. Because of the symmetry of the

problem, only the half of length has been studied in order to reduce the number of sections. Due to the low conductivity of the matrix compared to that of the superconductor, some small currents can circulate between the filaments. The difference of the currents in the filaments for two successive sections is equal to the current circulating in a section of matrix [2]. By using Kirchhoff's current law, we have obtained the relation between the currents inside the superconducting filaments (i) and the currents crossing the copper matrix (i_m) for the section k as follows:

$$i_k = \begin{cases} i_{k+1} + i_{mk} & ; k = 1, 2, \dots, (n/2 - 1) \\ i_{mk} & ; k = n/2 \end{cases} \quad (1)$$

where $i_{m0} = 0$ A.

And by using Ohm's law, we have obtained the relation between the currents and the voltages for the section k as follows:

$$i_{mk} = \begin{cases} 2v_k/R & ; k = 1, 2, \dots, (n/2 - 1) \\ v_k/R & ; k = n/2 \end{cases} \quad (2)$$

where $v_0 = 0$ V and R is representative of the resistance of a section of L/n length, its value could be determined by an electrokinetic formulation. It is interesting to note that, the resistance of the last section is twice because its length is two times smaller.

Fig. 1. 2D presentation of two filaments over a wire length L .

The equation of the electric fields (e_0) defined in Fig. 1 could be obtained as in [2].

$$e_{0k} = \frac{(v_{k-1} - v_k)}{(L/n)} \quad \text{at } z = \frac{(2k-1)L}{2n} \quad ; k = 1, 2, \dots, n/2 \quad (3)$$

Equation (3) can be rewritten as follows:

$$v_k = -\frac{L}{n} \sum_{i=1}^k e_{0i} \quad ; k = 1, 2, \dots, n/2 \quad (4)$$

By substituting (2) and (4) in (1), we have obtained the relation between the currents and the electric fields.

$$i_k = \begin{cases} i_{k+1} - \frac{2L}{nR} \sum_{i=1}^k e_{0i} & ; k = 1, 2, \dots, (n/2 - 1) \\ -\frac{L}{nR} \sum_{i=1}^k e_{0i} & ; k = n/2 \end{cases} \quad (5)$$

Equation (5) can be rewritten in the following matrix form:

$$I = [C]E_0 \quad (6)$$

where $I = [i_1 \ i_2 \ \dots \ i_{(n/2)}]^t$, $E_0 = [e_{01} \ e_{02} \ \dots \ e_{0(n/2)}]^t$ and $[C]$ is a matrix of constant value whose dimension is $(n/2) \times (n/2)$. For $n = 8$, we have found that:

$$[C] = \begin{bmatrix} 8c & 6c & 4c & 2c \\ 6c & 6c & 4c & 2c \\ 4c & 4c & 4c & 2c \\ c & c & c & c \end{bmatrix} \quad (7)$$

where $c = -L/8R$.

III. NUMERICAL MODELLING

The domain of the problem shows in Fig. 2 (in 2D). To reduce the computing time, by looking at the symmetries of the problem, we have only modelled a quarter of the domain. A technique proposed for this modelling is to execute $n/2$ computations of finite element in parallel. For that, we have just created a mesh and then regenerated a super mesh with $n/2$ times more elements and $n/2$ times more nodes. The coupling between the calculations of finite element would be done via (6).

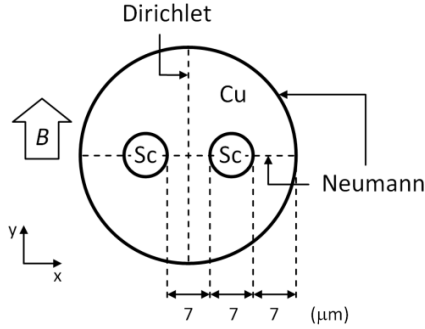

Fig. 2. Domain of the problem in 2D with given boundary conditions.

Bean's critical state model [3], which is replaced by a nonlinear function defined in [4], have been selected to characterize the electrical behaviour law of superconducting materials. As in [1], [5], in this case we have found that the matrix systems obtained by using the finite element method are as follows:

$$[M]\partial_t j_k + [A_e]e_k + [A_{ev}]e_{0k} = F \quad ; \quad k = 1, 2, \dots, n/2 \quad (8)$$

$$[A_{ev}]^t e_k + [A_v]e_{0k} = \partial_t i_k \quad ; \quad k = 1, 2, \dots, n/2 \quad (9)$$

where j is the current density. $[M]$ is the matrix of dimension $m \times m$. $[A_e]$, $[A_{ev}]$ and $[A_v]$ are the matrices of dimension $m \times m$, $m \times (n/2)$ and $(n/2) \times (n/2)$ respectively (m , n are the number of unknowns and the number of sections). F is the source vector.

IV. SIMULATION RESULTS

The simulation results have been obtained by using a code based on the finite element method and Bean's model. A series of numerical simulations has been realized for the superconducting filaments immersed in an external magnetic induction varying sinusoidally in time. Figure 3 shows the results of the current density distributions in the modelled domain at $t = T/8$ where T is the period of the applied

magnetic induction. The four subfigures from left to right indicate respectively the current density distributions at $z = L/16, 3L/16, 5L/16, 7L/16$. In the case that the wire length (L) is equal to the critical length (L_c), we have obtained the results in the case of partially coupled (Fig. 3(a)). We have observed that the total current in the middle of the wire is equal to $J_c \pi r^2$, where r is the radius of the filament and J_c is the critical current density (3×10^9 A/m²). These results show clearly the electromagnetic coupling phenomena in the superconducting filaments and are in agreement with those in [6]. For $L \gg L_c$ and $L \ll L_c$, the obtained results show the case of perfectly coupled (Fig. 3(b)) and perfectly decoupled (Fig. 3(c)) respectively. We could observe that the total current in the filament in Fig. 3(b) is the maximum value and the same in all sections. But in Fig. 3(c), this total current is zero and the same in all sections too. These results are in agreement with those shown in [1], [5]. In addition, the total magnetization of the wire could be computed by using the obtained value of the current density.

Fig. 3. Current density distributions in the modelled domain: (a) partially coupled case, (b) perfectly coupled case, and (c) perfectly decoupled case.

Abstract — This paper presents thorough investigations of the accuracy of the classical technique used to compute the eddy-current losses in nonlinear laminated electrical steel. The investigations show the weakness of the classical technique and point out how it should be improved. Based on the investigations and findings, an improvement is proposed and its accuracy is quantified. The accuracy of the classical and the improved technique is assessed by comparing the results of these techniques with results from a previously validated advanced method.

I. INTRODUCTION

The computation of power losses is a key feature in the design stage of electrical machines. The losses are conventionally separated into copper losses and core or iron losses. The latter ones are themselves separated into eddy-current, hysteresis, and excess losses. The adequate modeling of iron losses within the FE simulation of electrical machines requires advanced magnetodynamic vector hysteresis models of the underlying magnetic materials [1]. However, the computation time of these models when used in the design or within an optimization procedure presents a sever drawback.

Simplified techniques based on statistical or analytical methods are used in every day design. The most controversial techniques are related to the computation of eddy-current losses in the lamination of the machines. Two different variations of the classical technique [2] are widely used for this purpose. One is a direct application that does not put any condition on the waveform of the flux density, and the second one uses the Fourier decomposition of the flux density and applies the classical method to each harmonic separately.

In this paper we investigate the accuracy of the classical technique by comparing its results to these obtained from an advanced model [3], which is based on the numerical solution of the magnetic field in the depth of the steel sheet. Investigations on the accuracy of the second technique as well as its comparison with the classical one will be presented in the extended paper.

The advanced model itself has been previously demonstrated to give accurate results when compared with measured ones [4]. We also propose an improvement of the classical technique to make it more accurate without considerably increasing its computational burden.

II. DESCRIPTION OF THE MODELS

The advanced model is based on solving two coupled 1D magnetodynamic equations in the lamination depth. These equations are coupled through the material reluctivity and require iterative solution as the reluctivity is non linear

$$\begin{aligned}\frac{\partial^2 h_x(z,t)}{\partial z^2} &= \sigma \frac{\partial b_x(z,t)}{\partial t} \\ \frac{\partial^2 h_y(z,t)}{\partial z^2} &= \sigma \frac{\partial b_y(z,t)}{\partial t}\end{aligned}\quad (1)$$

where h_x and h_y are the components of the magnetic field strength and b_x and b_y these of the magnetic flux density in the lamination depth z . The instantaneous eddy-current losses are then computed from the current density $\mathbf{J}(z,t)$, the lamination thickness d , and the conductivity of the material σ as

$$p(t) = \frac{1}{d} \int_{-d/2}^{d/2} \frac{\mathbf{J}^2(z,t)}{\sigma} dz \quad (2)$$

The classical model has been derived from the analytical solution of (1), assuming uniform flux density in the depth of the material [2]. In both models the end effects of the eddy currents loops are ignored due to the small size of the lamination thickness.

In the classical model the instantaneous losses are given by

$$p(t) = \frac{\sigma d^2}{12} \frac{\partial \mathbf{B}}{\partial t} \cdot \frac{\partial \mathbf{B}}{\partial t} \quad (3)$$

The classical model does not take into account the nonlinearity of the magnetic material in the depth of the lamination and thus ignores the skin-effect related to this phenomenon. An improvement of the classical model consists of introducing in (3) terms that describe in a way or another, the effect of nonlinearity. In stead of (3), we propose that the instantaneous losses be calculated as follows

$$p(t) = \frac{\sigma d^2}{12} \left(\delta_x \left| \frac{\partial B_x}{\partial t} \right|^{\gamma_x} \frac{\partial B_x}{\partial t} + \delta_y \left| \frac{\partial B_y}{\partial t} \right|^{\gamma_y} \frac{\partial B_y}{\partial t} \right) \quad (4)$$

where $\delta_x = \text{signum}(B_x)$, $\delta_y = \text{signum}(B_y)$, and γ_x and γ_y are functions of B_x and B_y respectively.

In this version, the functions γ are quadratic functions of the magnetic flux density components. Different options for the choice of γ will be presented in the extended paper.

The instantaneous power loss in all the above cases is then integrated to obtain the power per unit volume P over one time period of the fundamental frequency.

III. COMPUTATION RESULTS

The three models described above have been implemented using 1D finite element method for the advanced one and related routines for the classical and improved ones. In all

computations the advanced model is fed from a predefined flux density, which is used to set its boundary values. The waveforms, frequencies, and amplitudes of the source flux density are varied and the relative difference between the power loss per unit volume over one time period of the fundamental frequency from the advanced model and the two other techniques are calculated as

$$\text{relative_error} = \frac{P_{\text{advanced}} - P}{P_{\text{advanced}}} \quad (5)$$

Fig. 1. Relative error in the computed losses from the advanced model and the classical one in the case of alternating flux density with different frequencies and amplitudes. The classical model works fine for most practical flux (under the dashed line) though it overestimates the losses in some cases.

Fig. 2. Relative error in the computed losses from the advanced model and the classical one in the case of alternating fundamental increased with the 25th harmonic with amplitude $B_{25} = 0.05B_1$. The frequencies and amplitudes are these of the fundamental one. The classical model does not give adequate results; it overestimates the losses in all practical cases (under the dashed line).

Fig. 3. Time dependence of the losses from the different models. When the flux density is alternating at 2000 Hz with an amplitude of 1.5 T. The classical technique gives losses that are lagging behind these of the advanced one while the improved technique models well the lag.

Fig. 1. shows the contour plot of this relative error (5) for the classical technique, when the source field was alternating with only the fundamental harmonic. Fig. 2. shows similar results when the field was alternating with the fundamental harmonic but contained also the 25th harmonic with an amplitude $B_{25} = 0.05B_1$. Fig. 3 presents the time dependency of the losses computed by the advanced model and these computed by the classical technique and the proposed improved one. It is clear that the classical technique can not model the lag of the losses behind the flux density caused by the time constant of the flux penetration phenomenon. The improved technique on the other hand can deal with this phenomenon thanks to terms that depend on the sign of the time derivative of the flux.

IV. DISCUSSION AND ANALYSIS

The classical eddy-current loss computation technique although gives acceptable average power losses in the case of a single harmonic (see Fig. 1.), does not model correctly these losses in time (see Fig. 3.) and thus introduces large errors as soon as the flux density contains higher harmonics (Fig. 2). The proposed improved method, though is not yet fully studied seems to be able to model the instantaneous power losses adequately (see Fig. 3).

In electrical machines, the situation is so that there is no localization where the variation of the flux density is purely sinusoidal, even if the supply voltage of the machine is sinusoidal. When the machine is used with frequency converters, the situation is even worse as the voltage harmonics of the supply will produce additional harmonics in the flux density resulting in low accuracy of the loss computation if the classical technique is used.

V. CONCLUSIONS

We presented investigations of the accuracy of different techniques for the eddy-current loss computation in nonlinear laminated electrical steel. The investigations showed the weakness of the classical technique and pointed out that there is a need for improved and time efficient techniques as well as the kind of improvements needed (lag of the instantaneous power loss). In the extended paper we will present different improvements and more comparisons of the losses computed with different techniques.

Abstract — This paper presents an efficient reluctivity model for taking account of two-dimensional (2-D) magnetic properties of grain-oriented electrical steel sheets. The measured hysteretic H -waveform is approximated to alternating one which the direction of H -waveform can be taken by a constant under a specific B -waveform, and the approximated H -waveform is expressed by using Fourier series expansion. The magnetic reluctivity model is proposed to apply the approximated 2-D magnetic properties to finite element analysis, and the effectiveness of the proposed method is investigated.

I. INTRODUCTION

Recently, an efficient magnetic reluctivity model considering two-dimensional (2-D) magnetic properties of silicon steel sheet has become an important issue for precise performance analysis of electrical machines. There have been researches, therefore, to effectively describe the 2-D magnetic properties of silicon steel including Grain-oriented materials as well as Non-oriented materials [1]-[6]. Under alternating field condition, in order to express the 2-D behavior of the magnetic field intensity (H), some magnetic reluctivity models have been developed [1]-[3]. In these models the hysteretic H -waveforms measured by using 2-D single sheet tester are approximated to alternating waveforms, and their magnitudes and phase angles are modeled as functions of magnitude and direction of the corresponding magnetic flux density (B). Although these models are quite effective and can be expressed as relatively simple form, they can hardly describe the 2-D magnetic properties under rotating magnetic field condition [1]. On the other hand, under rotating field condition, a few reluctivity models are developed based on Chua-type model by means of Fourier series expansion of B - and H -waveforms [4]-[6]. It is proven that the accuracy of these models can be enhanced by taking more harmonic components of the measured H -waveform into account [6]. However, as considering more harmonic components, these models become more complicated and require more data in terms of few hundred megabytes, and accordingly computing time becomes very huge when they are applied to non-linear FEM.

In this paper, a numerically efficient reluctivity model is proposed to describe the 2-D magnetic properties of silicon steel sheet under both the alternating and rotating field conditions, and applied to non-linear FEA.

II. APPROXIMATION OF H -WAVEFORM

For a specimen of silicon steel sheet, the H -waveform corresponding to an arbitrary B -waveform can be measured by using 2-D single sheet tester, shown in Fig. 1, where the

waveform of exciting voltage is controlled using waveform control technique so that a desired B -waveform is obtained. An elliptically rotating B -waveform is expressed, as shown in Fig. 2(a), for given parameters; maximum magnitude B_{max} , axis ratio $\alpha (=B_{min}/B_{max})$ and inclination angle φ , as follows:

$$B_k(\tau) = B_{mk}(\tau) \sin(\tau - \phi_k) \\ = R_{B_k} \cos \tau + I_{B_k} \sin \tau, \quad k = x, y \quad (1)$$

Fig. 2(b) shows the measured hysteretic H -waveform under 50Hz for a specimen of Grain-oriented silicon steel sheet 30PG158 when a rotating B -waveform of which parameters B_{max} , α , and φ are 1.0, 0.5 and 45° , respectively.

In this paper, the measured H -waveform is approximated, as shown in Fig. 2(b), to an alternating one of which maximum magnitude and phase angle are \hat{H} and θ_H , respectively. In this approximation, a magnetic field intensity (H) on the measured H -waveform correspond to its projection (H') on the approximated waveform as shown in Fig. 2(b). The approximated H -waveform for a rotating B -waveform with $(B_{max}, \varphi, \alpha)$ is defined as follows:

$$H'_m(\tau) = H_m(\tau) \cos(\theta_H(\tau) - \theta'_H), \quad 0 \leq \tau \leq 2\pi \quad (2-a)$$

$$\theta'_H(\tau) = \angle H_{max}, \quad 0 \leq \tau \leq 2\pi \quad (2-b)$$

where $H_m(\tau)$ and $\theta_H(\tau)$ are the magnitude and phase angle of H , respectively. In this approximation, H -waveform is expressed

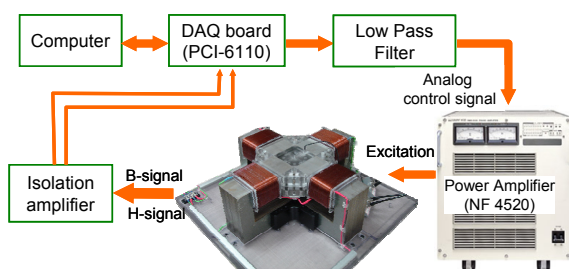

Fig. 1. A two-axes excitation two dimensional single sheet tester.

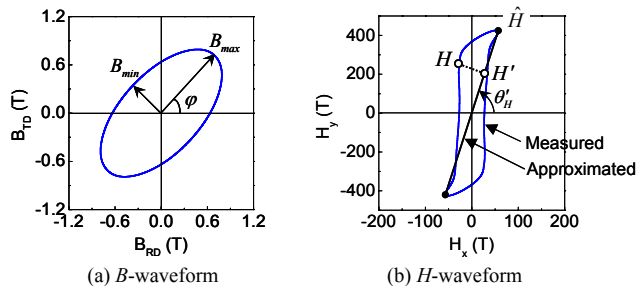

Fig. 2. Approximation of H -waveform ($B_{max}=1.0$, $\alpha=0.5$, $\varphi=45^\circ$)

as a function of direction of B , θ_B , when $(B_{max}, \alpha, \varphi)$ is defined.

III. MAGNETIC RELUCTIVITY MODEL AND FEA APPLICATION

The magnetic reluctivity model considering 2-D magnetic properties of anisotropic materials is defined as follows:

$$\begin{pmatrix} H_x \\ H_y \end{pmatrix} = \begin{bmatrix} v_{xx} & v_{xy} \\ v_{yx} & v_{yy} \end{bmatrix} \begin{pmatrix} B_x \\ B_y \end{pmatrix} \quad (3)$$

The approximated H -waveform is expressed, by using Fourier series expansion considering up to 5-th order harmonics, as follows:

$$\begin{aligned} H_x(\tau) &= \sum_{n=1}^3 H'_{(2n-1)m} \sin[(2n-1)\tau + \phi'_{(2n-1)H_m}] \cdot \cos \theta'_H \\ H_y(\tau) &= \sum_{n=1}^3 H'_{(2n-1)m} \sin[(2n-1)\tau + \phi'_{(2n-1)H_m}] \cdot \sin \theta'_H \end{aligned} \quad (4)$$

Substituting (1) to (3), and comparing (3) with (4), after some algebraic manipulations, the reluctivity tensor in (3) is derived, for fixed parameters $(B_{max}, \alpha, \varphi)$, as follows:

$$\begin{bmatrix} v_{xx} & v_{xy} \\ v_{yx} & v_{yy} \end{bmatrix} = \begin{bmatrix} \cos \theta_H & 0 \\ 0 & \sin \theta_H \end{bmatrix} \begin{bmatrix} k_1 & k_2 \\ k_1 & k_2 \end{bmatrix} \quad (5-a)$$

$$\begin{aligned} k_1 &= P(c_1 + c_2 \cos^2 \tau + c_3 \cos^4 \tau) - Q(c_4 - c_5 \sin^2 \tau + c_6 \sin^4 \tau) \\ k_2 &= R(c_1 + c_2 \cos^2 \tau + c_3 \cos^4 \tau) - S(c_4 - c_5 \sin^2 \tau + c_6 \sin^4 \tau) \end{aligned} \quad (5-b)$$

The coefficients in (5) are obtained, for a specific $(B_{max}, \alpha, \varphi)$, as follows:

$$\begin{aligned} c_1 &= R_{1H} - 3R_{3H} + 5R_{5H}, & c_2 &= 4R_{3H} - 20R_{5H}, \\ c_3 &= 16R_{5H}, & c_4 &= I_{1H} + 3I_{3H} + 5I_{5H}, \\ c_4 &= 4I_{3H} + 20I_{5H}, & c_6 &= 16I_{5H} \end{aligned} \quad (6-a)$$

$$\begin{aligned} P &= I_{B_y} / (R_{B_x} I_{B_y} - R_{B_y} I_{B_x}), & Q &= I_{B_y} / (R_{B_x} I_{B_y} - R_{B_y} I_{B_x}) \\ R &= I_{B_x} / (R_{B_y} I_{B_x} - R_{B_x} I_{B_y}), & S &= R_{B_x} / (R_{B_y} I_{B_x} - R_{B_x} I_{B_y}) \end{aligned} \quad (6-b)$$

where R_{nH} and I_{nH} ($n=1, 3, 5$) are real and imaginary parts of Fourier expansion of the magnitude of H -waveform approximated by the proposed method. The coefficients c in (6-a) are smoothed by using Bezier spline to be applied to the FEM. From (5), it is found that the number of the coefficients in the proposed method is a lot reduced compared with those in [4]-[6]. It is, therefore, expected to give better convergence characteristics when it is applied to FEM.

Fig. 3 shows the magnetic reluctivities calculated from (5) for Grain-oriented silicon steel sheet 30PG158 when the rotating flux condition is $\alpha=0.75$ and $\varphi=45^\circ$. It is observed that the curves are smooth enough to give a good convergence.

Fig. 4 compares the computed magnitudes and phase angles of H -vector using the proposed reluctivity for the case of $B_{max}=1.0$ (T), $\alpha=0.75$ and $\varphi=45^\circ$, shown in Fig. 3, with the measured ones. It can be seen that the computed H -waveform using the proposed magnetic reluctivity model has a good agreement with the measured one although the rotating field is approximated to an alternating field.

The overall flow of the FEM using the proposed reluctivity is as follows:

Step 1. Using conventional B - H curve method, analyze for one period,

Fig. 3. Magnetic reluctivities when $\alpha=0.75$, $\varphi=45^\circ$

Fig. 4. Computed and measured H -waveforms for $B_{max}=1.0$ (T), $\alpha=0.75$ and $\varphi=45^\circ$.

Step 2. Set the parameters $(B_{max}, \alpha, \varphi)$ for all elements using the analyzed results, and analyze again for one period using the proposed reluctivity. In this analysis, the derivatives, $\partial v_{ij} / \partial A_k = \partial v_{ij} / \partial \theta_B \cdot \partial \theta_B / \partial A_k$, for Newton-Raphson iteration is calculated, from Fig. 3, by using Bezier spline [6].

Step 3. Repeat the *Step 2* until converged parameters are obtained for all elements.

In the version of full paper, the proposed algorithm will be applied to the analysis of the single phase transformer core model in [6], and its results will be compared with experimental ones.

Abstract — Soft magnetic composite (SMC) material is widely applied in three-dimensional (3-D) magnetic flux machines. Conventional methods for detecting the magnetic properties of SMC material are not accurate due to the rotational magnetic domains. Taking the 3-D properties into account can help complete the understanding and modeling of the magnetization process. In order to precisely measure magnetic field distribution of the rotating flux machine, 3-D reluctivity tensor should be considered in the electromagnetic field analysis. By using a 3-D magnetic property tester, this paper presents the measurement of 3-D vector magnetic properties considering the 3-D magnetic reluctivity tensor. Moreover, finite element analysis is used in electromagnetic field calculation by means of Femap software package.

I. INTRODUCTION

One and two dimensional (2-D) measurements are widely employed for characterization of soft magnetic materials. However, they are still far from describing the actual properties of the materials, where the vector properties with 3-D magnetic fluxes should be considered [1]. By using a novel 3-D magnetic property tester developed at University of Technology, Sydney (UTS), a kind of SMC material, SOMALOY™500 developed by Höganäs AB, Sweden, is measured and analyzed [2]. A cubic SMC sample with the side length of 22 mm is cut from the cylindrical perform. Some experimental results under time-varying magnetic flux density vector \mathbf{B} loci and magnetic field strength vector \mathbf{H} loci, and the power losses when the \mathbf{B} loci are controlled to be circles with increasing amplitudes and ellipses evolving from a straight line into a circle in three orthogonal planes, respectively [3].

A 3-D reluctivity tensor which is a second-order three-dimensional full rank matrix can be constructed by means of the experimental data of \mathbf{H} vectors and \mathbf{B} vectors. Therefore, taking the off-diagonal elements into account can precisely express the relationship between \mathbf{B} and \mathbf{H} under rotational excitation conditions. The reluctivity tensor is a key factor for accurate numerical analysis of magnetic field in 3-D flux SMC electrical machines [4].

In this paper, the 3-D magnetic properties are expressed through tensor magnetic reluctivity under rotating flux conditions, which is used in the magnetic field analysis with the finite element method (FEM). A model of current-carrying

solenoid is built in Femap, and the FEM results are presented. Some key codes in the program are also presented.

II. IMPROVEMENT OF 3-D TESTING SYSTEM

A. Original Structure

The UTS 3-D magnetic property testing system consists of a tester, a digital control system, a data acquisition and three power amplifiers [2]. Fig. 1 shows the structure of the cubic sample with \mathbf{B} coils and surface \mathbf{H} sensing coils. The components of the sample surface field intensity \mathbf{H} are measured by 12 search coils and the flux density \mathbf{B} components are measured by three search coils wrapped around the cubic sample. The components of \mathbf{H} and \mathbf{B} on each coordinate axis can be calculated from the induced *emf* of the search coils by

$$H_i = \frac{1}{\mu_0 K_{H_i}} \int V_{H_i} dt \quad (i = x, y, z) \quad (1)$$

$$B_i = \frac{1}{K_{B_i}} \int V_{B_i} dt \quad (i = x, y, z) \quad (2)$$

where V_{B_i} and V_{H_i} are the terminal instantaneous voltages of the B_i and H_i search coils, K_{H_i} is the H_i search coil coefficient obtained by calibration, $K_{B_i} = N_{B_i} A_{sp}$ the coefficient of the B_i search coil, N_{B_i} the number of turns of the B_i coil, and A_{sp} the cross-sectional area of the sample.

Fig. 1. Cubic sample and \mathbf{B} , \mathbf{H} coils

Fig. 2. Improved structure

B. Improved Structure

The original tester structure can be improved considering that the surface area of the \mathbf{H} coil equals that of a side of the cubic sample and the magnetic field in the sensing area may not be uniform. An improved structure is proposed so that the \mathbf{H} coil size is minimized and it can be attached to the central area of each side of the cubic sample, as shown in Fig. 2. It has been found the field near the central area is quite uniform.

The tangential component of \mathbf{H} is continuous if no applied current flows on the sample surface. The sensing area is now centralized and the gap between sample and \mathbf{H} coil is contracted. The adoption of the guard piece which is the same material as the sample, can significantly improve the accuracy of measurement of the sample surface field since this structure can significantly decrease the equivalent reluctance of the magnetic circuit and the excitation current required to magnetize the sample can be reduced. The cubic sample, six \mathbf{H} search coils, and six guard pieces are integrated into the sample house. Furthermore, the method of wire wrapping is adopted, which can shrink the area of the circle and optimize the magnetic circuit.

C. Calibration of Sensing Coils

The \mathbf{H} coils must be calibrated for accurately measuring the magnetic field strength components. The calibration is performed in a long solenoid, which can generate a uniform magnetic field. The surface of the coil is set to be parallel to the generated field. The \mathbf{H} coil coefficient is calculated by

$$K_H = \frac{V_H}{\sqrt{2\pi f} \mu_0 H_m} \quad (3)$$

where f is the excitation frequency, V_H the *rms* value of the induced *emf*, and $\mu_0 H_m$ the peak value of the air flux density in the middle of the solenoid.

In experiment, when the magnetic field to be measured, $H = (H_x, H_y, H_z)$, is not parallel to any axis of \mathbf{H} box, the measured *emfs* in the \mathbf{H} coils can be expressed as

$$\begin{cases} E_x = -\mu_0 \left(K_x^x \frac{dH_x}{dt} + K_x^y \frac{dH_y}{dt} + K_x^z \frac{dH_z}{dt} \right) \\ E_y = -\mu_0 \left(K_y^x \frac{dH_x}{dt} + K_y^y \frac{dH_y}{dt} + K_y^z \frac{dH_z}{dt} \right) \\ E_z = -\mu_0 \left(K_z^x \frac{dH_x}{dt} + K_z^y \frac{dH_y}{dt} + K_z^z \frac{dH_z}{dt} \right) \end{cases} \quad (4)$$

Then the magnetic field components can be worked out.

III. MEASUREMENT RESULTS

By using the 3-D magnetic tester, the magnetic properties of an SMC sample have been systematically measured when the \mathbf{B} vectors with alternating, circular and elliptical loci are controlled to lie in the three orthogonal planes and the corresponding \mathbf{H} vectors have been investigated.

Fig. 3. Hysteresis loops and losses for alternating magnetizations on the x-, y-, and z-axes.

Fig. 3 plots the hysteresis loops and core losses when the \mathbf{B} is controlled to be sinusoidally alternating at 50 Hz along the x, y and z-axis, respectively. It is noticed that the loops for

the x and z axes are similar, while the y axis seems to be the easy axis, though the sample is expected to be isotropic. These measurements will provide the necessary data for modeling the reluctivity tensor and core loss.

IV. 3-D RELUCTIVITY TENSOR

In 3-D condition, \mathbf{H} and \mathbf{B} vectors are not parallel, so the x, y and z-axis components of \mathbf{H} and \mathbf{B} should be expressed as

$$\begin{cases} H_x = v_{xx} B_x + v_{xy} B_y + v_{xz} B_z \\ H_y = v_{yx} B_x + v_{yy} B_y + v_{yz} B_z \\ H_z = v_{zx} B_x + v_{zy} B_y + v_{zz} B_z \end{cases} \quad (5)$$

The reluctivity tensor which symbols to the relationship between \mathbf{B} and \mathbf{H} can be written to a second-order three-dimensional full rank matrix as

$$v = \begin{bmatrix} v_{xx} & v_{xy} & v_{xz} \\ v_{yx} & v_{yy} & v_{yz} \\ v_{zx} & v_{zy} & v_{zz} \end{bmatrix} \quad (6)$$

V. NUMERICAL ANALYSIS OF 3-D RELUCTIVITY TENSOR

Fig. 4 shows the finite element analysis of the 3-D model of a square current-carrying solenoid by using Femap software package in several directions. Based on laboratory test results, several types of experimental data at different locations by setting the parameter of the reluctivity tensor, the tendency distribution of magnetic flux density can be obtained.

(a) Diametric view (b) Front view (c) Top view of Solid
Fig. 4. FEM simulation of 3-D magnetic property model

VI. DISCUSSION AND CONCLUSION

This paper presents an improvement method of 3-D magnetic properties testing and simulation. Magnetic anisotropy is found in the 3-D measurement of SMC material. Under 3-D vector excitations, experimental data generates a magnetic reluctivity tensor which is a full matrix with off-diagonal elements due to the rotating magnetic flux. The results are verified by FEM analysis. More detailed analysis and results will be reported in the full paper.

Abstract— A new model is presented capable of taking account of the dependence of the specific loss curves (giving loss per weight versus flux density) of grain-oriented steel on the angle between the direction of the flux density and the rolling direction. It uses the loss curves in the rolling and transverse (i.e. the principal) directions only. It is assumed that, for constant loss per weight, the flux density vector traces a modified elliptic curve. The curves for flux densities not oriented in one of the principal directions are reconstructed and compared to measurements, illustrating the feasibility of the model.

I. INTRODUCTION

Grain oriented steel is routinely used in transformer cores and various shielding parts. These are invariably made of laminated steel and are designed so that the expected direction of the flux density in them should be parallel to the laminates and coincide with the rolling direction. Deviations from this ideal situation lead to additional losses. On the one hand, flux density components normal to the sheets cause large eddy currents flowing in the laminates. They can be taken into account by bulk models with an anisotropic conductivity [1], [2]. On the other hand, measurements indicate that the specific losses in the sheets (i.e. the sum of eddy current losses, hysteresis losses and excess losses, see e.g. [3]) are higher if the flux density is not parallel to the rolling direction (see Fig. 1).

The specific loss curves are obtained by measurements carried out in an Epstein frame [4] and are usually provided by steel manufacturers for the principal directions, i.e. the rolling direction of easy magnetization and the transverse direction perpendicular to the rolling direction. In some rare cases curves for intermediate directions are also measured (see Fig. 1) indicating that at angles around 60° to the rolling direction, the specific losses can be higher than at the transverse direction.

The aim of this paper is to present a model using the measured specific loss curves for the principal directions which predicts the specific loss curves in intermediate directions, too and takes account of the above behavior.

II. THE MODEL

The starting point is the well-known elliptic model often used for representing the magnetic anisotropy of nonlinear soft magnetic materials [6]. The model assumes that the loci of the magnetic flux density trace an ellipsis if the modulus of the magnetic field intensity is kept constant. This cannot

reproduce the typical property of grain-oriented steel having the worst direction of magnetization not in the transverse direction, but also at angles around 60° with respect to the rolling direction. Following an idea of [7] using modified elliptic curves to describe the loci of the magnetic field intensity for constant values of the co-energy density, a modified elliptical model capable of mimicking this behavior has been proposed recently [8].

Turning to the question of specific losses in anisotropic materials, let p denote the specific loss per unit weight of a grain-oriented steel sheet and B the modulus of the magnetic flux density. Typical measured $p(B)$ (or $B(p)$) curves obtained in an Epstein-frame [4] are shown in Fig. 1 [5]. The curve marked by 0° has been obtained on a cut wherein the magnetic flux density vector \mathbf{B} is parallel to the rolling direction whereas the curve denoted by 90° shows the p -values if \mathbf{B} is perpendicular to the rolling direction, i.e. it points in the transverse direction. For most commercial sheets, these two curves which will be denoted by $B_1(p)$ and $B_2(p)$, respectively, are routinely provided by the manufacturer. It is remarkable that the losses in $B_2(p)$ for flux densities in the transverse direction, are higher than in $B_1(p)$ with \mathbf{B} pointing in the rolling direction.

Fig. 1. Measured loss curves of grain-oriented steel in various directions

Let the unit vector \mathbf{e}_1 point in the rolling direction and the unit vector \mathbf{e}_2 in the transverse direction. Our proposed model predicts the losses for an arbitrary vector \mathbf{B} by assuming that, for constant p , \mathbf{B} traces a modified elliptical curve:

$$\left(\frac{\mathbf{B} \cdot \mathbf{e}_1}{B_1(p)}\right)^n + \left(\frac{\mathbf{B} \cdot \mathbf{e}_2}{B_2(p)}\right)^n = 1. \quad (1)$$

The exponent n defines the curve: a value of $n=2$ describes an ellipsis, $n=1$ corresponds to a straight line and for $n \rightarrow \infty$ the curve becomes a rectangle. Fig 2 shows the curve for $n=1.5$ at $p=1.8$ W/kg.

If the model is used to predict the specific losses from the magnetic field distribution obtained by a finite element analysis (as described in e.g. [2]), p has to be determined from (1) if \mathbf{B} is given. Since both $B_1(p)$ and $B_2(p)$ are monotonous functions, the nonlinear equation (1) can be easily solved by a simple regula falsi iterative method.

Fig. 2. The loci of \mathbf{B} described by (1) with $n=1.5$ for $p=1.8$ W/kg

III. MODEL TUNING

The key question of the model is the choice of the parameter n . For the particular steel represented in Fig. 1, the measured loss curves for some intermediate angles are also shown in the figure [5]. Using these curves, least-square techniques can be employed to determine the parameter n . It can be made to depend on p to improve the fit. This will be shown in the full paper.

On the other hand, in most practical cases, the measurements for the intermediate angles are not provided. It is, therefore, a relevant question, whether it is possible to obtain a model with a fixed value of n which reproduces the typical behavior seen in Fig. 1, i.e. that the losses for angles around 60° are higher for larger values of B than in the transverse direction. The answer is affirmative: the loss curves for various directions of \mathbf{B} with the choice $n=1.5$ are shown in Fig. 3. Comparison with Fig 1 indicates a good qualitative

agreement. It is, therefore, reasonable to use a value around 1.5 for n if no information on intermediate angles is available.

Fig. 3. Loss curves of grain-oriented steel in various directions reconstructed from the curves in the principal directions using (1) with $n=1.5$

Transient Performance of an Induction Motor with the Smith Connection

T. F. Chan¹, L. L. Lai², and L. T. Yan¹

Abstract — This paper investigates the starting and braking performance of a three-phase induction motor with the Smith connection. A time-stepping, coupled circuit, two-dimensional finite element method is used for the study. It is found that for certain rotor positions, short periods of speed reversal could happen during starting. Severe torque oscillations at low speeds could be excited when the single-phase voltage is applied at a positive zero-crossing instant. Optimum initial rotor position for starting has been identified. Two methods of electric braking, namely capacitor braking and regenerative braking, are also investigated.

I. INTRODUCTION

The Smith connection (Fig. 1) enables a three-phase induction motor to be started and run on a single-phase supply [1] and is useful for drive applications where only a single-phase supply is available. Transient performance of this asymmetrical motor system, however, has seldom been reported, in particular the dynamic motor response at very low speeds. The analysis is complicated due to the general phase imbalance, heavy saturation, existence of space and time harmonics, deep-bar effect in the rotor conductors, and mechanical motion. A rigorous and comprehensive analysis therefore requires an approach based on the finite element method (FEM). In this paper, a time-stepping, coupled circuit, two-dimensional (2-D) FEM [2] is used for studying the speed and torque responses during motor run up, with special emphasis on the low-speed region. Two important factors that may affect the run-up performance of the Smith motor system, namely, the initial time phase of the supply voltage and the initial rotor position, will be investigated. Typical motor transient run up characteristics of the induction motor will be presented. Besides, the transient performance for two braking modes will also be studied.

II. ANALYSIS METHOD

The time-stepping, coupled-circuit, two-dimensional finite element method (2-D FEM) developed in [3] will be the basis for the present study. Fig. 2 shows the schematic diagram of the FEA which consists of the following steps:

- Establish the state model for the stator circuit connection based on the circuit equations. For the Smith motor circuit, ten state variables, and hence ten state equations, are needed.
- Establish the rotor circuit model: the model will take into account the effect of uneven current distribution in the rotor bars and end rings.
- Coupled circuit and field analysis: the stator and rotor

circuit equations are coupled to the 2-D FEM equations with magnetic vector potentials as variables. The field and circuit equations are solved simultaneously for each rotor time step.

- Time-stepping: the Maxwell's stress method [4] is used to compute the electromagnetic torque and hence the rotor dynamics for rotor time-stepping.

Fig. 1 Smith connection for single-phase operation of a three-phase induction motor.

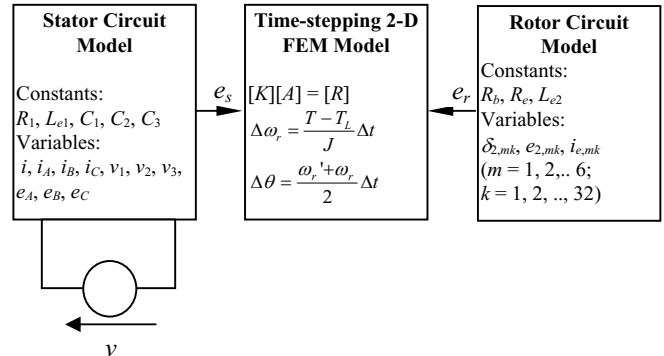

Fig. 2 Time-stepping 2-D FEM model for analysis of induction motor with the Smith connection.

III. RESULTS

A. Starting Performance

The subsequent computations refer to a 2.2-kW, 380-V, 50-Hz, four-pole, three-phase induction motor with the Smith connection (Fig. 2). The motor is started on no load with the starting capacitances ($C_1 = 147 \mu\text{F}$, $C_2 = 35 \mu\text{F}$ and $C_3 = 70 \mu\text{F}$) initially in the circuit. At a rotor speed of 1200 r/min, the starting capacitances are replaced by the running capacitances ($C_1 = 6 \mu\text{F}$, $C_2 = 30 \mu\text{F}$ and $C_3 = 60 \mu\text{F}$) in order to reduce the steady-state torque pulsations.

Two motor parameters that affect the rotor run-up performance are identified. They are the initial phase angle θ_u of the applied voltage and the initial rotor position θ_r . The angle $\theta_u = 0$ means that the motor is started at a voltage zero, while $\theta_u = 90^\circ$ means that the motor is started with maximum instantaneous voltage. The angle $\theta_r = 0$ refers to the rotor position such that the centre line of a rotor slot coincides with the centre line of the first slot of stator phase-A winding. The effect of θ_u on motor torque response, when $\theta_r = 0$, is illustrated in Table I. The initial motor torque is negative in general, implying that a brief period of rotor speed reversal would precede motor run up. It is also found that severe torque pulsations will be produced at low speeds when the the motor is started with $\theta_u = 90^\circ$ and $\theta_r = 0^\circ$, as shown in Fig. 3.

The effect of initial rotor position θ_r on the motor response at starting is shown in Table II. We may conclude that the experimental motor should be started with θ_r between 4° and 9° in order to avoid initial rotor speed reversal, and the best initial speed response is obtained when $\theta_r = 6.75^\circ$.

TABLE I
EFFECT OF INITIAL VOLTAGE PHASE ANGLE ON MOTOR RESPONSE AT LOW SPEEDS ($\theta_r = 0$)

Initial voltage phase angle θ_u ($^\circ$ e)	Initial value of motor torque (N.m)	Maximum value of torque during rotor speed reversal (N.m)	Duration of rotor speed reversal (ms)
90	-1.45	-12.9	6.1
60	-1.08	-15	6.7
30	-0.36	-14.4	7.9
0	0	-14.0	9.5

TABLE II
EFFECT OF INITIAL ROTOR POSITION ON NO-LOAD MOTOR RUN-UP PERFORMANCE

Initial rotor position θ_r ($^\circ$ e)	Initial value of motor torque (N.m)	Maximum value of negative torque (N.m)	Duration of rotor speed reversal (ms)
0	-1.45	-9.74	6.3
2.25	-0.62	-2.36	2.7
4.5	+0.95	nil	nil
6.75	+1.98	nil	nil
9	+0.42	-0.55	1.5

Fig. 3 Computed transient motor run-up performance at no load with starting capacitances ($\theta_u = 0$, $\theta_r = 0$): (a) Torque-time characteristic; (b) Speed-time characteristic.

B. Capacitor Braking

When the single-phase supply is cut out with the induction motor running at normal speed, the capacitances in the motor

circuit is sufficient to cause self-excitation and the machine runs temporarily in the generation mode. An electrical braking torque is produced and the rotor kinetic energy is converted to losses in the motor windings. Fig. 4 shows the speed and torque curves of the motor which is started on no load with the running capacitances and at $t = 600$ ms the supply is cut off. It is observed that an average negative torque is produced and the speed drops from about 1500 r/min to 1000 r/min within 1.2 s.

Fig. 4 Transient performance of motor started on no load with running capacitances, followed by capacitor braking.

C. Regenerative Braking

When the load is overhauling in nature, such as in crane hoists or winders, the motor may be driven by the load in the reverse direction. The motor enters the regenerating braking mode and at steady state the motor speed is maintained at a value slightly above synchronous speed. Electric energy is then returned to the single-phase supply. Fig. 5 shows the transient motor performance when a negative torque of 18.6 N.m is applied to the motor at standstill and with $C_1 = 16 \mu\text{F}$, $C_2 = 24 \mu\text{F}$ and $C_3 = 48 \mu\text{F}$.

Fig. 5 Transient performance of motor when driven in the reverse direction.

Multi-objective Shape Optimal Design of PMLSM Utilizing Response Surface Method and Grid Computing

Hee Sung Yoon, Nyambayar Baatar, Hong-soon Choi*, and Chang Seop Koh
 Chungbuk National University, *Kyungbuk National University

Abstract — A 9 pole 10 slot permanent magnet linear synchronous motor (PMLSM) is optimized in Pareto sense to reduce the detent force and to maximize the thrust force per mass of armature core. In the optimization, the objective functions are approximated by using response surface method with radial basis function to reduce the computing time related with finite element analysis. Additionally, the objective function values at sampling points are computed by using grid computing with 60 personal computers.

I. INTRODUCTION

Conventionally permanent magnet linear synchronous motors (PMLSM) with the structure of ($2\tau_p=3\tau_s$) or ($4\tau_p=3\tau_s$), where τ_p and τ_s are PM pole and winding slot pitches, respectively, have been exclusively used for general purpose applications in factory automation. However, the PMLSMs employing these conventional structures such as PMLSM with 8 poles and 12 slots or PMLSM with 12 poles and 9 slots, generate very big detent force composed of cogging and end force, and impede precise position and speed control purpose applications [1].

Very recently a new structure of ($9\tau_p=10\tau_s$) with two extra end-teeth without armature winding, as shown in Fig. 1, is developed based on that of ($8\tau_p=9\tau_s$) in rotating PM motor, and is proven to give almost no-cogging force [2]. In the new structure, each winding slot locates at $\pi/10$ shifted position from its previous slot, and only generates very small $10n$ order harmonic components of cogging force. This structure, although having very small cogging force, still has quite big detent force due to the end forces acting on the left and right end sides.

In this paper, in order to reduce the detent force and maximize the thrust force per mass of a PMLSM at the same time, the new structure of ($9\tau_p=10\tau_s$) is adopted and the shape of the exterior teeth are optimized in Pareto-optimal sense.

II. DESIGN PARAMETERS AND OPTIMIZATION ALGORITHM

A. Design Objectives and Parameters

The model PMLSM is initially designed as shown in Fig. 1 and Table I. The optimization targets are defined as follows:

$$\begin{aligned} \text{Minimize} \quad & \text{Cogging force} & (1-a) \\ \text{Maximize} \quad & \text{Back-emf/Armature mass} & (1-b) \end{aligned}$$

where the cogging force is computed by using nodal force method and back-emf by calculating the flux linkage of arma-

ture winding from the finite element analysis (FEA) results obtained at 34 moving positions of the primary during a pole pitch without applying armature current. The back-emf per mass is approximated as its maximum value.

In order to achieve the design objectives, the three design parameters are defined as shown in Fig. 2, where the parameter R determines the chamfering while X_1 and X_2 total length and mass of the armature core.

B. Optimization Algorithm

The two design objectives *Minimizing cogging force* and *Maximizing Back-emf/Armature mass* are in conflict with each other. For example, the exterior teeth might have enough thickness for minimizing the cogging force but it will decrease the Back-emf/armature mass via increasing armature mass.

In this paper, hence, Pareto-optimization technique is adopted. The fitness value for a design parameter vector, \mathbf{x}_i , is assigned as its corresponding Pareto strength [3].

As an optimization algorithm, $(1+\lambda)$ evolution strategy is employed. At the same time, in order to reduce the computing time required in non-linear FEA for objective function calculation, the two objective functions defined in (1-a) and (1-b) are approximated in design space by using response surface method with radial basis function. In the response surface construction, sampling points are generated by using random Latin hypercube design, and corresponding objective function values are computed through FEA.

III. GRID COMPUTING BASED ON INTERNET

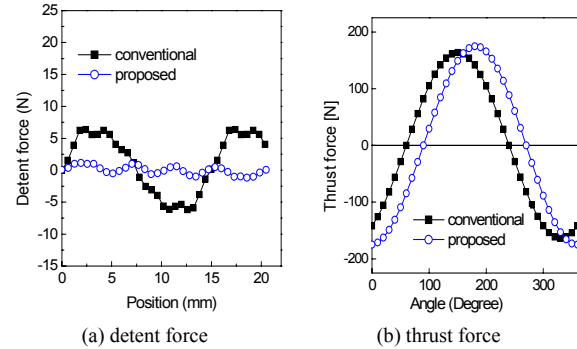

Among the whole process of optimization, most of the computing time is related with non-linear FEA for calculating objective function values. Even when the objective functions are approximated in design space by using response surface method, a lot of computing time should be given to the preparation of the sampling data, i.e. calculation of the objective function values at sampling points. Since the objective function values at sampling points are independent on each other and can be obtained through off-line FEA, the computing time can be dramatically reduced by utilizing grid computing system based on internet.

A grid computing system is generally composed of standardized Internet protocols such as TCP/IP, HTTP based web services, XML, etc. Such protocols have many advantages such as access to a number of computers in Internet, ease of communication, reliability, and firewall friendly. In this paper, the *sky@home* grid framework, which is developed by MEC Korea, Co. Ltd., based on *Korea@home* project [4]-[5], is adopted for the construction of a temporary and dedicated system. In this system, there are, as shown in Fig. 3, three major elements; users which request scheduled job, a server which distributes the job to computing agents according to job scheduling, and computing agents which actually perform assigned job. The user registers a job by sending specific programs and required data to the server. Then the server distributes the job to computing agents, and gathers the calculated results. The overall flow of the grid computing suggested in this paper is summarized as follows:

- Step 1 - Generate sampling points for predefined objective function in design space.
- Step 2 - Request a job by sending FEA, mesh generation programs and all sampling point data to server,
 - Repeat for all sampling points
 - ~ [Server]: to a computing agent, assign a part of job using dynamic load balancing, and send programs and assigned sampling point data

(a) detent force (b) thrust force
Fig. 5. Comparison of the performances.

- ~ [Agent]: generate finite element meshes for the sampling points, and calculate the objective function values and return the results to server,
- ~ [Server]: return all computed results to User,

IV. OPTIMIZATION RESULTS AND DISCUSSION

The suggested optimization algorithm is applied to an optimal design of the PMLSM shown in Fig. 1 and Table I. In the optimization, 180 sampling points are generated by using random Latin hypercube design, and 60 personal computers (PC) are employed as computing agent. Each computing agent performs the calculation of objective function values for 3 sampling points i.e., 102 times of non-linear FEA.

Fig. 4 shows a comparison of the optimized shape of the proposed PMLSM with a conventional one having 12 pole and 9 slots. It can be seen that the proposed PMLSM has 11.15(mm) longer armature than the conventional one. Fig. 5 shows the detent and thrust forces of the proposed PMLSM together with those of conventional one. It is shown that the proposed PMLSM gives both smaller detent force and higher thrust force.

Abstract — This paper presents the equivalent 2D FEA method for back-EMF of high speed permanent magnet synchronous motor in order to consider a leakage flux in the end region of stator and air-gap. The presented method can be also applied to low speed SPMSM that has a small air-gap length. For the general PMSM having small air-gap provides precise 2D FEA result of back-EMF. However, for the high speed PMSM, due to large air-gap length flux density in the air-gap is not uniform along axis direction. Therefore, 2D FEA does not provide precise analysis results for design. Presented analysis method is applied to the high speed SPMSM using a can, and verified by 3D FEA and experimental results.

I. INTRODUCTION

In maximum torque control of SPMSM, d-axis current will be zero ($i_d=0$) and at that time the electric torque equation is represented by (1). In equation (1), we can know the back-EMF is very important parameter that governs a performance of motor. Therefore, it is important to estimate accurate back-EMF.

$$T_e = \frac{3P}{2} (i_q \times \Lambda_{mf}) \quad (1)$$

where, T_e is electric torque, i_q is q-axis current, P is number of pole, and Λ_{mf} is back-EMF constant for peak of phase voltage per mechanical angular velocity. Generally, SPMSM has small air-gap length, therefore, leakage flux in the end of stator is small, and therefore, there is no problem with back-EMF analysis result. However, a can should be used for the high speed SPMSM, and this leads to the increase magnetic air-gap length and increased leakage flux in the rotor and stator end region [1]-[2]. In addition, for the margin of rotor dynamic, high speed motor generally has short axial length. Therefore, the effect in the stator end region becomes significant. And, the back-EMF analysis results by 2D FEA have significant difference with experiments from 10% to 3%. It is obvious that the 3D FEA provides more precise result. However, modeling and computation are expensive. Therefore, this paper presents the 2D equivalent analysis methods.

II. MODEL AND ANALYSIS METHOD

A. Limitations of 2D FEA Model with Large Air-gap

Fig. 1 shows the 2D FEA model of high speed SPMSM having relatively large air-gap comparing to low speed SPMSM. For the analysis of 2D FEA, it is assumed that the analysis model has symmetric along axial direction with

Fig. 1. 2D FEA model of high-speed motor with can

symmetric flux distribution. However, due to axial leakage flux, 2D FEA results shows higher back-EMF comparing to experiments.

B. Equivalent 2D FEA Model and Assumption

Fig. 2(a) shows a equivalent 2D FEA model corresponding to 2D FEA model, and derating coefficient of back-EMF is calculated by equivalent 2D FEA. In the Fig. 2(a), L is the stack length of stator and R is outer radius of rotor.

For the equivalent 2D FEA, following assumptions are made.

Firstly, the flux in tooth and yoke is not saturated. In general motor design, flux in tooth and yoke is designed to be not saturated. Therefore, the first assumption is reasonable. Secondly, there is linear relation between flux density on a surface of teeth in 2D FEA model and equivalent 2D FEA model. The second assumption is reasonable by the first assumption. In equivalent 2D FEA model, to block flux saturation on teeth and yoke, and to prevent leakage flux that can go to yoke directly, length of teeth, width of yoke and length to yoke from end of permanent magnet is modeled by $3R$, L and $2L$ for each other.

Fig. 2(b) shows definition for line regions of $(slot\ length)/2$ and $(surface\ of\ teeth)$. Line regions have the length that is equal to stack length of stator and y-axis position that is equal to length from zero point to half of slot length by radial direction and length from zero point to teeth for each other.

$$EMF_{derating} = \frac{B_{avg}|_{(slot_length)/2}}{B_{peak}|_{(surface_of_teeth)}} \quad (2)$$

$$EMF_{final} = EMF_{derating} \times EMF_{2d-FEM} \quad (3)$$

Fig. 2. (a) Equivalent 2D-FEM Model, (b) Definition of line region for $(surface\ of\ teeth)$ and $(slot\ length)/2$

The derating coefficient of back-EMF by equivalent 2D FEA is represented by (2), and final estimated back-EMF is represented by (3). $EMF_{derating}$ is derating coefficient of back-EMF, $B_{avg}|_{(slot\ length)/2}$ is the average flux density at $(slot\ length)/2$ line region, $B_{peak}|_{(surface\ of\ teeth)}$ is the peak flux density at $(surface\ of\ teeth)$ line region, and EMF_{final} is final estimated back-EMF by 2D FEA and equivalent 2D FEA.

Fig. 3 shows flux density distribution at $(surface\ of\ teeth)$ line region. When $B_{peak}|_{(surface\ of\ teeth)}$ is selected, flux density at $(surface\ of\ teeth)$ should be saturated and has constant value at center of teeth by axis direction. If flux density is not saturated around center of teeth, stack length of stator(L) of equivalent 2D FEA model could be modified to be longer more than actual stack length of stator to get more precise result.

Fig. 3. Definition of saturation flux density on surface of teeth (red line)

C. Analysis Model

Fig. 4 and Table I show the cross-section and brief specifications of the analysis model-1.

Fig. 5 and Table II show the cross-section and brief specifications of the analysis model-2. Especially, permanent magnet of model-2 is buried in magnetic shaft so that flux leakage and drop of back-EMF is larger.

III. RESULT AND DISCUSSIONS

Fig. 6(a) and Fig. 7(a) show the comparison of back-EMF of model-1 calculated by 2D FEA, corrected by equivalent 2D FEA, and measured or 3D FEA back-EMF waveform for each analysis model-1 and model-2. And Fig. 6(b) and Fig. 7(b) show the flux density distribution of equivalent 2D FEA at the position of $(slot\ length)/2$ and $(surface\ of\ teeth)$ along axis for each analysis model-1 and model-2.

Table III shows result of back-EMF peak by 2D FEA, corrected by equivalent 2D FEA, and measured or 3D FEA back-EMF waveform, and error of corrected back-EMF by experimentally measured or 3D FEA.

TABLE III
BRIEF SPECIFICATIONS OF ANALYSIS MODEL-2

Analysis Model	2D FEA	Equivalent 2D FEA	Experimental	3D FEA	Error
Model-1	242.77V	234.52V	233.29V	-	0.5%
Model-2	192.67V	175.52V	-	176.43V	0.5%

Fig. 6. (a) back-EMF, (b) flux density each line region

Fig. 7. (a) back-EMF, (b) flux density each line region

IV. CONCLUSION

High speed SPMSM with large magnetic air-gap has flux leakage more than low speed SPMSM in air-gap and stator because of can and larger mechanical air-gap for reducing eddy current loss in can and core loss of stator.

In this paper, correction method of back-EMF is suggested by equivalent 2D FEA, and that is verified by experimental measurement or 3D FEA. And the result of suggested method is very precise with 0.5% error comparing to experimental measurement or 3D FEA.

Abstract—The goal of this paper is the simulation of an induction motor driven with a PWM three phase bridge. The approach taken here decouples the circuit simulation from the electromagnetic field simulation by first constructing a performance model of the machine using 2d finite element analysis. The model consists of the complete matrix of the self- and mutual inductances of the stator windings and each of the rotor bars. Skew is taken into account by a correction applied to the winding-bar inductance entries in the matrix.

I. INTRODUCTION

Induction motor design has more than a century of history, but recently a new approach has become necessary. The advent of inexpensive power electronics allows complete control over the synchronous frequency and phase voltage, which gives better performance for variable speed drives but also gives rise to new design challenges. Understanding the design trade-offs requires a multiphysics approach with cosimulation of the electromagnetic and circuit physics. However, the time scale is different for these two domains: the motor rotates at speeds on the order of 10-100 Hz, whereas the PWM bridge usually switches at frequencies on the order of 10-100 kHz. A time-stepping finite element analysis coupled to the circuit equations [1,2] has a prohibitive computational cost if the time step is small enough to capture the switching waveform, since it requires on the order of 10000 time steps to simulate even one revolution of the rotor. This cost is exacerbated if skew is present in the stator or rotor since this requires either the simultaneous solution of several 2d slices [3] or a 3d approach [4] which would be intractable. A 2d unskewed time-stepping approach with coupled circuit equations to a PWM three-phase bridge is presented in [5] and [6], but in both cases the authors do not give the switching frequency or the computational cost of the method.

The alternative is to decouple the electromagnetic and circuit equations. This necessitates a two step process, where the first step is to use finite element analysis (either 2d or 3d) to create a performance model of the motor, after which a time-stepping simulation of the circuit coupled to the performance model is performed in a second step. The conventional equivalent circuit model is not suitable for the performance model, since it treats each phase independently, whereas in reality there is significant coupling between the phases. One successful approach [7-9] uses a D-Q model for the rotor. A similar approach [10] uses an impedance matrix model for the stator coupled with a harmonic decomposition of the rotor currents. A more detailed comparison of these methods is given in [11].

II. METHOD

The approach introduced here uses finite element analysis to create a full impedance matrix model of the motor including the mutual inductances between rotor bars and also between stator windings and rotor bars. This is in contrast to [10] which uses the impedance matrix only for the stator windings.

A. Motor performance model

The full motor impedance matrix can be decomposed into three inductance matrices and two resistance matrices. In the following, a subscript capital ‘‘A’’ refers to the stator windings, while a lowercase ‘‘a’’ refers to the rotor bars. The three inductance matrices are: L_{AA} , a 3×3 matrix of the mutual inductances between stator windings, L_{aa} , a $N_{\text{bar}} \times N_{\text{bar}}$ matrix of mutual inductances between rotor bars, and L_{aA} , a $3 \times N_{\text{bar}}$ matrix of mutual inductances between stator windings and rotor bars. The two resistance matrices are: R_A , a 3×3 diagonal matrix of the resistances of each stator winding, and R_a , an $N_{\text{bar}} \times N_{\text{bar}}$ matrix of rotor resistances. We also use $L_{aA} = L_{AA}^T$, and note that this matrix is actually a function of the rotor position. Also note that the skin-effects due to the PWM will not be taken into account in this model, since it assumes that the current distribution in the rotor bars is fixed.

B. State equations

Given the inductance and resistance matrices, the state equations for the stator and rotor are:

$$V_A = R_A \cdot I_A + L_{AA} \cdot dI_A/dt + L_{aA} \cdot dI_a/dt + dL_{aA}/dt \cdot I_a \quad (1)$$

$$0 = R_a \cdot I_a + L_{aa} \cdot dI_a/dt + L_{aA} \cdot dI_A/dt + dL_{aA}/dt \cdot I_A \quad (2)$$

where I_A is the vector of stator winding currents, I_a is the vector of rotor bar currents, and V_A is the vector of stator winding voltages. Solving the second equation for dI_a/dt gives:

$$dI_a/dt = -L_{aa}^{-1} (R_a \cdot I_a + L_{aA} \cdot dI_A/dt + dL_{aA}/dt \cdot I_A) \quad (3)$$

Substituting this into the first equation and collecting factors of the current terms gives:

$$V_A = (R_A - L_{aA} \cdot L_{aa}^{-1} \cdot dL_{aA}/dt) \cdot I_A + (dL_{aA}/dt - L_{aA} \cdot L_{aa}^{-1} \cdot R_a) \cdot I_a + (L_{AA} - L_{aA} \cdot L_{aa}^{-1} \cdot L_{aA}) \cdot dI_A/dt \quad (4)$$

Equation (4) can be solved for dI_A/dt in conjunction with the circuit equations of the three-phase PWM bridge.

C. Matrix Structure

The physics of the induction motor imply that there are far fewer unknowns in the model than the number of matrix entries. This section gives the detailed structure of each

matrix, which allows it to be represented more economically and, more importantly, determined more accurately.

A. Stator matrices

Assuming a balanced symmetric three-phase winding, the stator inductance matrix L_{AA} has only two independent values, the self-inductance and the mutual inductance between any two stator phases. The stator resistance matrix R_{AA} is diagonal with only one independent value.

B. Rotor matrices

By symmetry, and ignoring the effect of stator slots, the rotor bar-bar inductance matrix L_{aa} is a symmetric Toeplitz matrix, which means it has only $N_{bars}/2+1$ independent values. Solving the state equations requires the inverse of L_{aa} , which is also Toeplitz and symmetric, and can be precomputed before the circuit simulation. The rotor resistance matrix is tridiagonal (the off-diagonal terms are due to end-ring resistance).

C. Stator-rotor matrix

The mutual inductance matrix between stator winding and rotor bars is position dependent, but the entire matrix can be represented by a function of the angle between the stator winding and the rotor bar. Since this function is even and periodic, a Fourier cosine series can be used to represent it.

III. DETERMINATION OF MATRIX VALUES

The matrix values are determined using a least squares fit to three time-harmonic finite element solutions. The first solution is at the rated voltage and slip, and is quasi-nonlinear in that permeabilities are taken from the material B-H curve at the RMS field values. The permeabilities are frozen for the other two solutions, the first of which excites one stator winding, the second excites one rotor bar.

IV. RESULTS AND CONCLUSION

This model was validated by comparison to a time-stepping transient simulation of a 12 slot, 13 bar, 4 pole induction motor at 1000 rpm and driven with sinusoidal voltages. Comparison of the rotor bar currents (Fig. 1) shows that the model agrees well with the time-stepping simulation and also shows that it captures effects which are not present in the simpler D-Q models (the ripple on the bar currents). It should be noted that each time step of the circuit simulation requires several matrix multiplies, however the entire simulation including the FE solves for parameter estimation is more than 100 times faster than the time-stepping transient FE simulation. Finally, Fig. 2 shows the waveforms from a simulation with a PWM three-phase bridge. In conclusion it can be said that this model has been demonstrated to be accurate and compatible with a circuit simulator.

Design of a Dual-Rotor Dual-Output Radial-Flux Motor for Variable Speed Air Conditioners

Min-Fu Hsieh¹, Yu-Han Yeh¹, D. G. Dorrell², and Samsul Ekram¹

¹Department of Systems and Naval Mechatronic Engineering, National Cheng Kung University, Tainan, Taiwan

²Faculty of Engineering, University of Technology, Sydney, Australia

Abstract—This paper presents the design, analysis and test of a dual-rotor, dual-output-shaft, radial-flux, PM BLDC motor. In conventional air conditioners, two motors are usually used to drive the condenser and evaporator. This paper develops a motor with two rotors and two shaft outputs as an alternative. The motor has an inner and outer rotor with a stator in between which is toroidally-wound (such that the two rotors are synchronous). The power sharing on the two rotors is designed to meet the requirement of the condenser and evaporator. Finite element analysis (FEA) is employed to verify the design. A prototype is made and tested for performance evaluation. Surface (radial) windings for individual rotors to achieve asynchronous rotation between the rotors are also investigated using FEA.

I. INTRODUCTION

Some applications, such as the condenser and evaporator drives in an air conditioner, require two electric motors of different speeds and power ratings in the same unit for high efficiency operation. The power rating of the evaporator motor is less than that of the condenser motor. Usually, two independent motors of appropriate ratings are used. Alternatively, one motor with two side shaft outputs can be utilized although it may not meet the requirement for the different power ratings and cause low system efficiency.

This paper aims to develop a radial-flux PM brushless DC motor with dual rotors, dual air-gaps and two output shafts to fit the demand of air conditioners, as illustrated in Fig. 1(a). Dual rotor induction machines were first reported by Kelly [1]. Qu and Lipo [2-3] discussed dual-rotor, radial-flux, toroidally-wound PM machines. However, the machine combined the two rotors to form a joint shaft output. The characteristics of the individual rotors were not discussed and it is not suitable for the application here. Some comparative analyses for dual-air-gap radial-flux machines and axial-flux machines were described in [4-6]. Both types of machines were designed to produce a joint shaft output.

In this paper, the individual specifications of the inner and outer rotors are first determined from the load requirement of the condenser and evaporator in an air conditioner. With a toroidally-wound stator [2], the two rotors are designed to satisfy the two output power ratings. Hence, this configuration has a different design principle from that presented in [2-3]. It only has one control and allows the two rotors to run only at the same synchronous speed. To explore the feasibility of operating the two rotors asynchronously, the stator can be radially-wound in slots with two independent winding sets, as shown in Fig. 1 (b). In this paper, FEA is conducted to verify the design and a prototype machine is fabricated. Experiments are carried out to evaluate the machine performance.

II. MACHINE SPECIFICATIONS AND DESIGN

The dual-shaft (dual-rotor), radial-flux, permanent-magnet (DSRFPM) machine has a power sharing ratio for the rotors of 62.5 % and 37.5 %. This is obtained from a total power rating of 80 W, as indicated in Table I. This specification was derived from the test data of an air conditioner manufacturer. At a speed of 1150 rpm, the two rotors should be able to separately offer 50 W and 30 W at 35 V. The outer rotor, with a larger diameter, is more suitable as the larger condenser drive while the inner one is used as the evaporator drive. When designing the DSRFPM motor, the output characteristics of both rotors can be regulated by other parameters such as magnet length, etc., to meet the specification (Table I).

Some air conditioners may require the evaporator to operate with variable speed. For the present study, the evaporator is set to run at 1150 rpm, 950 rpm and 850 rpm while the condenser remains at 1150 rpm.

Fig. 1. DSRFPM motor with (a) toroidal and (b) radial windings.

TABLE I
DSRFPM MOTOR SPECIFICATIONS

Parameter	Value	Parameter	Value
Rated voltage [V]	35	Overall rated power [W]	80
Outer rotor power [W]	50	Inner rotor power [W]	30
Rated speed [rpm] (cond.)	1150	Rated torque [N-m] (cond.)	0.415
Rated speed [rpm] (evap.)	1150 (regulable to 950, 850)	Rated torque [N-m] (evap.)	0.249
Magnet (NdFeB)	Br = 1.243 T; Hcb = 943kA/m; Hcj = 1469kA/m		

The stator has 18 slots while each rotor has 12 poles. The effective length for both rotors is the same but the diameters are different. The torque of a motor can be expressed as:

$$T = kD^2L \quad (1)$$

where k is a constant for the electric and magnetic loadings, D is the diameter of the rotor/air-gap, and L is the motor stack length. The ratio of the inner diameter to the outer diameter (D_i/D_o ratio) can roughly determine the load sharing characteristics for the two rotors. An appropriate selection of the length-to-diameter ratio (L/D ratio) allows the motor to be compact, hence increasing power density. The main dimensions of the design results are shown in Table II.

TABLE II
DESIGN RESULTS FOR DSRFPM MOTOR

Parameter	Value	Parameter	Value
Outer rotor diameter [mm]	79.9	Air-gap length [mm]	0.67
Inner rotor diameter [mm]	46.7	Magnetic length [mm]	3
Stack length [mm]	25.6	Air-gap Flux density [T]	0.92

Fig. 2. Asynchronous flux distributions for two different relative rotor positions at: (a) 1150 rpm/950 rpm and (b) 1150 rpm/850 rpm

III. FINITE ELEMENT ANALYSIS

FEA is used to verify the design. The toroidally-wound arrangement (which has synchronous-speed rotors) was studied but is omitted in this digest. For the radially-wound stator (Fig. 1), the speeds of the inner and outer rotors can be asynchronous. Example flux distributions are given in Figs. 2(a) and (b) (1150 rpm outer - 950 rpm inner; 1150 rpm outer - 850 rpm inner); they show some flux interaction which varies with the relative position of the two rotors and their position with respect to the stator. Nevertheless, the flux linkage from the other side of the stator will still contribute to torque production with a noticeable but minor effect. In Fig. 3, the air-gap flux density for individual rotors at the three speed ratios is not significantly affected by the asynchronous speeds between the two rotors. Another simulation (result not presented here) also reveals that the peak flux linkage in any phase of the inner stator for the 1150 rpm - 850 rpm case drops by only about 10 % compared to the synchronous case. The performance drop seems acceptable when compared to the advantages gained from the machine configuration. This indicates that it is feasible to utilize radial windings in the DSRFPM machine for asynchronous operation. The complete simulation results will be presented in the final manuscript.

The DSRFPM design was fabricated (Fig. 4) and tested to verify the design and FEA analysis. The verification proved successful. Detailed findings are omitted here; however, the synchronous operation of the rotors over a speed range is shown in Fig. 5, where the test power sharing matches that of the design. Also, the efficiency for both rotors is around 85 %.

IV. CONCLUSION

A dual rotor, dual output shaft, radial flux, permanent magnet brushless DC motor has been developed for a variable-speed air conditioner. The two rotors have been designed to meet the requirement for the condenser and evaporator under

the machine configuration. FEA and experiments were carried out to verify the design. The design successfully achieved the requirement. Also, from the simulation, the performance drop due to flux interaction between the two rotors during asynchronous operation was found to be acceptable. From the results presented in this paper, a cost-competitive high-power-density motor design, suitable for use in an air conditioner application, has been achieved.

Abstract—An approach for synthesizing electromagnetically excited vibrations in electrical machines is presented. The structural vibration responses for a machine’s generic set of force excitation shapes are calculated. They are scaled by the operating point dependent force excitation amplitudes and superposed. This leads to a computationally efficient process. It allows to use complex structural 3D models and to synthesize the vibrations in the entire operating range of the machine. Furthermore, the influence of different control strategies on the vibration characteristics can be investigated. As a first result, measured and synthesized vibration spectrograms of a run-up test on a traction motor are presented.

I. INTRODUCTION

For electric or hybrid electric vehicles low acoustic emissions of the electric traction motor are required. The acoustic characterization of the machine needs to be efficiently integrated into the design process. This addresses machine designer (machine configuration, force shapes), control engineer (operating point dependent currents) and mechanical design engineer (housing, mounting).

The approach presented here can be summarized as follows: In a first step, the force excitation for the entire operating range of a machine is calculated using 2D electromagnetic FEM. The vibration responses for the machine’s generic force excitation shapes are calculated in a second step by 3D structural FEM for the entire frequency range. Operating point dependent machine vibrations are subsequently found by superposing the vibration responses scaled by the operating dependent force excitation. The high computational costs that typically limit 3D models to selected frequencies as pointed out in [1] can be overcome with the presented approach. Simulated and measured run-up spectrograms are a first result and underline the validity of this approach. The electromagnetic noise components inherent to the machine design [2] are considered. Switching frequency harmonics are currently not included. The force decomposition and vibration synthesis is performed using MATLAB. ANSYS is used for solving the electromagnetic and structural FE models. SolidWorks is used for CAD data handling.

II. ELECTROMAGNETIC FORCE EXCITATION

The investigation is based on a 15 kW interior permanent magnet synchronous machine (IPMSM) for a hybrid electric vehicle. The outer diameter is 30 cm and the stack length 7.5 cm. It is a 3 phase machine with 10 pole pairs, 24 stator slots and $q = 0.4$ slots per pole per phase.

IPMSM for traction applications are typically current controlled in terms of d- and q-axis currents (i_d, i_q) [3]. The force excitation has been calculated for the entire i_d/i_q range. It is mapped to the torque T and speed n range as defined a control strategy. The effect of different control strategies will be investigated.

The electromagnetic simulations here are performed statically using non-linear 2D FE models of a symmetry section of the machine. The force distribution $f_{d,M}(\alpha)$ in N/m along the airgap is described by the superposition of excitation modes m up to the M^{th} spatial component as

$$f_{d,M}(\alpha) = \sum_{m=0}^M (a_{d,m}(t) \cdot \cos(m\alpha) + b_{d,m}(t) \sin(m\alpha)), \quad (1)$$

where α is the angle of a location in the airgap. Index d denotes the direction, i.e. radial ('r') or tangential ('t'). Skewed machines are going to be investigated in a next step.

The time dependent amplitude factors $a_{d,m}(t)$ and $b_{d,m}(t)$ are decomposed into their complex frequency components [4].

$$a_{d,m}(t) \circ \bullet A_{d,m}(f) \quad \text{and} \quad b_{d,m}(t) \circ \bullet B_{d,m}(f) \quad (2)$$

Displaying $A_{d,m}$ and $B_{d,m}$ over the i_d/i_q or T/n range allows to judge and compare the force excitation characteristics of a machine as will be shown in the full paper.

Due to the magnetic configuration of the machine in this study, the frequency components of all modes are multiples of $20f_{\text{mech}}$. The circumferential orders of the two dominant excitation modes are 0 and 4. Mode 0 has frequency components at $60, 120, \dots f_{\text{mech}}$ while those for mode 4 are at $20, 40, 80, 100, \dots f_{\text{mech}}$ with f_{mech} being the shaft speed in Hz.

III. STRUCTURAL VIBRATION RESPONSE

The 3D structural model is built directly from the machine assembly’s CAD drawing. Non-critical structural details are eliminated to decrease the model size. In this study, the model consists of the machine stator in a test bench housing which is flange mounted to a test bench.

Harmonic analyses based on the modal superposition method using force excitations $\mathbf{F}_{\text{unit},k}$ are performed. $\mathbf{F}_{\text{unit},k}$ represents a force excitation with a unit amplitude of 1 N and a spatial distribution associated with one particular $A_{d,m}$ or $B_{d,m}$.

$$\mathbf{v}_{\text{unit},k}(f) = \mathbf{H}(f) \cdot \mathbf{F}_{\text{unit},k} \quad (3)$$

where $\mathbf{H}(f)$ is the general structural transfer function and $\mathbf{v}_{\text{unit},k}(f)$ the resulting surface vibration for one spatial force excitation shape with unit amplitude.

IV. VIBRATION SYNTHESIS

For synthesizing the machine vibration $\mathbf{v}(f)$ at a frequency f for a particular operating point, the K unit force velocity responses $\mathbf{v}_{\text{unit},k}(f)$ from (3) are superposed with the complex amplitudes $F_k(f)$ of force excitation modes k as weighting factors for this particular operation point,

$$\mathbf{v}(f) = \sum_{k=1}^K \mathbf{v}_{\text{unit},k}(f) \cdot F_k(f). \quad (4)$$

$F_k(f)$ represents an $A_{d,m}(f)$ or $B_{d,m}(f)$ from (2).

Superposing the force contributions leads to low computational costs for the full frequency range 3D structural simulations (6 h in total on a 2 GHz Intel Core 2 PC with 3 GB of RAM for a 44405 element model and 345 frequency points). The superposition can be performed within seconds.

The interface between electromagnetic force excitation and structural dynamic response on the basis of force excitation shapes is very flexible. Any type of model (FE, analytical, etc.) and simulation (2D or 3D, static or transient, etc.) can be used. For example, an analytical force calculation may be used as in [5] for an induction machine.

V. RESULTS

Using the above presented process of force excitation calculation, structural dynamic response calculation and vibration synthesis, a run-up spectrogram is synthesized as shown in Fig. 1. The force excitation uses mode 0 at 60 and $120f_{\text{mech}}$ and mode 4 at 20, 40, 80 and $100f_{\text{mech}}$ with radial and tangential components. The simulated spectrogram is compared to a measured spectrogram of this run-up in Fig. 2. For the sake of comparability, higher electromagnetic frequency components, low frequency mechanical noise components and switching frequency harmonics are filtered from the measurement. Both figures use the same dB-scale on the color-axis. The vibration was measured at 4 sensor positions along the circumference of the housing, evaluated as the power sum of these signals and synthesized accordingly.

The simulated and measured spectrograms match well, in particular in terms of the amplitudes of the simulated vibration. The simulated eigenfrequencies tend to be higher than the measured ones which is attributed to a too high stiffness for the stator and the neglected winding mass in the simulation. Structural tests (i.e. an experimental modal analysis [6]) or a detailed analysis of material parameters (e.g. for laminations [7] and windings; damping ratios) have not been performed on the model. This data would further improve the results.

VI. CONCLUSION

A modular and universal approach for simulating electrical machine vibrations is presented and validated. The given results show that the vibration characteristics of a machine can be synthesized without any measurement input, only based

Fig. 1. Spectrogram of synthesized surface vibration for run-up from 0 to 6000 r/min

Fig. 2. Spectrogram of measured surface vibration for run-up from 0 to 6000 r/min

on machine configuration, control strategy and engineering drawings. The approach presented here can easily be applied to other electrical machines or vibrating structures in general. Skew or eccentricity effects as well as mechanical vibrations and switching harmonics can be included. Further details and results will be given in the full paper.

Abstract— This paper presents the efficient calculation method for torque ripple of permanent magnet assisted synchronous reluctance motor (PMA-SynRM) by FEM analysis for load angle curve. On an assumption that the sinusoidal current of stator is controlled by inverter, torque ripple characteristic according to load angle is calculated by superposing load angle curves from each instantaneous three phase current. Therefore, the load angle range having minimum torque ripple as well as the average torque according to the load angle can be induced easily by the proposed method. Finally, torque ripple characteristics of PMA-SynRM with different rotor are analyzed.

I. INTRODUCTION

Although PMA-SynRM is similar to interior permanent magnet (IPM) motor from an aspect of utilizing reluctance torque as well as magnetic torque, demerit of IPM motor compared with PMA-SynRM is the generation of large d-axis current at a high speed region which corresponds to field weakening control [1]. On the contrary PMA-SynRM has larger torque ripple due to its complex barrier structure. So, several papers for decreasing method of torque ripple have been presented [2]. The target of this paper is not the study on the reduction of torque ripple, but the study on the analytical calculation method for torque ripple. In this paper, we present an efficient calculation method for torque ripple of PMA-SynRM without steady state analysis by FEM including motion equation. The magnitude of torque ripple as well as average torque according to load angle is changed.

The paper presents torque ripple calculation method from an analysis of load angle curves with each instantaneous three phase current. We also perform the experiment for the verification of proposed method. We can find the load angle for minimum torque ripple with ease by proposed method. Moreover, we analyzed the torque ripple characteristics according to rotor types.

TABLE I
 SPECIFICATIONS OF ANALYSIS MODEL

	Item	Unit	Specification
Rated	Voltage / Current	V / A	12 / 10.5
	Speed	rpm	1000
	Power	W	130
Stator	Stack width / Outer diameter	mm	40 / 86
	Parallel Circuit		4
	Series turns / phase		44
Rotor	Number of poles		4
	Outer diameter	mm	46.2
	Rib Thickness	mm	0.3
	Remanence of Magnet	T	1.2 @ 20°C
	Mechanical air gap	mm	0.4

II. ANALYSIS MODEL

For the best use of reluctance torque with PMA-SynRM, barriers in the rotor and stator slots are designed to have the maximum saliency ratio and maximum gap of d-axis and q-axis inductance [3]. Three pieces of permanent magnets per pole are inserted in the middle of each barrier. Fig. 1 shows the picture of analysis model, and Table I shows the specification of size and rated operation point of the motor.

Fig. 1. Stator and permanent magnet rotor structure of PMA-SynRM.

III. TORQUE RIPPLE ANALYSIS BY LOAD ANGLE CURVES

The general method for calculating load angle curve by FEM is as follows. We input $\sqrt{2}$ times of rated current into the region of coil A, and then we input the half times of rated current with minus sign into the regions of coil B and C. Secondly, we calculate the output torque according to rotating angle while rotating the rotor. This is somewhat adequate analytical method for load angle curve with small reluctance torque or no reluctance torque such as interior PMSM and surface PMSM.

Fig. 2. The analysis results of load angle curve by using static FEM.

Fig. 2 shows the load angle curve of PMA-SynRM. There is so much fluctuation in it. In this figure, we cannot calculate the average torque owing to load angle. This paper presents the effective calculation for torque ripple as well as average torque without dynamic FEM simulation of time domain. Fig. 3 shows the balanced sinusoidal current waveform of three phase winding. The load angle curve in Fig. 2 is analyzed under the condition of dc current set at 1st state in Fig. 3. In

case the motor is operated with sinusoidal current controller, we can calculate another load angle curve with the dc current set at 2nd state. The remaining dc current set from 3rd to 7th state also can calculate load angle curves in the same way. The dc current conditions are repeated again with interval of 30°. We can make synthetic load angle curve by superposition of seven kinds of load angle curves as shown in Fig. 4.

In Fig. 4, average torque curve is calculated by averaging seven torque values at each load angle, and torque ripple curve is calculated by subtracting minimum torque from maximum torque at each load angle. We can find that torque ripple in the vicinity of 90° load angle is smaller than that of 130° load angle. That is, the PMA-SynRM is usually expected to be controlled with 130° load angle for the maximum torque production. However, torque ripple is also increased at this load angle.

In order to verify the proposed method, we perform the dynamic analysis by FEM with sinusoidal rated current 10.5A and load angles of 90° and 130°, respectively. Fig. 5 shows the results of torque ripple waveform and it gives good agreement with torque ripples by the proposed method.

Fig. 3. Condition of input currents for load angle curve analysis

Fig. 4. Torque ripple and average torque owing to load angle

Fig. 5 Torque waveform according to load angles by dynamic FEM simulation

IV. EXPERIMENT AND DISCUSSION

Fig. 6 shows the experimental set for load angle test of PMA-SynRM. The test result of load angle curve is shown in

Fig. 7(a) when dc current set of 1st state is inputted in each winding and the rotor is rotated by dynamometer, we can see the fluctuation of torque according to the load angle is similar to Fig. 4. Fig. 7(b) shows the experimental results of torque at two kinds of load angle 90° and 130°. Vector inverter is used and the rated current is distributed to d-axis and q-axis current relevantly according to the load angle. The comparison results between analysis and experimental result of load angle curve is shown in Fig. 8 for the verification of validity of the proposed method.

Fig. 6. Experimental set for load angle test

(a) Load angle curve test by dc current source
(b) Test results on the average torque and torque ripple at 90° and 130° load angle by vector inverter

Fig. 7. Experimental results.

Fig. 8. Load angle curve by analysis and experiment. (average torque)

V. CONCLUSION

In this paper, we proposed a calculation method for torque ripple of PMA-SynRM by superposing load angle curves calculated by FEM. Moreover, we calculate an exact load angle curve which represents the average torque at each load angle in case of a motor with large torque ripples.

On the Importance of Incorporating Iron Losses in the Magnetic Field Solution of Electrical Machines

Emad Dlala, Anouar Belahcen, and Antero Arkkio
Helsinki University of Technology, P.O. Box 3000 FI-02015 TKK, Finland
Email: emad.dlala@tkk.fi

Abstract—This paper is aimed at studying the effects of iron losses on the magnetic field solution and evaluating their impacts on the overall performance of electrical machines. Because of the complications associated with the inclusion of iron losses into the magnetic field solution, the losses are usually computed as a posteriori and hence omitted in the finite-element (FE) analysis, leading to an inaccurate solution of the magnetic field and other relevant quantities. We propose a comparative FE analysis to assess the role of iron losses in defining the behavior and operation of electrical machines.

I. INTRODUCTION

Recent developments in material modeling have helped estimate iron losses using macroscopic models that can imitate the magnetization behavior quite accurately. From an engineering point of views, modeling of the magnetization curves (or the B - H loops) can be considered as the most “accurate and simple” way to predict iron losses, including the static hysteresis and dynamic eddy-current losses. Such an iron-loss model based on modeling the loop shapes usually entails the development of a hysteresis model incorporated into Maxwell equations. The resulting magnetodynamic problem is three-dimensional (3-D) in nature, but it can be reduced to the solution of two 1-D penetration equations when the edge effects are neglected. If the geometry of the device at hand can be expressed by a 2-D instead of 3-D approach, as is the common practice adopted for modeling an electrical machine, then coupling the 2-D model of the machine with the 1-D model can represent a somewhat complete analysis of iron losses. In practical situations, even the latter simplification cannot be sufficient to avoid a highly augmented computation time and convergence problems resulting from solving the two coupled nonlinear problems of the 1-D and 2-D models. Another occurrence that complicates the numerical analysis of an electrical machine and requires the employment of vector hysteresis models is the rotation of flux density in significant parts of the machine.

For all these reasons and perhaps more, researchers and developers of finite-element (FE) software packages have frequently given up the inclusion of iron losses in the field solution. Their alternative to predict iron losses is the employment of much more simplified techniques as a posteriori (usually based on the statistical loss theory), leading to the avoidance of the hysteresis and eddy-current models while using a lossless single-valued magnetization curve for the field solution. In addition to their recognized inaccuracy, the

simplified techniques have no means to include the iron losses into the field solution.

The third possibility that could be best suited for many applications is to predict the iron losses by employing the 1-D model as a *posteriori*. This would alleviate the computation time and convergence problems, but will, on the other hand, affect the accuracy to some extent that has not been well figured out. It is therefore highly desirable to assess the significance of incorporating the iron losses into the field solution of electrical machines. To do so, we propose to conduct a comparative analysis on two electrical machines using a simplified version of the 1-D model, called the hybrid model, which also, like the 1-D model, predicts the magnetization curves and loop shapes but it is more stable and efficient. The hybrid model will first be incorporated into a 2-D time-stepping FE code and, second, be also implemented as a posteriori in the same code while using a lossless single-valued magnetization curve for the magnetic field computation.

The machines chosen for the analysis are an induction machine and a machine-like device that has no air-gap (see Fig. 1). In rotating electrical machines, the air-gap plays a vital role in characterizing the behavior and operation of the machine and could therefore depreciate the impacts of iron losses.

II. MODEL FOR ANALYSIS

The constitutive nonlinear relation can be expressed by the fixed-point method as follows:

$$\mathbf{H} = \nu_f \mathbf{B} + \mathbf{M} \quad (1)$$

where \mathbf{H} is the magnetic field strength, \mathbf{B} is the magnetic flux density, \mathbf{M} is a magnetization-like quantity, and ν_f is a constant, which is optimally calculated at each time-step.

If a 2-D approach is performed, applying the magnetic vector potential ($\mathbf{B} = \nabla \times \mathbf{A}$) with the fixed-point formulation (1) results in the following

$$-\nabla \cdot (\nu_f \nabla A) + \sigma \frac{\partial A}{\partial t} - J = (-\nabla \times \mathbf{M})_z \quad (2)$$

where A and J are the z -components of the magnetic vector potential and the electric current density, respectively. The resulting 2-D FE equations are coupled with the voltage equations of the stator windings and rotor cage. The overall system of equations of the FE equations is solved iteratively and discretized in time using the Crank-Nicolson time-stepping scheme [1].

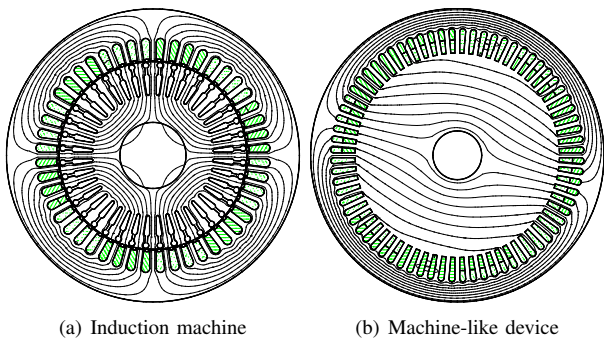

Fig. 1. Flux distributions and geometries of the simulated machines.

The Mayergoyz model of vector hysteresis is applied in its inverted version [1] as the magnetic flux density \mathbf{B} is projected over several directions e_{φ} specified by an angle φ to calculate the magnetic field strength

$$\mathbf{H}(\mathbf{B}) = \frac{1}{Q} \sum_{i=1}^N e_{\varphi_i} H_{\varphi_i}(B_{\varphi_i}) \quad (3)$$

where N is the number of directions, Q is a parameter to be identified, B_{φ_i} are the projections of \mathbf{B} along e_{φ_i} .

Now depending on whether the iron losses are included into the field solution or are only computed as a posteriori by the hybrid model, the scalar function $H_{\varphi_i}(B_{\varphi_i})$ will be served by

$$H_{\varphi}(B_{\varphi}) = H_h(B_{\varphi}) + H_{ed}(B_{\varphi}) + H_{ex}(B_{\varphi}) \quad (4)$$

or

$$H_{\varphi}(B_{\varphi}) = H_{sv}(B_{\varphi}) \quad (5)$$

where in (4), the hybrid model is used to predict three magnetic field strength components, H_h , H_{ed} , and H_{ex} , which are respectively responsible for generating the iron hysteresis, eddy-current, and excess losses. In (5), the function H_{sv} is a single-valued curve and must be prepared by averaging the major loop used by H_h in (4) to ensure that the same magnetic properties are used (most importantly the saturation property).

The procedure is carried out as follows:

- When the iron losses are *included* into the field solution, (4) is employed and subsequently used with (3), (1), and (2) in the iterative, time-stepping solution.
- When the iron losses are *not included* into the field solution and only computed *posteriorly*, (5) is employed and subsequently used with (3), (1), and (2) in the iterative, time-stepping solution. After the field solution is obtained at each time-step, (4) and (3) are employed to compute, posteriorly, \mathbf{H} , and hence, the iron losses.

In the two cases, the iron losses are determined using the Poynting vector theorem. It should be noted that even in the case when the iron losses are not included into the field solution, (3) was used to calculate \mathbf{H} with the single-valued function (5) in order to make sure again that the saturation properties for the two cases of (4) and (5) are identical, even though one would not normally need to use (3) in the case of (5).

III. NUMERICAL RESULTS

The influence of iron losses on the field solution will be evaluated here through the simulations of two electrical machines: a conventional squirrel-cage induction machine and a machine-like device, which has a conventional stator topology but no air-gap in it, as the rotor has not been punched out from the stator sheets (see Fig. 1 and [2]).

Numerical results carried out at the synchronous speed are shown in Table I. The results were obtained by feeding the machines from a 50-Hz, 380-V sinusoidal voltage supply. The time-stepping, 2-D FE simulations of the models introduced in Section II were run until the steady-state was reached.

TABLE I
SIMULATIONS CARRIED OUT WHEN THE IRON LOSSES WERE INCLUDED IN FIELD SOLUTION AND WHEN THEY WERE NOT

(a) Induction machine			
Computed Quantity	Iron loss included	Iron loss not included	Relative error %
Terminal current [A]	22.76	22.56	-0.87
Shaft power [W]	-146.12	-26.58	-81.80
Stator winding losses [W]	107.48	105.54	-1.80
Rotor-cage losses [W]	8.43	6.22	-26.21
Iron losses [W]	483.13	497.05	+2.90
Air-gap flux density [T]	0.845	0.845	+0.00
Power factor	0.0289	0.0056	-80.62
(b) Machine-like device			
Computed Quantity	Iron loss included	Iron loss not included	Relative error %
Terminal current [A]	0.75	0.26	-65.33
Stator winding losses [W]	1.60	0.20	-87.50
Iron losses [W]	365.76	391.69	+7.12
Air-gap flux density [T]	0.260	0.264	+1.54
Power factor	0.7125	0.0011	-99.84

The simulated results show that the inclusion of iron losses into the field solution has influenced the physical quantities of the two machines, especially, the machine-like device. The air-gap has a dominant role in rotating electrical machines as manifested in the current drawn by the induction motor, which is mainly resulting in reactive power. The loss inclusion has obviously increased the power factor in the two machines, particularly in the machine-like device. The effect of the iron-loss incorporation on the iron losses themselves is not that significant in the two machines, it could be also because the machines were fed from a voltage source.

The induction machine was deliberately run at the synchronous speed in order to provide a basis for comparison with the machine-like device. It is therefore interesting to study the effects of iron losses on a loaded machine. The type of supply, whether sinusoidal or non-sinusoidal, voltage or current source, is of interest too. These issues will be dealt with in the extended paper in which experimental results will be provided to support the simulations.

Abstract—This paper deal with the efficiency evaluations in a Synchronous reluctance motor(SynRM) Vs. PMASynRM using a coupled transient finite element method(FEM) and preisach modeling, which is presented to analyze the characteristics under the effect of saturation and hysteresis loss.

The focus of this paper is the efficiency evaluation relative to hysteresis loss, copper loss, etc. on the basis of load condition in a SynRM and PMASynRM. Computer simulation and experimental result for the efficiency using dynamometer shoe the propriety of the proposed method.

I. INTRODUCTION

In high-speed applications of a SynRM, hysteresis loss can become the major cause of power dissipation. Therefore, whereas in other kinds of machines a rough estimation of hysteresis loss can be accepted, their importance in a SynRM justifies a greater effort in calculating them more precisely.

The preisach model is now generally accepted to be a powerful hysteresis model, and is therefore intensively studied [1]-[3].

By adding a proper quantity of permanent magnets the torque density and power factor of SynRM can be greatly increased. It is called Permanent Magnet Assisted Synchronous Reluctance Motor (PMASynRM).

But, it must be that PMASynRM is more saturated than SynRM, due to the additional magnet flux density.

In this paper, a coupled finite element analysis and Preisach modeling for a PMASynRM and SynRM are presented and characteristics analysis and efficiency evaluations are performed under the effect of saturation and hysteresis loss.

The focus of this paper is the efficiency evaluation relative to hysteresis loss, copper loss, etc. on the basis of load condition in a SynRM and PMASynRM.

Also, TMS320C31 DSP installed experimental device and dynamometer are equipped and experiments are performed.

Computer simulation and experimental results for efficiency show the propriety of the proposed a coupled a coupled finite element analysis and Preisach model.

II. ANALYSIS METHOD

A. Governing Equation of PMASynRM and SynRM

Maxwell's equations can be written as

$$\nabla \times \vec{H} = \vec{J}_0 \quad (1)$$

$$\nabla \cdot \vec{B} = 0 \quad (2)$$

$$\vec{B} = \frac{1}{\nu_0} \vec{H} + \vec{M} \quad \vec{B} = \frac{1}{\nu_0} \vec{H} + \vec{M}_{PM} \quad (3)$$

where, \vec{M} , \vec{M}_{PM} are the magnetization of magnetic material and permanent magnet with respect to the magnetic intensity \vec{H} . \vec{M}_{PM} is removed in a SynRM. The magnetic vector potential \vec{A} and the equivalent magnetizing current \vec{J}_m , \vec{J}_{PMm} are expressed as follows

$$\vec{B} = \nabla \times \vec{A} \quad (4)$$

$$\vec{J}_m = \nu_0 (\nabla \times \vec{M}), \quad \vec{J}_{PMm} = \nu_0 (\nabla \times \vec{M}_{PM}) \quad (5)$$

The governing equation derived from (1)-(5), is given by

$$\nu_0 (\nabla \times \nabla \times \vec{A}) = \vec{J}_0 + \vec{J}_m + \vec{J}_{PMm} \quad (6)$$

B. System Matrix

The system matrix can be written as

$$[K^{(e)}] \{A^{(e)}\} + \{F^{(e)}\} + \{M^{(e)}\} + \{M_{PM}^{(e)}\} = 0 \quad (7)$$

The overall model is therefore described by the matrix as follows

$$[K] \{A\} + \{F\} + \{M\} + \{M_{PM}\} = 0 \quad (8)$$

C. Application of Preisach's Model

The magnetization M can be expressed as a scalar model, because the rotor rotates according to the input current angle synchronously. Therefore, it can be supposed that the domain in stator is an alternating field with reference to x axis and y axis. B and H of the domain in rotor is constant and is a rotating field, but it is an alternating field with reference to x axis and y axis, also [4]-[6]. It is natural that M, H which is calculated on the same axis has a same vector direction.

$$M(t) = \iint_{\alpha \geq \beta} \mu(\alpha, \beta) \gamma_{\alpha\beta}(H(t)) d\alpha d\beta \quad (9)$$

$$= \iint_{S^+(t)} \mu(\alpha, \beta) d\alpha d\beta - \iint_{S^-(t)} \mu(\alpha, \beta) d\alpha d\beta$$

A more convenient treatment of this model is also to substitute the Everett plane for Preisach's one as shown in (10).

$$E(\alpha, \beta) = \iint_{\alpha \geq \beta} \mu(\alpha, \beta) \gamma_{\alpha\beta}(H(t)) d\alpha d\beta \quad (10)$$

In the Everett plane, the distributions of M, which is accepted from experimental data of material S40 and ferrite magnet, are Gaussian ones.

D. Computing Algorithm

The simple iteration method is applied to the iteration loop for the rapid convergence and magnetization M is modified.

$$M_{i+1}^{(\theta)} = M_i^{(\theta)} + r(M_{i+1}^{(\theta)} + M_i^{(\theta)}) \quad (11)$$

Where r is the relaxation factor and 0.5 is used in this paper.

Flux density and magnetic field intensity, which are composed of x-axis and y-axis components, are calculated from FEM. Each component of magnetization is calculated independently from x-axis and y-axis magnetic field intensity with Everett density distribution.

III. RESULT AND DISCUSSION

In this case of PMASynRM and SynRM, the hysteresis responses of a teeth part's element are shown in Fig. 3, 4 when P.M. is 0.4[T] and current i_d is 5[A], 25Hz.

It can be found that PMASynRM is more saturated than SynRM, but have similar hysteresis characteristics in spite of inserting a permanent magnet.

Fig. 1 B-H Curve in a teeth of SynRM

Fig. 2 B-H Curve in a teeth of PMSynRM

Fig. 3. Efficiency, current angle and runaway point of SynRM and PMASynRM according to load in experimental test

Fig. 4 loss analysis in each load condition of SynRM

Experimental Comparisons are given with output power and currents characteristics of normal Synchronous reluctance motor (SynRM) and those of PMASynRM according to load as shown in Fig. 3, respectively. And It is confirmed that the PMASynRM result in high output power performance than SynRM. Fig. 4 shows the each loss ratio to the total loss in each load condition of SynRM.

Through the more detailed analysis, the various loss and efficiency evaluations of PMASynRM and SynRM will be represented in next extended version.

Av. Prof. Luciano Gualberto, tr. 3 n°380, 05508-970, São Paulo-SP - Brazil
everton.yoshida@gmail.com, leb@pea.usp.br

Abstract — This work proposes the optimization of a Magnetic Bearing applied to a Ventricular Assist Device using the Pareto Archived Evolution Strategy. The optimization problem is to minimize the power consumption and rotor oscillation. The optimization of the control system was also taken into account. The magnetic force was computed by the Finite Element Method to allow a dynamic simulation of the magnetic bearing.

I. INTRODUCTION

The Ventricular Assist Device (VAD) and similar equipments that provide assistance to patients with cardiological diseases plays an important role in Health. Based on information from Brazilian Health Ministry, heart diseases represent about 27% of all deaths caused by pathological reasons in 2002. Previous studies about one degree of freedom magnetic bearing [1] shows that high consumption of energy makes unviable the implantation of a VAD for long periods. The magnetic bearing control system should be highly reliable.

The objective of this work is to elaborate a methodology to perform the optimization of magnetic bearing in order to work in an efficient and stable condition. Therefore, a process that uses the Finite Elements Method (FEM), a bearing dynamic model to evaluate the mechanical solution and an algorithm to perform the optimization, using the Pareto Archived Evolution Strategy (PAES), have been developed. The obtained solutions were used to improve the performance of an existing prototype.

II. PROBLEM DESCRIPTION

The magnetic bearing suspension provides to the rotor the elimination of the attrition by magnetic forces. The active magnetic bearing, as shown in Fig.1 [2], has a control circuit with a sensor on the base of the rotor. Thus, the circuit increases or decreases the current of the coils connected on series to control the force and the position of the rotor. Only the rotor will have contact with the blood.

A. Bearing dynamic model

A simulation using FEM software has been done, and the resultant forces on the rotor were computed as a function of several parameters as position, number of turns and current. Theses forces values allow calculating the position of the rotor as a function of time, when an external mechanical perturbation is present on the bearing.

A control circuit is then necessary, as presented on prototype and a proportional-derivative control was adopted in our simulations. In this model, a reference current (I_{ref}) is

Fig.1. Magnetic Bearing and Rotor Structure

adopted to make the resultant forces null. The current is adjusted 300 times per second to keep the rotor stable even with external forces actuating over it.

For each pair of numbers of turns N_1 and N_2 for the electromagnets, a different reference current (I_{ref}) value is necessary to sustain the rotor. Hence, in order to not calculate the reference current at the beginning of each simulation, a database, which determinate these current as a function of N_1 and N_2 has been done and the current is calculated by interpolation of these points.

The Proportional-Derivative control circuit parameters K_p and K_d should be also evaluated. After some computer experiments we have observed that for a given ratio N_1/N_2 , is possible to determine K_p and K_d , which provide a minimum overshoot and settling time.

B. The Optimization Problem

The standard PAES, as proposed in [3] were adopted with some adaptations to include the constraints existing on magnet bearing design. The objective functions are to minimize the average power consumption during the simulation and to minimize the rotor oscillation. In order to measure this oscillation, we sum up the squares of the differences between the actual rotor position and the nominal rotor position. In this work, we will call it $\Sigma(\text{Displacement})^2$. The problem has the following constraints: the coil region for the upper and for the lower electromagnet was fixed; the ratio between coil volume and copper volume was defined as 0.80, the wire section varies from 1 to 39 AWG, the wire section was defined to occupy all available volume and the position (x) is constrained to a maximum value and a minimum value. The integration of

11. ELECTRIC MACHINES AND DRIVES C) ACTUATORS

the electromechanical problem with the optimization problem could be understood on Fig.2

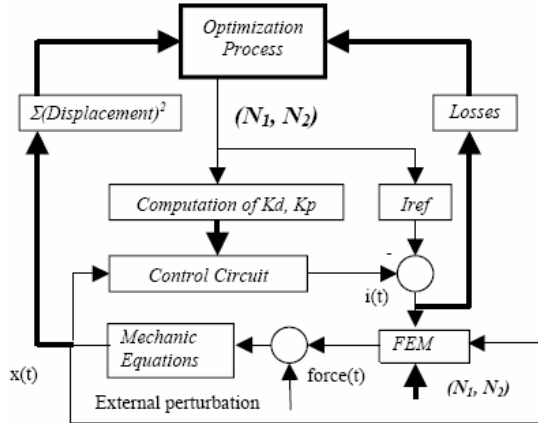

Fig.2 . The Optimization Process

III. RESULTS

The first step to solve this problem is to correlate the reference current and the parameters of the PD control system with respect to N_1 and N_2 . Fig 3 and.4 show the used data.

Fig 3 Reference Current as a function of N_1 and N_2

Fig 4 Parameters of the PD Control System as a function of the ratio N_1/N_2

Due to the complexity of the dynamic model, the computation of the power consumption and rotor movement in function of time spend about five seconds for each pair (N_1 , N_2). The final result was obtained after 36000 iterations or five hours of processing. Fig. 5 is a zoom of the Pareto-set generated by PAES with some points generated by an exhaustive search. The nondominated solutions have a trend toward results between 3.7 W and 3.9 W and $\Sigma(\text{Displacement})^2$ about 50mm^2 .

Fig. 6 represents the position and the current for one of the non-dominated solution. It is possible to observe the reaction of the bearing for the 4 external perturbations, except for the initial condition, they are respectively, 20N upward, 20N downward, 0 to 30N upward and 0 to 10N downward. These same perturbations were applied in all generated solutions and the Average Power Consumption and the $\Sigma(\text{displacement})^2$ were computed.

Fig.5 Pareto Set – PAES and Exhaustive Search

Fig 6. Position and current as a function of time for a non-dominated solution

IV. CONCLUSIONS

In this work, a multi-objective optimization of a magnetic bearing was performed. Besides the improvement suggested to the device, it has also changed some process on PAES algorithm, adapting it to handle with a constraint problem. Using the dynamic model of the bearing, the FEM simulation was only necessary in the beginning to obtain the Force x Position curve, while varying the number of turns and the current. Therefore, it was possible to apply the methodology to the magnetic bearing problem, obtaining the optimal values for its construction. This methodology has proved to be potentially appropriate and applicable to the optimization of an electric device.

Design of High Performance Line Start Permanent Magnet Synchronous Motor with High Inertia Load

Jian Li, Byongkuk Kim, Yunhyun Cho
 Dept. of Electrical Engineering
 Hadan 2 Dong, #840, Saha-gu, 604714, South Korea
 lijian613@gmail.com

Abstract—This paper describes the design process of a high performance 3-phase 3.7kW 4-pole line start permanent magnet synchronous motor. The starting torque characteristics of line-start with high inertia load were optimized by studying the width and height of permanent magnet. Time-step two-dimensional finite element analysis was utilized to perform electromagnet simulation. The dynamic characteristics are described and compared with those of the squirrel cage induction motor.

I. INTRODUCTION

The induction motors have been widely used in industry application. But in recent years, the high efficiency motors are demanded in a large variety of industrial products for energy save. The line start permanent magnet synchronous motor (LSPMSM) has a high efficiency and an advantage in constant speed operation regardless of the effect of load variation, presenting an interesting alternative for induction motors. It has permanent magnets (PMs) buried bellow the squirrel cage in rotor, thus operates in steady state as conventional interior permanent magnet synchronous motor (PMSM); the squirrel cage is used for line starting on a conventional AC power source and damping of dynamic oscillations at fast load changes. Thus it combines the advantages of induction motor (robust construction and line-starting capability) and PMSM (high efficiency, power factor and torque density). So, characteristics of LSPM have very complex characteristics until the synchronization and if the design is not suitable, the LSPM cannot be synchronized [1]-[2].

II. DESIGN PROCESS

Through a combination of optimization methods and standard design techniques, the efficiency of an induction motor is increased by 3.8%. This motor is then used as basis for the design of a line start permanent magnet synchronous motor. Fig.1 shows the configuration of V-shape magnet LSPMSM and rotor of prototype. The performance of the 3-Phase 3.7kW 4-poles LSPM was simulated by dynamic finite element analysis and was compared with the squirrel-cage induction motor in Table 1. At full load, the rms phase current decreased from 7.6A to 6.4A, and the efficiency increases by 10%.

Fig. 1. Configuration of V-shape magnet LSPMSM and rotor of prototype.

Fig. 2. Phase currents of LSPMSM.

Items	Induction motor		LSPM	
	Simulation	Experiment	Simulation	Experiment
Input voltage [V]	380	380	380	380
Input current [A]	8.2	7.6	6.5	6.4
Rated speed [rpm]	1,730	1,760	1,800	1,800
Rated torque [Nm]	20.4	20.0	19.6	20.0
Efficiency [%]	84.4	86.3	94.3	94.1
Power factor	0.81	0.80	0.91	0.90
Output [W]	3,700	3,686	3,700	3,768

A LSPM, which presents good steady state performances, may have problems to start and synchronize, especially with high inertia load [3]. The start can fail because of a too high braking torque in comparison to the asynchronous torque. The braking torques (due to permanent magnets and flux barriers) in the asynchronous operation region, which mainly depends on the placement and dimensions and the value of energy product of PMs, has principle effect on the synchronization capability. The design of high performance motor should make compromise between an adequate starting characteristic in the asynchronous operating region and power rating and efficiency in the motor's synchronous operating region.

Fig.3 shows the simulation results of the characteristics of LSPMSM braking torque with different height and width of permanent magnet. The nonlinear relationship between leakage flux and the permanent magnet thickness is shown in Fig.3 (a). Torque characteristics changes a lot with different saturation degree between air duct and squirrel cage bar. The linear relationship of braking torque with difference permanent magnet width is shown in Fig.3 (b).

Table1 shows the result of simulation and experimental comparison between induction motor and LSPM. The efficiency of LSPM is 10% higher than induction motor according to experimental test. Performance experimental results and FEM result are matched, which verifies the validity of this analysis.

III. CONCLUSIONS

The design process of a high performance 3-phase 3.7kW 4-pole line start permanent magnet synchronous motor was describes in this paper. Based on a high efficiency induction motor, the prototype was designed and analyzed by using time-step finite element method. The efficiency of LSPM is 10% higher than induction motor according to experimental test. In order to improve the starting capability, models with permanent magnet of different widths and heights were simulated. It could found that the shape of permanent magnet embedded under rotor bar has a large influence on braking torque.

Abstract — This paper shows a transverse flux rotary machine (TFRM) with laminated stator cores, which consists of two part laminated silicon steel cores in which the direction are perpendicular to each other. Although the TFRM is laminated to reduce eddy current losses, it exhibits rapidly increasing core losses as frequency increases. To solve the problem, slits are introduced on the stator core. The effect of the slits is confirmed experimentally first, then the effect is explained by 3-dimensional finite element analysis of eddy current losses in nonlinear laminated cores.

I. INTRODUCTION

Transverse Flux Machines (TFM) have a 3-dimensional magnetic flux path, and due to this characteristic, fabrication with silicon steel cores can be difficult. [1] and [2] present stators with silicon steels, in which the silicon steel pieces are laminated circumferentially. Since TFMs have 3-dimensional flux path, either the stator or rotor has to be skewed; however, for manufacturing the stators, it is difficult to bend the laminated stator core pieces.

In the prototype transverse flux rotary machine (TFRM) of this paper, in order to ease the manufacturing process with laminated stator core and to eliminate bending, the TFRM is manufactured with two part laminated stator cores in different directions. Although the lamination is incorporated to reduce eddy current losses, it exhibits increasing core losses as frequency increases. To solve the problem, slits are introduced on the stator core.

This paper presents the slit effect with both experimental and analysis results. First, the configuration of the prototype TFRM is introduced in section II. And to show the slit effect, the experimental condition and the results are presented in section III. Then, the effect is explained by 3-dimensional finite element analysis (FEA) of eddy current losses with nonlinear laminated cores in section IV.

Usually, lamination is not modelled in order to reduce computation time in the FEA process. In this paper, however, the lamination is expressed in the analysis to show the high eddy current loss even on the laminated core. To reduce the number of elements and save the computation time, the lamination is expressed with a few layers and with boundary condition instead of air-gap between layers, and electromotive force (EMF) is calculated by source variation without motion instead of rotor movement.

II. A TFRM WITH LAMINATION STATOR CORE

Fig. 1 shows the configuration of a permanent magnet (PM) type, direct drive TFRM. A brief specification including

magnetic material information is listed in Table 1. The PMs on rotor are arranged in circumferential direction and magnetized as shown in Fig. 1 (b) to concentrate the magnetic flux to the rotor core. Although such a construction is good for producing high power density, skewing the rotor to allow for the 3-dimensional flux path can be difficult. Therefore, the stator is divided into two sections that are laminated in different directions. The inner and outer sections are a yoke and teeth, respectively, and the laminations of two sections are perpendicular to each other as shown in Fig. 1 (b). Additionally, the outer teeth core is divided into upper and lower parts, and the lower teeth are shifted by a half pole-pitch with respected to upper teeth to create skewing effect.

Fig. 2 shows flux path on cross section of L-L' in Fig. 1 (b) when current flows in counter-clockwise. From the Fig. 2, it is clear to see that both inner and outer laminations accommodate the flux flow and do not interfere. The lamination also intends to reduce core losses.

Fig.1. Conceptual drawing of a prototypal TFRM

Fig.2. Flux path on the cross section area along L-L'

Table 1. Specifications of a Prototyp TFRM

Stator	Material	S23 (Silicon steel, Lamination core)
	No. of Phase	2 phases (phase A and phae B)
Mover	Material	Somaloy 550 (Soft magnetic composite (SMC) core) + Ferrite PM

III. EXPERIMENTAL RESULTS

Fig. 3 shows the original stator configuration without slits and modified stator configurations with different numbers of slits. Slits are only on the outer teeth core. Fig. 4 shows the experimental results of EMF of different configurations as a function of electric frequency under no load condition. The EMF value is normalized with the base value being the EMF at 50 Hz.

When the stator has no slit ($N_s=0$), as shown in Fig. 3 (a), the EMF is highly non-linear as shown in Fig. 4. This result indicates that the core loss of the prototype TFRM is increasing rapidly as frequency increases.

While experimenting to reduce core losses, slits are inserted as shown in Fig. 3 (b), (c), and (d), and the experimental results show that the slits on teeth core improve the problem. As shown in Fig. 4, as the number of the slits increases the EMF characteristic become more linear. This experimental result indicates that the core losses are reducing with increasing the number of slits.

IV. 3-DIMENSIONAL FEA OF EDDY CURRENT LOSSES

The prototype TFRM exhibits high core losses in spite of laminated core construction. The experiment indicates that the slits reduce the core losses, and to confirm and understand the slit effect from experimental results, the original and modified conditions are analyzed.

Three models are considered for analysis. First is modeled without lamination as shown in Fig. 5 (a). Second and third is modeled with lamination as shown in Fig. 5 (b); however, the second does not include slits, while the third model includes slits.

Fig.3. Stator configuration depending on number of slits (N_s)

To explain the slit effect, eddy current losses in nonlinear laminated cores of the three models are computed by 3-dimensional FEA. For effective computation, transformer EMF is calculated instead of motional EMF by time varying current. Furthermore, the lamination is modeled by boundary condition instead of air-gap modeling between layers [3].

From the FEA, the eddy current state on the stator cores and the quantity of core losses and magnetic flux are compared among the three models. The analysis results will be presented in extended paper.

Abstract— In this paper a design and analysis method for a single-phase written-pole (WPM) is proposed. The magnet properties for a WPM are determined by using FEM. With the determined magnet, a steady state analysis is carried out with an equivalent circuit based on a symmetric field method. Experimental tests are also performed and compared with simulation results.

I. INTRODUCTION

A written-pole motor (WPM) is a very special synchronous motor because it has an exciter in stator which is a magnetization fixture [1]-[3]. A WPM also has self-starting ability owing to conducting bars and end-ring on a rotor, like an induction motor. The interesting feature of a WPM is such that the magnet on a rotor loses its magnetism by field of stator during start-up and it regains the magnetism through action of the exciter just before synchronization, which brings an advantage of no braking torque and high efficiency simultaneously.

Authors previously published a study on design of exciter pole [3]. In this paper, for a next procedure, methods for design and characteristic analysis of a single-phase WPM are suggested. At first, the design procedure for magnet using FEM is proposed, and then the analysis method for a steady state is given by using a symmetric field method.

II. DESIGN AND ANALYSIS METHOD OF A SINGLE-PHASE WPM

Fig. 1 shows the structure and circuit of a WPM which consists of a stator and a rotor. As shown in Fig. 1, the stator has an exciter pole which is driven by a common voltage source just before the rotor gets into synchronization.

Fig. 1. A single-phase WPM

A. Design of Magnet Layer

For a WPM to normally operate, the magnet should be demagnetized as much as possible during start-up. Conversely it should not be demagnetized up to the maximum load after re-magnetization by exciter operation. Thus the coercive force of magnet is a very important factor for design of a WPM. In

this study, a coercive force is searched through FE-analysis for an Nd-bonded magnet which has a flux density of 0.7T and a thickness of 1.5mm. In order to determine it, first, the field intensity in the magnet is calculated for the maximum load condition in synchronous operation without considering irreversible demagnetization. In other words, the linear B-H curve is used in the analysis, and a point *a* is found in Fig. 2. In turn, by analyzing field intensity during start-up, the point *b* is also found.

Fig. 2. Properties for magnet for a WPM

Two simulations above are respectively performed, and both the maximum fields in the magnet obtained by simulations are depicted according to angular positions in Fig. 3. From the results, we can see that the point *a* is near -400kA/m and the point *b* is near -500kA/m. So we determine -450kA/m for the knee point and -500kA/m for coercive force.

Fig. 3. Magnetic field intensities on magnet (without consideration of irreversible demagnetization)

To calculate how much demagnetization occurs in start-up, the no-load starting characteristics are simulated with FEM considering the irreversible demagnetization. Assuming that the initial magnet has been fully magnetized with 0.7T, the residual induction after start-up is calculated as shown in Fig. 4. It shows that most part of magnet is demagnetized above

50% of the initial state.

Fig. 4. Residual induction of magnet after start-up

B. Steady State Analysis

As stated above, the exciter in Fig. 1 operates and magnetizes the magnet just before synchronization. The design of an exciter pole and winding was presented in previous study [3]. The magnetization waveform is plotted in Fig. 5 and the back EMF can also be expected as 160V (RMS).

Fig. 5. Residual flux density in magnet (Simulation)

In operation in synchronous speed, steady state characteristics can be obtained by using time-step FEM but it requires very huge computation times. Therefore, in this study, the symmetric field method is introduced to analysis of a WPM in steady state. With the symmetric field method, the stator circuit is depicted in Fig. 6 where the subscript p and n mean positive and negative components respectively. Using superposition theory, the circuit including a rotor part is represented in Fig. 6 where $E(d)$ means a back EMF in the load angle d . The calculated torque, power distributions and efficiency in steady state characteristics are shown in Fig. 8.

Designed WPM is actually fabricated and back EMF is measured after exciter operation as shown in Fig. 9. The measured voltage (153V) coincides with the simulated value (160V). Other measured characteristics such as efficiency and maximum torque will be reported in the full paper.

Abstract — A calculation method and an experiment method for the d- and q-axis inductances of interior PM synchronous motor are introduced in this paper. The calculation method is based on the torque and energy relationship, which are calculated by the magneto-static field finite element analysis. And the experiment is a standstill method. The motor is excited by 3-phase AC voltage source. The measured 3-phase voltage and current will be used to calculate the inductances. Both the calculation and experiment methods consider the saturation and couple-magnetization effects, i.e. the inductances are described with the current magnitude and vector angle. Finally the calculated and experiment results will be verified by the results of conventional method.

I. INTRODUCTION

The dominant influences in the correct prediction of the steady-state characteristics and precise vector control for the interior PM synchronous motor (IPMSM) are the d- and q-axis armature inductances [1]. However, due to the nonlinear electromagnetic characteristics including the saturation and cross-magnetization effect in the rotor of IPMSM [2], the d- and q-axis armature inductances of IPMSM become much difficult to be calculated accurately.

So far, the most arguments on the inductance calculation methods of IPMSM concentrate on three finite element methods (FEM). They are frozen permeabilities method, flux linkage vector method, and flux-linkage perturbation method.[3] Unfortunately, however, there is no special d- and q-axis calculation module in the most commercial FEM software. And making an associated program is not easy for usual users. A general method which is suit for all FEM software becomes more meaningful. Based on this issue, a novel d- and q-axis inductances calculation method is proposed in this paper. It uses the magnetic energy and average torque which can be easily calculated by any commercial FEM software to calculate the inductances. This method not only can consider the saturation and cross-magnetization effect like the previous numerical methods, but also can easily eliminate the influence of space harmonics.

Considering the practical requirements, this paper proposes a relative low cost, simple and tradeoff inductance measurement method. It measures the inductances in standstill condition, in order to avoid utilization of dynamometer. It uses a 3-phase low voltage AC source so that the vector controller and inverter are not required. Hence, it is very suitable for normal laboratory experiment. The most meaningful point is that this method still can consider the saturation and cross-magnetizing effect. In this paper, the principle of this method

will be introduced. And then, based on the deduced equations, the experiment scheme and the processing methods of measured data will be proposed. After briefly introduce a conventional inductance calculation method which has been verified by previous literatures, the results from the proposed calculation and measurement methods will be compared with those of the conventional method. These two inductance evaluation methods will be suitable for most software and hardware environments.

II. PRINCIPLE OF INDUCTANCE CALCULATION METHOD

A. Magneto-static field FEA

The 2D magneto-static field FEM is used to calculate the magnetic field distribution and energy with the known current waveforms. Its governing equation, i.e. the nonlinear Poisson equation, is described in (1).

$$\nabla \times v(\nabla \times A) = J + \nabla \times (v\mu_0 M) \quad (1)$$

where A : magnetic potential vector,

J : current density vector,

M : magnetization vector,

v : reluctivity,

B. Flux linkage vector method

Flux linkage vector method has been verified by the previous literatures. Its principle is shown in Fig. 1, the IPMSM phasor diagram in steady state in the dq frame of reference. As the relationship between the no-load flux linkage vector and load flux linkage vector, (2) and (3), the formula of the d- and q-axis inductances calculation can be obtained.[1]

$$L_d = \frac{\psi_0 \cos \alpha - \psi_a}{i_d} \quad (2)$$

$$L_q = \frac{\psi_0 \sin \alpha}{i_q} \quad (3)$$

C. Energy-torque method

A novel calculation method which makes use of the magnetic energy and torque are proposed in this paper. The principle is,

Step 1: Calculating magnetic energy in no-load condition W_m and flux linkage of PM with FEM;

Step 2: Calculating magnetic energy in load condition W_l with certain current magnitudes and vector angles, meanwhile, get the generated torque.

Fig. 1. Phasor diagram of IPMSM in dq frame of reference

Step 3: Calculating the mean value of obtained torques.

Step 4: Depending on the simultaneous equations (4), (5), and (6), the d- and q-axis inductances can be calculated.

$$W_l = W_t - W_m \quad (4)$$

$$W_l = \frac{1}{2} (L_d i_d^2 + L_q i_q^2) \quad (5)$$

$$T_{mean} = P [\psi_a i_q + (L_d - L_q) i_d i_q] \quad (6)$$

where W_m : magnetic energy in no-load condition,

W_t : total energy in load condition,

W_l : magnetic energy in armature windings,

Due to the using of magnetic energy and mean torque, this method is named energy-torque method. The advantages and shortages of this method will be analyzed in the extended paper.

III. PRINCIPLE OF INDUCTANCE MEASUREMENT METHOD

The voltage equation of the IPMSM in the stationary reference frame is described in (1) [4].

$$\begin{bmatrix} v_q^s \\ v_d^s \end{bmatrix} = \begin{bmatrix} r_s & 0 \\ 0 & r_s \end{bmatrix} \begin{bmatrix} i_q^s \\ i_d^s \end{bmatrix} + \begin{bmatrix} p & 0 \\ 0 & p \end{bmatrix} \begin{bmatrix} \psi_q^s \\ \psi_d^s \end{bmatrix} \quad (7)$$

$$\begin{bmatrix} \psi_q^s \\ \psi_d^s \end{bmatrix} = \begin{bmatrix} L_q & -L_{qd}^s \\ -L_{qd}^s & L_d \end{bmatrix} \begin{bmatrix} i_q^s \\ i_d^s \end{bmatrix} + \begin{bmatrix} \psi_m \sin \theta_{er}^s \\ \psi_m \cos \theta_{er}^s \end{bmatrix}$$

$$L_q^s = L + \Delta L \cos(2\theta_{er}^s)$$

$$L_d^s = L - \Delta L \cos(2\theta_{er}^s)$$

$$L_{qd}^s = \Delta L \sin(2\theta_{er}^s)$$

where the subscript e : the unit in electrical angle,

θ_{er}^s is the rotor position in stationary reference frame,

and

$$L = \frac{L_q^r + L_d^r}{2} \quad (8)$$

$$\Delta L = \frac{L_q^r - L_d^r}{2} \quad (9)$$

i.e.,

$$L_q^r = L + \Delta L \quad (10)$$

$$L_d^r = L - \Delta L \quad (11)$$

where L_q^r and L_d^r are the desired q- and d-axis inductances in the rotation reference frame.

It is obvious that the terms with ω_{er}^s can be eliminated in the standstill condition. And in order to eliminate the sine and

cosine terms, the rotor position θ_{er}^s is set to 0° (or 90°). Thus (7) are simplified as (12).

$$v_q^s = r_s i_q^s + L_q^r \frac{d}{dt} i_q^s$$

$$v_d^s = r_s i_d^s + L_d^r \frac{d}{dt} i_d^s \quad (12)$$

According to the dq transformation in the stationary reference frame, the d- and q-axis inductances can be represented by 3-phase voltages and currents that are directly measurable variables. The experiment configuration is shown in Fig 2. More explanation will be extended in the full paper.

IV. RESULTS AND DISCUSSION

Fig. 3 shows the calculated d- and q-axis inductance results by the flux linkage vector method. And Fig. 4 shows the experiment results by the proposed inductance measurement method. The large difference can be seen in d-axis inductances. The measured is greater. This is because the d-axis aligns to the stator tooth at standstill condition. The motor parameters and more discussion will be presented in the full paper.

Abstract — The shape optimization of a Thomson-coil actuator used in an arc eliminator is done for fast response by adopting topology modification method. The performance of the actuator is analyzed by using an equivalent circuit method. Both shape optimization and performance analysis are accomplished based on the segmentation of plate. The effectiveness of the proposed method is proved by the comparison of results before and after the shape optimization.

I. INTRODUCTION

An arc eliminator (AE) is a fault throwing device, as shown in Fig. 1, to protect electric systems and human lives from an arc fault by bypassing the power current to a ground with high speed in terms of just a few milliseconds at the moment of an arc fault ignition. Owing to the fast function, the AE can provide arc extinction and mitigate the after-effects by the prolonged arc with poisonous and contaminating gas flow. For this reason, Thomson-coil actuator is being more and more employed as the driving unit of the arc eliminator for its remarkable high speed compared with a conventional electromagnetic actuator utilizing electromagnetic attractive force [1].

The Thomson-coil actuator is mainly composed of, as shown in Fig. 1, an exciting coil and a moving plate having ground connection. In order to get a quick ground connection when the switch S is on, the parameters, such as capacitance and its initial charging voltage, exciting coil configuration, might be optimally decided. When selection of the parameters is limited for economic reason (the peak current is very often limited for a cheap switching device), however, the shape optimization of the conducting plate is a good alternative for quick response.

In this paper, the conducting plate of a Thomson-coil actuator for an arc eliminator is shape optimized using ON/OFF method based on the contribution of each segment to objective function [2].

II. PERFORMANCE ANALYSIS

The electromagnetic force of the Thomson-coil actuator is generated by the interaction between the magnetic field by the exciting coil and eddy current induced on the conducting plate. The precise approximation of the eddy currents on the plate, therefore, is essential for accurate performance analysis. In this paper, the conducting plate is divided into a series of segments, as shown in Fig. 2(a), and the eddy current, in each segment, is assumed to be uniform. Each segment, then, physically corresponds to a conductive ring with its circuit parameters of resistance and inductance as shown in Fig. 2(a).

In this way the whole system is transformed into equivalent circuits as shown in Fig. 2(b). The circuit equations, magnetic flux equations and motional equation are obtained, if the plate is divided into N segments, as follows [3]:

$$q/c + I_s R_s + d\lambda_s/dt = 0, \quad (1)$$

$$I_i R_i + d\lambda_i/dt = 0 \quad i = 1, 2, \dots, N \quad (2)$$

$$\frac{d\lambda_s}{dt} = L_{ss} \frac{dI_s}{dt} + \sum_{j=1}^N L_{sj} \frac{dI_j}{dt} + \sum_{j=1}^N I_j \frac{\partial L_{sj}}{\partial z} \frac{dz}{dt}. \quad (3-a)$$

$$\frac{d\lambda_i}{dt} = L_{is} \frac{dI_s}{dt} + I_s \frac{\partial L_{is}}{\partial z} \frac{dz}{dt} + \sum_{j=1}^N L_{ij} \frac{dI_j}{dt}, \quad i = 1, 2, \dots, N \quad (3-b)$$

$$(M + M_a) \frac{d^2 z}{dt^2} = (F_e - F_g - F_f) \quad (4)$$

where the subscripts s and i stand for the exciting coil and i -th segment of the plate, respectively, λ is the linkage flux, F_e , F_g , and F_f are the electromagnetic, gravitational and friction forces, M and M_a are masses of the plate and mechanical appendage, respectively, and other symbols have their usual meaning. The electromagnetic force, F_e , acting on the conducting plate is computed as follows:

$$F_e = \sum_{i=1}^N f_i = - \sum_{i=1}^N I_s I_i \frac{\partial L_{si}}{\partial z} \quad [N] \quad (5)$$

III. SHAPE OPTIMIZATION USING ON/OFF METHOD

The optimization target, in this paper, is the displacement of the conducting plate after 3.5 milliseconds from switching-on. When the conducting plate is divided into N small segments, each segment will contribute to acceleration of the plate by developing electromagnetic force on its eddy current

Fig. 1. The simplified mechanism of the Thomson coil type actuator.

Fig. 2. Equivalent circuit model of the system.

and, at the same time, to deceleration by its own gravitational force.

The acceleration of the plate is calculated from (4), and can be rewritten as follows:

$$a = [F_e - (M + M_a)g - F_f] / (M + M_a) \quad (6)$$

where g is the acceleration of gravity. When the i -th segment is removed from the plate, the acceleration of the plate will be expressed as follows:

$$(a)_i = \{ (F_e)_i - ((M)_i + M_a)g - F_f \} / ((M)_i + M_a) \quad (7)$$

where $(\cdot)_i$ is the quantity obtained without i -th segment. It is assumed, here, that elimination of the i -th segment does not change the friction force and eddy currents in other segments. The contribution factor of i -th segment to the acceleration of plate is finally estimated as follows:

$$c_i = \int_{t_i}^{t_f} (a - (a)_i) dt = m_i / (M + M_a - m_i) \int_{t_i}^{t_f} (a_i - a) dt \quad (8)$$

$$a_i = (f_i - m_i g) / m_i \quad (9)$$

where m_i is the mass of the i -th segment. The final displacement of the plate, finally, can be increased by removing the segments which have small contribution factor from the plate after computing the contribution factors for all segments.

The overall procedure of the shape optimization of the proposed algorithm is summarized as follows:

Step 1. Decision of the initial segmentation

The number of segments should be enough to guarantee an accurate performance analysis.

Step 2. Performance analysis and calculation of contribution factors

The final displacement of the conducting plate, contribution factors of all segments are computed through performance analysis by using the equivalent circuit method.

Step 3. Modification of topology

According to the contribution factors the segments having small contribution factor are removed from the plate. At this stage some segments can not be removed due to a structural constraint.

Step 4. Accept or not the modified topology

With the modified topology, the performance will be analyzed again. If the modified topology gives a better performance (i.e. more displacement), the new topology is accepted as a new topology and go to Step 3 for next iteration.

Step 5. Refinement of the segments

If the modified topology gives worse performance than the previous topology in Step 4, it means the optimum shape exists between the previous and current topologies. If the sizes of all the segments to be removed are small enough, the previous topology is considered as an optimal shape. If some of the segments to be removed are not small enough, they will be divided into smaller segments, and go to Step 2 for more precise topology modification.

IV. RESULTS AND DISCUSSION

chanical strength. In the performance analysis the moving contact is ignored, and its mass is taken into account as the additional mass. The exciting circuit parameters are shown in Table.1. The optimized shape of plate with eddy current density distribution is compared with the initial one as shown in Fig. 4. Fig. 5 shows the variation of the final displacement and mass of the plate with respect to iterations. After 10 iterations, an optimum shape which gives 47.5mm displacement with 0.325kg mass is obtained.

Abstract—Axially magnetized tubular permanent magnet actuators can be designed to obtain a sinusoidal back-electromotive force waveform and almost zero cogging force. The shape optimization of the translator iron pole-pieces is proposed to further enhance the actuator design. This is particularly beneficial for actuators with an external translator where a significant permanent magnet leakage flux is apparent. A space-mapping type of optimization algorithm is implemented to solve the corresponding design problem. A modified approach that considers a semi-analytical coarse model employing Fourier analysis and a simplified magnetic equivalent circuit is proposed and verified in this paper.

I. INTRODUCTION

TUBULAR permanent magnet (PM) actuators provide high efficiency, high power/force density and excellent servo characteristics [1]. In this respect, it has been shown that the particular topology of the tubular PM actuators using axially magnetized patterns have a number of attractive characteristics such as a sinusoidal back-electromotive force (back-EMF) waveform, which coincides with a very low electromagnetic force ripple, and the possibility of being optimized to achieve almost zero cogging force [2]. A particularly attractive advantage is the ease of manufacture of the axially magnetized translator. For an inner translator configuration without back-iron, this magnetization pattern provides virtually "self-shielding", hence most of the magnetic loading is concentrated in the airgap. However, when an external translator configuration is considered, a large amount of leakage magnetic flux is apparent. The shape optimization of the iron pole-piece is proposed in this paper to reduce the leakage flux. This approach provides both an increased airgap flux density and a lower translator mass. The resulting core geometry is also rather easy to manufacture.

To enable a fast optimization procedure, a space-mapping (SM) based technique is considered [3]. Automated electromagnetic actuator design can be achieved by means of several approaches. For example, one might consider fast, however, accuracy deficient coarse models or, in contrast, the design could be achieved exclusively by employing accurate, time expensive, fine models. The SM-based optimization, with its input, output or implicit mapping implementations, merges the advantages of the two extremes. Generally, finite element (FE) models are the predominant choice for fine models, while magnetic equivalent circuits (MEC) are considered as

Fig. 1. Cross-section of the external translator tubular PM actuator with axially magnetization pattern illustrating (a) rectangular magnets (b, c) shape optimized pole-pieces (b) triangular, (c) circular.

coarse models for actuators due to the presence of the iron core [4]. However, MEC models provide only a restricted validity because of the designer pre-defined flux paths, which makes these models rather unsuited for optimization problems that can lead to significant modifications of the geometrical configuration of the actuator. Therefore, this paper proposes a modified approach where a semi-analytical model, considering Fourier analysis and a simplified MEC, is employed as a coarse model.

II. SEMI-ANALYTICAL COARSE MODEL

The tubular structure of the actuator presents an axial symmetry and hence a 2D-cylindrical coordinate system, (r, z) , can be considered. This semi-analytical model calculates the airgap field due to the PMs, where a linear PM demagnetization characteristic, infinite iron permeability and infinite motor length are assumed. As shown in Fig. 1, four regions are considered: the slotless winding region (R_s to R_w), the airgap (R_w to R_g), the PM region (R_g to R_m) and the air region outside the actuator. The PM region is separated to include the pole-pieces. Appropriate boundary conditions are defined at the interfaces between the defined regions and on the outside boundary of the design domain. Essentially, at this stage the back-iron and the pole-pieces are excluded from the problem. The resulting boundary value problem is solved by considering the magnetostatic Maxwell equations, reduced to a Poisson equation written in terms of the magnetic vector potential \vec{A} as $\vec{B} = \nabla \times \vec{A}$,

$$\nabla^2 \vec{A} = -\mu_0 \nabla \times \vec{M}, \quad (1)$$

where $\vec{M} = 0$ for the winding the airgap regions. Fourier analysis is employed to describe the magnetization vectors in

Fig. 2. Flux density in the middle of the source free region by semi-analytical means compared to FE analysis.

the PM region and consequently, the solution for the radial and axial flux density distribution is obtained as a Fourier series [5]. The Poisson equation (1) is solved with the method of separation of variables. This approach provides for a very good agreement with the FE analysis if highly permeable, linear iron is considered or saturation is not reached for non-linear core material. Such a situation is illustrated in Fig. 2. Once the distribution and amplitude of the magnetic flux in the airgap and PM regions are obtained, a simplified MEC model is used to approximate the magnetic flux amplitude in the back-iron and pole-pieces. As such the geometry of the pole-piece is included in the problem by approximation. It is understood that this does not represent the real non-linear material or flux distribution and hence an FE model is introduced as a fine model to accurately determine the influence of varying the shape of the pole-pieces. The SM optimization routine compensates the misalignment between the coarse and fine models by exploiting a reduced number of fine model evaluations and effectively directs the optimization effort onto the coarse model.

III. OPTIMIZATION APPROACH

The main idea of SM optimization is to replace a computationally expensive fine model, $\mathbf{f} : \mathbf{X} \subseteq \mathbb{R}^n \rightarrow \mathbb{R}^m$, with a surrogate based on an iteratively updated coarse model, $\mathbf{c} : \mathbf{Z} \subseteq \mathbb{R}^n \rightarrow \mathbb{R}^m$, which is significantly less time demanding at the expense of accuracy. As a principle, the aggressive output space-mapping (AOSM) algorithm, which is considered in this paper, replaces the original optimization problem $\mathbf{x}^* = \operatorname{argmin}_{\mathbf{x} \in \mathbf{X}} \|\mathbf{f}(\mathbf{x}) - \mathbf{y}\|$, where \mathbf{y} is a set of design specifications, with the surrogate problem given by $\mathbf{x}^* = \operatorname{argmin}_{\mathbf{x} \in \mathbf{X}} \|\mathbf{o}(\mathbf{c}(\mathbf{x})) - \mathbf{y}\|$, where \mathbf{o} is a so-called output mapping. However, from an algorithmic point of view, the following inverse formulation to obtain a new iteration point is preferred:

$$\mathbf{x}_{k+1} = \operatorname{argmin}_{\mathbf{x} \in \mathbf{X}} \|\mathbf{c}(\mathbf{x}) - \mathbf{t}_k(\mathbf{y})\|, \quad (2)$$

i.e., the unmodified coarse model is re-optimized with respect to an updated set of specifications. The updated coarse model specifications, \mathbf{y}_k , account for the misalignment between the coarse and fine models and are determined from quasi-Newton steps considering a Broyden-type Jacobian update [4].

Fig. 3. Airgap flux density for the rectangular and triangular pole-pieces (Fig. 1b).

IV. RESULTS

The proposed analysis and optimization approach is used to determine the optimal magnet to pole-piece ratio (τ_m/τ_{pp}) and the depth of the triangular slot of the external translator tubular PM actuator for a given set of design specifications regarding the actuator force, a maximum limit on the iron flux density and a minimized translator mass. The influence of a modified pole-piece on the airgap flux density is shown in Fig. 3. This figure shows that the peak and RMS values of the airgap flux density are increased when the pole-piece shape is considered in the design procedure. Consequently, the pole-piece shape directly influences the force and acceleration of the external translator tubular PM actuator.

V. CONCLUSIONS

The shape optimization of the translator iron pole-pieces of a tubular PM actuator with external translator is proposed in this paper. As such, an increase in airgap flux density and a reduction of the translator mass can be obtained. A computationally efficient SM-based optimization algorithm is employed to obtain the corresponding design solutions. In this paper, a modified approach is proposed that exploits a semi-analytical coarse model, considering Fourier analysis and a simplified MEC, and an FE fine model. This combined approach for the coarse model provides a significantly higher accuracy of the airgap field calculation compared to a traditional MEC model.

Electric Power Division

Tel: (+30)-210-7723765, e-mail: laskaris@central.ntua.gr

Abstract— Permanent magnet motors due to their increased efficiency are favored for electric vehicle applications. The geometry optimization of the motor enables to achieve an adequate compromise between the two important parameters of performance and efficiency. The paper presents a methodology based on 2D FEM and sensitivity analysis techniques providing such optimization for the cases of surface and internal permanent magnet motors. The obtained results are validated by measurements on respective prototypes.

I. INTRODUCTION

Wheel motor is a promising traction solution that minimizes transmission loss. Meanwhile the cost of energy storage is considerably higher than the motor production cost and thus affects importantly the design and construction procedures of Electric Vehicle (EV) motors [1], [6].

Torque optimization is a very important issue when selecting a direct coupling of the motor into the wheel, as it is no more possible to increase power by increasing speed. The mean Magnetic Flux Density (MFD) in the air gap, per pole part, determines importantly the output torque capability of a motor. However, over sizing the magnetic loading of a motor can create disadvantages, due to the associated core loss [2].

Fig. 1. Wheel Motor Magnetic components geometry
a. SPMM configuration, low magnetic loading 0.6 Tesla
b. IPMM configuration, high magnetic loading 1.2 Tesla

Two motor topologies and the respective prototype implementations, with different MFD values in the air gap, are being studied. A low power compaction 24 pole, 10 kW, Surface Permanent Magnet Motor (SPMM) shown in fig. 1a and a high power compaction 8 pole, 12 kW, Internal Permanent Magnet Motor (IPMM) shown in fig. 1b.

II. METHODOLOGY

A. Sensitivity analysis based on 2D FEM

A two dimensional finite element model (2D FEM) has been employed to analyze the alternative motor topologies. Geometry optimization has been performed by using sensitivity analysis techniques, in order to obtain an appropriate compromise involving all geometrical criteria of the motor configuration [1].

Fig. 2. IPMM flux density distribution for different values of loading current

As shown in Fig. 2 the important flux on the right side of the pole part brings the iron core into saturation area. The MFD accumulation, limits down the capacity of the motor to produce torque [3], [5].

B. Iron loss evaluation technique

This section introduces our method of computing iron core loss for a given motor geometry.

Fig. 3. IPMM Loss Matrix graphical representation at 50 Hz under no load

The motor area is quantized into small subregions, each of which is assigned the value of losses that derives from the material core loss curve, accordingly. The method makes use of the formula (1), in order to determine the total stator core loss:

$$P_{core} = th \cdot P \cdot l_a \cdot \Delta S \cdot \sum_i w(B_{max,i} | f) \quad (1)$$

where th is the number of stator teeth per pole, P is the number of poles, l_a is the axial length of the motor, ΔS is the cross section area of the elementary surface used and w is the volume specific loss, as a function of the maximum flux density during rotation of one pole pitch and the supply frequency. i regards every square element that composes one stator tooth.

C. Global optimization procedure

The optimization procedure is based on a composite cost function that takes into account the total cost of construction and defines the relationship between performance, efficiency and cost. The adopted composite optimizing function F to be minimized is defined in (2), and consists of two parts, denoted by C_K and C_A , defined in (3) and (4) respectively, which are expressed in cost units.

$$F(p_1, p_2, \dots, p_n) = C_K(p_1, p_2, \dots, p_n) + C_A(p_1, p_2, \dots, p_n) \quad (2)$$

where p_1, p_2, \dots, p_n are the parameters that affect construction or operation cost.

$$C_K = c_{mV} \cdot V_m + c_{IL} \cdot L_l + c_{IS} \cdot S_l + c_{FeV} \cdot V_{Fe} + c_{wL} \cdot L_w \quad (3)$$

$$C_A = c_e \cdot E_{tot} \quad (4)$$

where C_K : total construction cost
 C_A : total operation cost
 c_{mV} : specific magnet cost (€/cm³)
 c_{IL} : specific lamination cost (€/m)
 c_{IS} : specific laminated iron core cost (€/m²)
 c_{FeV} : specific solid iron core cost (€/m³)
 c_{wL} : specific winding cost (€/m)
 c_e : specific energy cost (€/kWh)
 $V_x/S_x/L_x$: Volume/Surface/Length x respectively
 E_{tot} : total energy consumed in motor lifetime.

The parts assembly of the optimizing function is made according to the needs and design specifications. The convergence obtained by using different numerical methods such as Golden Section Search, Simulated Annealing and Enumeration is investigated [7].

III. RESULTS AND DISCUSSION

The proposed methodology has been implemented in the design of a surface and an internal permanent magnet motor, shown in Fig. 1. In order to validate the simulation results, two respective prototypes have been constructed.

As an example, Fig. 4 compares the simulated values of the losses compared to the measured ones in the case of IPM motor configuration. The phase voltage ripple observed is mainly caused by the stator tooth harmonic distortion. Loading current increase accumulates field in one side of the pole, which is translated from space to time by distorting the

voltage waveform, as shown in Fig. 5. Core saturation not only increases iron loss but also makes stator current less capable of producing torque [4], [5]. Saturation effects during high load can equally be observed in Fig. 5.

The good agreement between simulated and measured results illustrates the proposed method suitability for this class of problems.

Abstract – The multiple advantages of the switched reluctance machines (SRM) allow them to have various applications. Hence, this led to a growing interest for the design of new structures more successful and better adapted to the new requirements. This paper describes the influence of the geometrical parameters, especially the shape of the teeth, on the performance of SRM based on a coupled finite elements method and equivalent magnetic circuit approach FEM-EMC for an optimal design.

Keywords – SRM, FEM, equivalent magnetic circuit, geometrical parameters, optimization.

I. INTRODUCTION

The robustness, simplicity, reduced cost and high mass torque ratio of the SRM allow them to have various applications at high speed or low speed and high torque [1], [2]. The drawback of these machines is the presence of a pulsatory torque that the researchers try to minimize by optimizing the geometric and control parameters [3-9].

The prediction of the behavior of an electromagnetic system from the knowledge of its non-linear parameters, also connected to external sources, has always been a difficult problem to solve. The numerical solution is *a priori* appealing for solving complex problems with better accuracy but the computing time is penalizing [10]. While easy to implement, the analytical models are relatively inaccurate due to the simplifying assumptions [11].

Consequently, we choose a numerical-analytical method by FEM-EMC modeling to properly design a prototype of a doubly salient 6/4 SRM. The initial results are validated and are encouraging for an optimization procedure of geometric parameters which we develop in this paper [12]. The originality of this work is mainly the study of the influence of the teeth shape, particularly their tilting.

II. PRELIMINARY DESIGN PROCESS

A. The choice of a structure for study

The choice of the number of stator N_s and rotor N_r teeth is important since they have significant implications on the torque. Usually, N_s is selected to be greater than N_r with some conditions [13]. Since the speed is related to the frequency of the supply ($f = N_r * \Omega$), to minimize the iron losses without using material of high quality, we try to reduce the number of rotor poles. Among the most frequently used structures, we finally chose to study a three phase 6/4 SRM represented Fig.1.

The parameters of the 110 Nm, 3000 rpm, 6/4 SRM studied machine are given in Table I.

B. Choosing angles teeth

The choice of the stator and rotor angles teeth ($\beta_s ; \beta_r$) has significant effects on the torque ripple, duration of output torque, winding space and is an important factor in motor design optimization. Initially, they can be selected in the middle of the lower half of the feasible triangle where $\beta_s \leq \beta_r$ and with the three following conditions [7], [8], [13]

$$(2\pi / 3Nr) = 30^\circ \leq \beta_s \leq 45^\circ = (\pi / Nr) \quad (1)$$

$$(2\pi / 3Nr) = 30^\circ \leq \beta_r \leq 60^\circ = (4\pi / 3Nr) \quad (2)$$

$$(\beta_s + \beta_r) < 90^\circ = (2\pi / Nr) \quad (3)$$

III. FEM-EMC MODELING

A. Results by FEM simulation

By combining all of the electromagnetic equations, the vector potential equation governing the problem is

$$\nabla \times \left(\frac{1}{\mu} \nabla \times A \right) = J \quad (4)$$

where A is the vector potential, J is the current density and μ is the permeability.

We solve equation (4) by finite element method which is implemented in FEMM software [14].

Fig. 1. Flux plot at fully unaligned position of the studied 6/4 SRM

Fig. 2. Tilting of the rotor teeth

11. Electric Machines and Drives

Fig. 3. Effect of rotor teeth tilting on magnetic flux curves

Fig. 4. Effect of rotor teeth tilting on average torque

Among the various results obtained by FEM approach and validated [3-8], we will present in this paper only the influence of the slope of rotor teeth (Fig.2) which is not studied in any paper. In the case of the slope inclined towards the outside ($\alpha_s > 0$), Fig. 3 shows an increase in the area included between the magnetic characteristics of aligned and unaligned positions which induces an increase in the average torque (Fig. 4). We obtained the same results for the stator teeth.

B. Results by EMC simulation

This is a classic analytical method based on the calculation of reluctance portions of the equivalent magnetic. For the two extreme positions of the rotor, we had to work with seven equal flux tubes quite representative of the field lines [15]. We have exploited the previous results of the FEM to make our calculations under *MATLAB* environment with very user-friendly software. The process of optimization is based on the constancy of the following expression of the copper losses

$$P_{cu} = K\rho Lm(NtI)J \quad (5)$$

where K represents the current waveform coefficient, ρ the copper resistivity, Lm the mean length of turn, Nt the number of turns per phase, I the current level and J the current density. Since the excitation NtI is a constant for a design, copper losses are thus proportional to current density.

Among the various results obtained by EMC approach, we show here the optimal values: $\beta r \approx 40^\circ$ for the rotor tooth (Fig. 5) and $kcs \approx 1$ for the stator yoke thickness ratio (Fig. 6).

Fig. 5. Effect of rotor pole arc on average torque/copper losses ratio at $\beta_s = 30^\circ$

Fig. 6. Average torque vs. kcs ratio at $P_{cu} = 1513$ W and $\beta_s = \beta_r = 30^\circ$

TABLE I
PARAMETERS OF THE STUDIED 6/4 SRM

Quantity	Value
Stack length	150 mm
Outer diameter	250 mm
Rotor diameter	150 mm
Shaft diameter	42 mm
Air-gap length	0.8 mm
Height of stator teeth	26.2 mm
Height of rotor teeth	28 mm
Stator yoke thickness	24.8 mm
Number of turns per phase	23

IV. CONCLUSION

In this paper, we presented a sufficiently simple numerical-analytical procedure by *FEMM* to *MATLAB* software to design and optimize the geometrical parameters of a 6/4 SRM. The obtained results are very interesting.

Abstract—Flow visualization is essential to provide an insight into complex flow patterns of electromagnetic devices. In this paper, a method for the detection and evenly-spaced seeding of closed flux lines in 3D quasi-static electromagnetic fields is presented. The seeding is performed by weighting the magnetic flux on a specified cutting surface. Due to discretization of a finite element simulation, which is also applied for the flux density solution, the force lines are usually not closed. Therefore, an algorithm is introduced, monitoring the force line computation, to provide the generation of closed force lines.

I. INTRODUCTION

An intuitive method for the visualization of vector fields are flux lines, which provide a straightforward visual impression of the field characteristic and the magnetic circuit. Applying this technique to an electromagnetic field solution, one directly encounters the problem of closed flux line computation arising from its solenoidal field characteristics. In this paper, a method is introduced that monitors the stream computation to detect closed curves and minimize the computational effort. Afterwards, the flux line algorithm is combined with a seeding strategy that places starting points in correlation with the flux on a specified cutting surface to support quick flow pattern recognition. The proposed method is generally applicable to the electromagnetic field and comparable flow fields such as eddy current distributions.

II. CLOSED FLUX LINE COMPUTATION

A. Flux Line Computation

A flux line is an oriented curve ρ in a vector field ν on a domain Ω , which is everywhere tangential to the vector flow, with the properties

$$\frac{\partial \rho}{\partial \tau}(\tau) = \nu(\rho(\tau)) \quad (1)$$

$$\rho(\tau = 0) = a \quad (2)$$

where $\rho(\tau)$ is a certain point on the flux line, $\nu(\rho(\tau))$ the corresponding field vector and a an arbitrary start point in Ω . Each point in Ω is strictly mapped to exact one curve ρ .

According to Maxwell equations, the evoked electromagnetic vector field has an solenoidal field characteristic, so that each flux line ρ has a characteristic, but unknown length L , where

$$\rho(\tau + n \cdot L) = \rho(\tau), \forall n \in \mathbb{N} . \quad (3)$$

For a given start point $\rho(\tau = 0)$, the flux line ρ is obtained by integrating (2) iteratively over a discrete length $\Delta\tau$ (integration

step length), yielding

$$\rho(\tau + \Delta\tau) = \rho(\tau) + \int_{\tau}^{\tau + \Delta\tau} \nu(\rho(\tau)) \partial\tau \quad (4)$$

For a rapid and accurate flux line computation, (4) is solved by using a fourth-order Runge-Kutta integrator with adaptive step size and error control [1].

B. Closed Loop Detection

In general, the numeric solution of (4) leads to a continuous summation of the integration error, so that a computed curve does not comply to (3), a typical example is given in fig. 1. To detect such closed flux lines, without any knowledge of

Fig. 1. Typically integration error of eq. (4) in 3D Space. Top and lateral view of a flux line around a current excited rectangular wire in z direction.

the location and shape within the magnetic field, stop criteria are necessary that evaluate the integration process step-by-step and detect the characteristic length L . Basically, an end point $\rho(\tau_i)$ is located in a sphere around $\rho(\tau_0)$ with an error radius ϵ , e.g.

$$\|\rho(\tau_i) - \rho(\tau_0)\| \leq \epsilon . \quad (5)$$

Since the mesh size of Ω typically varies, e.g. in the comparison of an air gap to a back yoke, a more accurate end point detection is required.

Therefore the basic idea of the algorithm is to monitor the integration process and evaluate a modification of (5) by only verifying a possible closing of the curve in 3D space. Counting the number of sign reversal in:

$$\delta(\tau_{i+1}) = \|\rho(\tau_{i+1}) - \rho(\tau_i)\| \cdot \|\rho(\tau_1) - \rho(\tau_0)\| \quad (6)$$

A closed curve, independent from the simulated geometry, requires at least $2k + 1, k \in \mathbb{N}^0$ sign alternations. For point candidates that meet the latter precondition, the point distance perpendicular to the stream direction, given by

$$\|(\rho(\tau_i) - \rho(\tau_0)) \times (\rho(\tau_1) - \rho(\tau_0))\| \leq \epsilon \quad (7)$$

is computed and compared to ϵ . The error control by (7) is, in contrast to (5), independent from the displacement in curve direction, caused by the variable step size $\Delta\tau$.

III. SEEDING STRATEGY

Magnetic flux lines provide a visual impression of the vectorial field direction, and if colored an additional information of the intensity of magnetic field density. To support a quick recognition of the flow pattern by a set of flux lines, their seeding points have to be correlated with the magnitude of the vector field. By this requirement, the better part of seed points is located in an area with high field values and vice versa. Therefore, in this paper a seed point computation on a user defined cutting surface, $C \subseteq \Omega$, is presented. The proposed algorithm is as follows:

- Initially, the flux on all cutting elements in C is evaluated by

$$\Phi = \vec{B}_C \cdot \vec{a}_C \quad (8)$$

where \vec{B}_C is the vectorial flux per element and \vec{a}_C the corresponding oriented surface vector.

- According to a used specified flux range $[\Phi_{min}, \Phi_{max}]$, the plane C is sub-divided into a given number N_{plane} of sub-planes

$$C = \{C_1, C_2, \dots, C_{N_{plane}}\} \quad (9)$$

so that each sub-domain contains all elements with the corresponding flux interval.

- To weight the flux in each sub-domain C_i , the average flux $\Phi_i^{average}$ over all elements N_{C_i} on C_i , given by

$$\Phi_i^{average} = \sum_i^{N_{C_i}} \Phi_i^{elem} \quad (10)$$

is computed, [2], [3].

- For a given number of starting point N_{tot} , the ratio of

$$N_i = \frac{\Phi_i^{average}}{\sum_i^{N_{plane}} \Phi_i^{average}} N_{tot} \quad (11)$$

defines the number of seeding point per sub-domain N_i .

In the final step of the seeding algorithm, the points N_i are placed in the sub-domains C_i . At present state, the starting points are moved to those elements within C_i which have the largest magnitude of the magnetic flux. This leads, as exemplified in fig. 3, to a rough evenly-spaced seeding. An alternative placing strategy is to place N_i on the inner boundary of C_i equidistantly. The latter method is in preparation and will be discussed and compared to the flux-value-based seeding strategy in the full paper.

IV. APPLICATION

A rectangular wire surrounded by air is used as a test model for the seeding strategy in combination with the presented closed flux line algorithm presented in section II-B and III. The source current density J_s is injected into the cross section area of the wire. Fig 2, visualized by [4], shows the applied test scenario together with its vectorial representation of the

Fig. 2. Current excited rectangular wire in z direction together with its flux density distribution.

flux density distribution, obtained by [5]. Fig. 3 shows the seed point distribution of 100 start point, by a chosen flux interval from 50 to 100 and a decomposition into 10 subdomains. It can be noticed, that the starting point population density

Fig. 3. Closed flux lines seeded around the current excited rectangular wire.

increases by a distance reduction from the wire. The latter provides a visual impression of the flux density distribution. The flux lines are rough evenly-space which helps to recognize the corresponding flow pattern.

V. CONCLUSION

In this paper, an algorithm which detects closed flux lines by extending the integration process by a monitoring routine is presented. The method relies on the assumption of a solenoidal vector field characteristic. To give a visual impression of the vector field solution, a seeding strategy is presented which places seeding points in correlation with the magnetic flux on a cutting surface. As a first test case, the proposed method is exemplified on a 3D air surrounded wire model yielding a flux line distribution which corresponds to the expected flow field pattern.

cougo@laplace.univ-tlse.fr

Abstract— This paper presents an accurate method to calculate high frequency copper losses in InterCell Transformers (ICTs) made with low permeability cores. Since this type of transformer cannot be well represented by 1D model, analytical calculation of the high frequency resistance is not accurate. The method presented here is based on 2D FEM simulations of the ICT. By the nature of this type of transformers, some 2D FEM simulations must be made in order to take into account non-sinusoidal differential and common-mode currents.

I. INTRODUCTION

Interleaved converters are used when high power density is needed. This type of converter has some advantages when comparing to standard converters, such as the increase of the apparent frequency of the voltage applied across the output filters and the improvement in the dynamic behavior of the converter.

Usually an interleaved converter is composed by some identical commutation cells with the outputs interconnected through separate inductors. The association of these inductors may result in large ripple in the current flowing in each cell [1]. This leads to high conduction losses in the switches and high copper losses in the inductors. If we magnetically couple the inductors, we may obtain the same relative current ripple in the commutation cells and at the output. This is obtained by the use of InterCell Transformers (ICTs) [2].

II. SIMPLE INTERCELL TRANSFORMERS

Let’s analyze the operation of ICTs by taking as an example the transformer on Fig. 1. In this transformer, each winding is connected to a commutation cell in such a way that the fluxes from both legs (Φ_1 and Φ_2) are summed up and are obliged to pass by the air (leakage flux). If we use the transformer of Fig. 1 in an interleaved converter composed of 2 commutation cells, and supposing that output voltage is filtered (which is usually the case), we can note that the voltage across each winding is rectangular. Consequently, a triangular flux is imposed in each leg of the transformer.

Fig. 1. Simple intercell transformer and current directions

A. Low Permeability Cores Used in Intercell Transformers

Usually high permeability cores are used in the construction of ICTs in order to minimize magnetizing current. However, in certain applications it is preferable to use low permeability cores if we regard globally the magnetic flux density saturation, cost, size and loss density when designing the transformer.

In an ICT, if a low permeability core is used, the core reluctance is comparable to the leakage reluctance. In this case, the current in each cell will be the sum of the magnetizing current (which the fundamental frequency is equal to the switching frequency) and the coupled current (which the fundamental frequency is equal to the double of the switching frequency), as shown in Fig. 2.

Fig. 2. Phase currents of a 2-phase ICT

III. FEM SIMULATION TO COPPER LOSSES

Analytical calculation of AC resistance of conductors in a transformer was explained by Dowell, in his famous paper from 1966 [3]. He explains the proximity effect mathematically, solving Maxwell’s equations for a 1-D model of transformers. Since Dowell’s 1-D analytical approach models a 3-D phenomenon, several authors make use of FEM simulation to obtain more precise results [4,5]. In our case, 2D and/or 3D simulation is necessary since a great part of the windings is not contained inside the core window.

The use of 3D FEM simulation may result on accurate calculation of the copper losses, but it is very time consuming. 2D FEM simulation can be considered if the procedure used in the simulation takes into account 3D effects.

As we can see in Fig. 2, the component of the current due to the magnetizing current in cell 1 has 180° of phase difference when comparing to the same one in cell 2. Additionally, the components of the current due to the coupled current are in phase in both cells. These facts confirm the need of FEM simulations. In this case, two different 2D simulations are needed: one for the magnetizing current and another one for the coupled current.

The drawing of the transformer in the FEM software is the same for both simulations. When simulating the magnetizing current, the current imposed in each winding must have the same direction inside the core window, as in Fig. 1a. However, when simulating the coupled current, the current imposed in each winding must have opposite directions inside the core window, as in Fig. 1b.

Since most of FEM softwares only allow sinusoidal current simulation, Fourier analysis may be applied to non-sinusoidal currents [6]. Both magnetizing and coupled currents must be decomposed into Fourier series, and a simulation for each important harmonic must be carried out. The easiest way to calculate total AC copper losses is to simulate for each frequency separately and then sum up all results to post calculate 4 equivalent AC resistances, which are:

$R_{ACeqintmag}$ (AC equivalent resistance of the conductors inside the core window, due to the magnetizing current), $R_{ACeqextmag}$ (AC equivalent resistance of the conductors outside the core window, due to the magnetizing current), $R_{ACeqintcou}$ (AC equivalent resistance of the conductors inside the core window, due to the coupled current) and $R_{ACeqoutcou}$ (AC equivalent resistance of the conductors outside the core window, due to the coupled current). The equation of the ratio between the equivalent AC resistance and the DC resistance has the following form:

$$Fr_{eq} = \frac{R_{ACeq}}{R_{DC}} = \sum_{n=1}^{\infty} Fr_n a_n^2 \quad (1)$$

where Fr_n is the ratio between the equivalent AC resistance and the DC resistance of the n^{th} harmonic and a_n is the normalized amplitude of the n^{th} harmonic of the triangular current. a_1 is always equal to 1 to facilitate the calculation.

The DC resistances (R_{DCint} and R_{DCext}) are different for the conductors inside and outside the core window since their lengths may be different. For example, in the transformer in Fig. 1, the length of the conductors inside the core window is equal to the core window depth, while the mean length of the conductors outside the core window is equal to the mean turn length subtracted by the core window depth.

IV. SIMULATION RESULTS

An example will be used to illustrate the method. The ICT of Fig. 1, draw with 6 turns in each winding, was simulated using FEMM software, version 4.2. An example of the simulation output graphs, for one specific frequency, is shown in Fig. 3. We can see the difference between the magnetizing and coupled current density distributions. We also observe a difference in the current density distribution when comparing the current passing inside and outside the core window.

Fig. 3. FEMM simulation of a simple ICT (Current density plot)

The ratios between AC and DC resistances simulated in FEMM are shown in Table I along with the first 5 terms of the Fourier series of the magnetizing and coupled currents when the duty cycle is equal to 0.25 (as the one shown in Fig. 2). Simulations were made at fundamental frequency equal to 15kHz.

		Fr_{eq} ext-mag	Fr_{eq} ext-mag		Fr_{eq} ext-cou	Fr_{eq} int-cou
TOTAL		1,95	1,69		3,21	2,46

Note that the equivalent AC/DC resistance ratios for the conductors outside the core window are different from the ones related to the conductors inside. Also, these ratios are usually higher for coupled current since its fundamental frequency is the double of that for magnetizing current.

Having the four Fr_{eq} , we can calculate the four equivalent AC resistances. The total copper losses are calculated by using these resistances and the phase current.

V. CONCLUSION

Intercell transformers are used in interleaved converters in order to reduce current ripple in each commutation cell. Low permeability cores may be used in intercell transformers but its utilization results in the increase of the magnetizing current, which is superposed to the existing coupled current. We have proposed a simple procedure, based on 2D FEM simulations, which allows the precise calculation of AC resistances associated to the magnetizing and coupled currents, inside and outside the core window. Accurate prediction of these resistances is crucial in an ICT design. An example was given to illustrate the method.

Abstract — This paper deals with the loss analysis and efficiency evaluations in a synchronous reluctance motor (SynRM) using a coupled transient finite element method (FEM) and Preisach modeling, which is presented to analyze the characteristics under the effect of saturation and hysteresis loss. The focus of this paper is the efficiency evaluation relative to hysteresis loss, copper loss, etc. on the basis of speed, load condition in a SynRM. Computer simulation and experimental result for the efficiency using dynamometer show the propriety of the proposed method.

I. INTRODUCTION

In high-speed applications, hysteresis loss can become the major cause of power dissipation. Therefore, whereas in other kinds of machines a rough estimation of hysteresis loss can be accepted, their importance in a SynRM justifies a greater effort in calculating them more precisely. The Preisach model is now generally accepted to be a powerful hysteresis model, and is therefore intensively studied [1]-[3].

Some papers which discussed the influence of hysteresis loss on a machine have been presented.

Reference [4], [5] have been investigated the steady state characteristics of inductances etc. using coupled FEM & Preisach modeling in a PMA SynRM. Reference [6], [7] have been developed the transient analysis method coupled with vector control algorithm in a LIM and a SynRM respectively.

Reference [8], [9] have been discussed the hysteresis loss influence on the transient behavior of a SynRM and which have the coupled control algorithm & the analysis method.

Reference [10] have been proposed the control algorithm, which selects appropriate stator d, q-axis current component combination that the influence of iron core loss on the developed torque can be minimized in torque control, by the coupled finite element analysis and Preisach modeling in a SynRM.

In this paper, a coupled finite element analysis and Preisach modeling for a SynRM are presented and dynamic characteristic analyses are performed under the effect of saturation and hysteresis loss. The focus of this paper is the efficiency evaluation relative to hysteresis loss, copper loss, etc. on the basis of speed, load condition in a SynRM.

Also, TMS320C31 DSP installed experimental device and dynamometer are equipped and experiments are performed.

Computer simulation and experimental results for efficiency show the propriety of the proposed a coupled finite element analysis and Preisach modeling method.

II. Coupled Fem And Preisach'S Modeling

Coupling governing equation and circuit equation, the system matrix is given as follows:

$$\left[\begin{array}{cc} \mathbf{v}_0[S] & -[N] \\ [0] & [R] \end{array} \right] + \frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \left\{ \begin{array}{c} \{A\} \\ \{I\} \end{array} \right\} = \quad (1)$$

$$\frac{1}{\Delta t} \left[\begin{array}{cc} [0] & [0] \\ [LG]^T & [L_0] \end{array} \right] \left\{ \begin{array}{c} \{A\} \\ \{I\} \end{array} \right\}_{t-\Delta t} + \left\{ \begin{array}{c} \{M\} \\ \{V\} \end{array} \right\}_t$$

Where, $\{E\}$: emf. vector in the winding, $\{V\}$: Supplying voltage vector, $\{I\}$: Phase current vector, $[L_0]$: Leakage inductance, $[LG]$: Coefficient matrix related to emf, $\{M\}$: Magnetization calculated by Preisach modeling

Fig. 1 shows the simulation scheme for the proposed analysis method. The torque acting on SynRM at each time is calculated by the line integral of the Maxwell stress tensor.

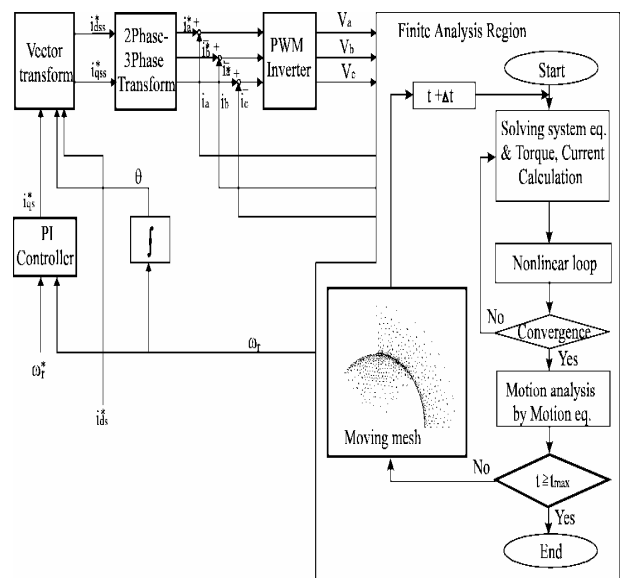

Fig. 1 Block diagram of analysis system

III. Result & Discussion

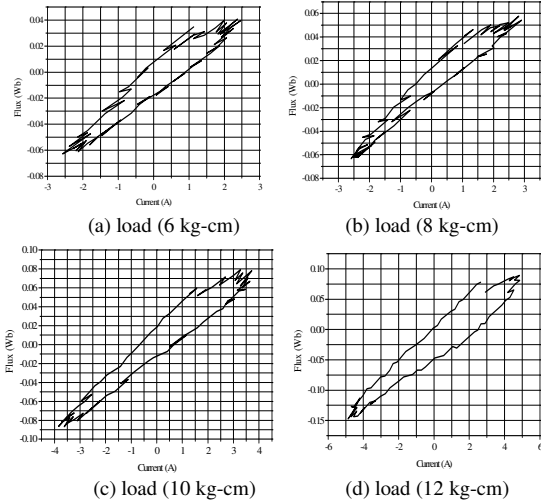

Fig. 2 i-λ loci in each load condition at 2000 rpm

TABLE I
LOSS EVALUATION IN SIMULATION AT 2000 RPM

load (kg-cm)	output (W)	Hysteresis loss (W)	Copper Loss (W)	mechanical loss (W)	the rest loss (W)	phase current (A)
6	122	13.70	4.7	5	4.6	2.2
8	163	12.96	9.03	5	8.01	2.7
10	204	9.92	15.65	5	15.4	3.68
12	244	16.02	25.61	5	21.3	4.7

TABLE II
EFFICIENCY EVALUATION IN EXPERIMENTAL TEST AT 2000 RPM

Load (kg-cm)	input (W)	output (W)	Efficiency (%)	q-axis current (A)	phase current (A)	current angle (deg.)
6	150	122	80	2.35	2	39.2
8	198	163	82	2.8	2.77	47.9
10	250	204	83	3.3	3.65	55.2
12	312	244	78	3.9	4.7	61.5

Fig. 3 Efficiency in each load condition

Fig. 4 loss analysis in each load condition

Fig.2 shows the i-λ loci per 1 cycle in each load condition at 2000 rpm.

The hysteresis loss can be calculated by the area of the i-λ loci times the frequency (66.7 Hz), and the copper loss can be calculated by the resistance times rms value square of phase current.

The mechanical loss is about 5 (W) in each load condition, which is experimental data.

The rest losses are the eddy current loss and the stray load loss, etc. These losses are denoted in TABLE I.

Output powers in simulation are the same with that developed in experimental test. Therefore, phase currents are similar to the experimental phase current as shown in TABLE II.

Fig.3 shows the efficiency of each load condition.

It is confirmed that the maximum efficiency current angle (55.2°) is deviated from 45°, as shown in Fig. 3.

Fig. 4 shows the each loss ratio to the total loss in each load condition. Whereas in copper loss increasing current due to the increasing load should be enlarged, their rate in a hysteresis loss should be minimized in maximum efficiency condition precisely.

Through the more detailed analysis and experiment for the another speed (rpms), the variable comparisons for performance of the SynRM will be represented in next extended version

Abstract — In order to investigate the propagation of partial discharge pulses in transformer winding, the simulation models of a 40 turn and a 180 turn continuous transformer winding based on multi-conductor transmission line (MTL) theory are constructed. A novel method is proposed to calculate the K matrix that decreases distinctly calculation cost without loss of accuracy. This new method also has been extended to inductance and resistance calculation, and obtained very good effect. To verify this method further, we solve PD propagation along winding, and compare with the experimental result. And in consequence, the simulation result can meet the experimental result very well. Therefore, this novel method is very reliable.

I. INTRODUCTION

In order to study the partial discharge (PD) propagation characteristics along transformer winding, we have built a distributed line model based on multi-conductor transmission line (MTL) theory [1]. Apparently, the calculation of distributed parameters is quite important for MTL model because it greatly determines the accuracy and efficiency of numerical model. However, although the analytical method is most commonly used, it is very limited because the formulas are from experience and just suitable for special winding with a simple geometry. According to the complexity of transformer winding, the field method has been proved to be more applicable. But for a large n -conductor system, it is considerably time consuming. Therefore, this paper proposes a novel method to calculate distributed parameters which decreases distinctly calculation cost without loss of accuracy.

II. THE ESTABLISHMENT OF WINDING MODEL

This paper chooses to establish two winding model: 40 turn winding model and 180 turn winding model. The structural diagram for winding model is shown as Fig. 1. The 40 turn winding is a single layer continuous hollow winding model. The 180 turn winding consists of 18 coils sections.

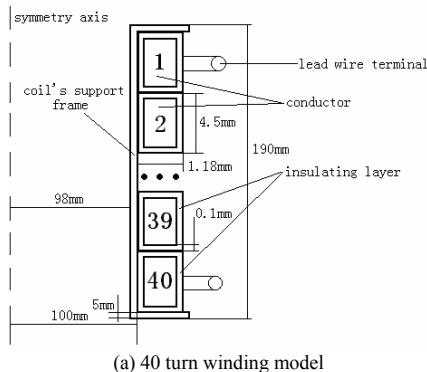

Fig. 1. Structural diagram for winding model

III. THE PROPOSAL OF NOVEL CALCULATION METHOD

In order to simplify the verification for this novel method, we choose 40 turn winding model as analysis model firstly. If this method proves to be reliable, it can be extended to 180 turn winding model. Because induction coefficient is scarcely affected by frequency, the distributed law is easier to analyze than inductance and resistance. Therefore, we try to propose a novel method by analyzing the induction coefficient calculation result firstly. Then, we can apply to inductance and resistance calculation to verify this novel method.

Usually, we can calculate induction coefficient based on electromagnetic theory, total static electric energy W of an n -conductor system in region V can be written as follows [2]:

$$W = \frac{1}{2} \sum_{i=1}^n \left(K_{ii} U_i^2 + \sum_{\substack{j=1 \\ j \neq i}}^n K_{ij} U_i U_j \right) \quad (1)$$

As the winding's special structure, analytical formulas are hard to list. So a normal procedure to evaluate K by field method is as follows.

K_{ii} —First, apply a unit potential on the i th conductor, while the others are set to zero potential. Due to an approximate axisymmetrical structure of the model, a 2-D static electric field FE analysis can calculate W . Then by (1), the diagonal elements of K are obtained.

K_{ij} —Apply unit potentials on the i th and j th conductor, while the other $n-2$ conductors are set to zero potential. As in step 1, after the FE analysis, other elements of K are obtained as well by (1). ($i \neq j$, i is from 1 to $n-1$, j is from $i+1$ to n)

Following the procedures above requires $n(n+1)/2$ FE solution steps to get K , which is almost impossible for large-scale transformer winding ($n > 100$) [3]. Some alternative methods should be carried out. By analyzing K of 40 turn

winding model, we can find some interesting characteristics that will help us overcome this difficulty. It is known that the K_{ij} decrease rapidly with the distance between i th and j th conductor increasing due to the shielding effect of their interval turns. This feature enables that we need fill a few elements in \mathbf{K} only, which greatly reduce \mathbf{K} 's half bandwidth and changes it to a banded matrix. Because $K_{i,i+3}$ is little enough to be ignored, we only consider the interaction between each coil with adjacent two turns. Considering that the winding model is symmetric with respect to the 20th turn, we can calculate the first 21 turns, and then obtain $\mathbf{K}[40 \times 40]$ by matrix transformation. According to the novel method, we only require $3(n/2+1)$ FE solution steps to get \mathbf{K} . As shown in Fig. 2, this novel method decreases distinctly calculation cost without loss of accuracy. Thus, the novel method can be applied to inductance and resistance calculation.

Fig. 2. Distributed law of K_{ij} ($i=1,2,\dots,40$)

Fig. 3. Distributed law of L_{ii} ($i=1,2,\dots,40$) at 1 MHz

Due to the frequency effect, AC inductance and resistance should be calculated. However, if completely adopting FEM to calculate \mathbf{L} and \mathbf{R} , it would occupy great system resources and cost maximal computing time. Even if in static magnetic field, DC inductance calculation of 40 turn winding should cost 40GB hard disk space. So we must do some simplifications in calculation process. In this paper, we propose calculation of AC inductance and resistance based on the relation between apparent power and complex impedance [4]. In this method, inductance and resistance can be calculated together. Because of winding's symmetry, we also only need calculate the first 21 turns just as the induction coefficient calculation. It takes $n/2+1$ FE solution steps and $(n/2+1)(n/2+n)/2$ postprocessing steps to get \mathbf{L} or \mathbf{R} . Owing to considerable reduction of FE solution steps, the efficiency of this novel method can be improved greatly. To our excited, the novel method can replace completely FEM very well as shown in Fig. 3. In Fig. 3, both "direct" and "fluxv" are based

on magnetic induction intensity integration. "VA" represents this novel method, and "ansoft" is inner macro instruction based on energy principle in ANSOFT environment. The efficiency and accuracy of this novel method are shown as TABLE I.

TABLE I
COMPARISON OF DIFFERENT CALCULATION METHODS

Parameter	Calculation method	FE solution steps	Maximum error	Computing time(min)
\mathbf{K}	FEM	$n(n+1)/2$	0	138
	Novel method	$3(n/2+1)$	0.5%	25
\mathbf{L}	FEM	$n(n+1)/2$	0	255
	Novel method	$n/2+1$	1%	53
\mathbf{R}	FEM	$n(n+1)/2$	0	255
	Novel method	$n/2+1$	1%	53

Because the novel method has been verified by calculation result of 40 turn winding model, it can be extended to 180 turn winding model. According to theory of novel method, except K_{ii} , we need only evaluate the K_{ij} ($i=1,2,\dots,n$, $i+1 \leq j \leq i+2$) in the same section and next to the section. As shown in Fig. 1(b), for example, in order to calculate the induction coefficient of 18th conductor, it is necessary to consider 11 conductors in all coils: the 16th,17th,18th,19th,20th conductor in second section, the 2nd,3rd,4th conductor in first section, and 22nd,23rd,24th in third section. Furthermore, only half of conductors (1~10 section) are necessary to be calculated due to the plane symmetry of transformer winding model.

IV. SOLUTION OF PD IMPULSE ALONG WINDING

In order to verify the parameter calculation result further, we can solve PD propagation characteristics along winding. If the simulation result can meet the experimental result very well, the distributed parameters can be verified once more. Therefore, this novel method can be extended to the parameter calculation of real transformer winding model.

V. CONCLUSION

Because of the shielding effect of interval turns, the turn's K_{ij} decreases rapidly with the distance. \mathbf{K} can be simplified as a banded matrix, and most of its elements need not to be evaluated. A novel method is proposed to calculate the \mathbf{K} matrix that decreases distinctly calculation cost without loss of accuracy. This novel method also can be extended to inductance and resistance calculation. It is very important for us to research on PD propagation characteristics in winding.

Optimal Regularization for MEG Source Reconstruction by Inverse Methods

Feng Luan, Chany Lee, Jong-Ho Choi, Hyun-Kyo Jung

School of Electrical Engineering and Computer Science, Seoul National University, Seoul 151-742, Korea
luanfeng1979@hotmail.com

Abstract — The accuracy of reconstruction of the MEG source is crucially dependent on the conditioning of the leadfield matrix to be inverted. However, the problem of reconstructing MEG source distributions from leadfield is very often ill-posed. In such cases, Tikhonov regularisation is widely employed in order to produce reasonable solutions. However, determination of the amount of regularisation is not straightforward in practical applications without prior knowledge of either the MEG sources or the contaminating measurement noise. Thus, two methods have been introduced, GCV and the L-curve method, which do not require prior information in order to determine the optimal regularisation parameter. In the present work, the abilities of the two methods are illustrated when these kinds of inverse problems are dealt with using Tikhonov regularisation. Finally, through simulations, some guidelines are proposed for determining the optimal degree of regularization for MEG inverse problems.

I. INTRODUCTION

Magnetoencephalography (MEG) is a typical non-invasive human brain mapping technique to estimate neuronal electrical activities on the human cerebral cortex. The main object of MEG inverse problems is to accurately estimate neural current sources from external electromagnetic measurements [1, 2]. For the inverse problem, the field is sampled at different sensor locations and the underlying activity pattern must be determined [3, 4]. The accuracy of reconstruction of the MEG source is crucially dependent on the conditioning of the leadfield matrix to be inverted. However, the problem of reconstructing MEG source distributions from leadfield is very often ill-posed. In such cases, by using only the simple least-squares method, one cannot ensure a successful reconstruction of the MEG source distribution. Therefore, Tikhonov regularisation is widely employed in order to produce reasonable solutions. However, determination of the amount of regularisation is not straightforward in practical applications without prior knowledge of either the MEG sources or the contaminating measurement noise. Thus, two methods have been introduced, GCV and the L-curve method, which do not require prior information in order to determine the optimal regularisation parameter [5-7]. In the present work, the abilities of the two methods are illustrated when these kinds of inverse problems are dealt with using Tikhonov regularisation. Finally, through simulations, some guidelines are proposed for determining the optimal degree of regularization.

II. SIMULATIONS AND RESULTS

We use simulations for the advantage that the correct answer is known a priori, allowing more detailed illustrations of the performance of the methods. A three-shell BEM model

is made as the physical model. The outer shell models the skin, and the middle shell represents the skull surrounding the centrally located brain tissue. Fig.1 shows the cortical source patches to construct artificial MEG data which is contaminated by different levels of noise.

Fig. 1. True sources with contaminating noise

Fig. 2. Reconstruction results produced by Tikhonov regularization using L_curve (contaminated sources)

Fig. 3. Reconstruction results produced by Tikhonov regularization using GCV (contaminated sources)

As illustrated in Fig.2, Fig.3 and TABLE I, the relative errors of L_curve and GCV is almost same, however as the signal noise ratio (SNR) of active sources decreases the L_curve method produces more successful reconstruction results than the GCV method.

In order to compare directly the abilities of the two regularization parameter-determination methods in the different measurement noise environment, Fig.4 shows the sensor data with different SNR.

Fig. 4. Sensor data with contaminating noise

Fig. 5. Reconstruction results produced by Tikhonov regularization using L_curve (contaminated sensor measurement data)

It is clearly evident from Fig.5, Fig.6 and TABLE II that GCV seems to be more robust than the L_curve in the region with relatively high level noise contaminating the sensor measurement data. In other word, GCV method works well particularly in the regions completely dominated by measurement errors compared with L_curve. Therefore, based on the results presented, there seems to be no best method for determining proper regularization parameters in all situations. However, in the cases investigated, L_curve can be more reasonable when the sources with contaminating noise, whilst the GCV method may provide an effective method when the MEG sources reconstructed results are mainly dominated by measurement noise.

III. CONCLUSIONS

The abilities of two different methods, GCV and the L_curve method, for the determination of the proper degree of

regularisation have been simulated for a range of MEG reconstruction conditions in conjunction with sensor and source error. Based on the results of the numerical simulations, it appears that GCV is a better choice for estimating optimal regularisation parameters when the sensor noise levels are relatively high. However, the L_curve method seems to be a more effective method when the active sources are mainly dominated by errors such as contaminating noise. The results presented here may become useful guidelines for the right choice of regularisation parameter-determination method in real-world MEG source reconstruction.

Abstract—In this paper, the transient short circuit current of a three-phase saturated core high temperature superconducting (HTS) fault current limiter (FCL) is investigated by using a method combining 3-dimensional (3D) finite element analysis (FEA) and equivalent dynamic nonlinear model. The numerical computations are verified by the experiment results on a 380V prototype. Based on the short circuit current of the FCL, the three phase transient magnetic field is simulated and analyzed by 3D FEA. According to the simulated results, the short circuit electromagnetic forces of a 220kV and a 35kV saturated core HTS FCLs are calculated. Combined with numerical calculation method, the relationship between prestress and peak dynamic force and displacement of each pancake coil are analyzed and the influence of prestress on axial kinetic characteristics of winding is revealed. Elliptical and circular windings are applied on the 35kV and 220kV FCLs respectively, and the dynamic force and displacements of each pancake coil of the two types of windings are compared and analyzed.

I. INTRODUCTION

Short circuit is one of the major problems facing the power system, which immensely affects the system safety and reliability. All the devices in the power system, such as circuit breakers and transformers, have to be designed to withstand high mechanical and thermal stresses caused by the short-circuit current. The superconducting fault current limiter (FCL) has been expected as a possible type of power apparatus to reduce the fault current in power transmission lines, and various types of FCLs have been proposed and tested [1-2]. The saturated core high temperature superconducting (HTS) FCL offers a fast and effective current limitation with automatic recovery [3].

When the short-circuit fault occurs, an enormous short-circuit electromagnetic force is induced and the windings may be distorted and damaged resulting in limiting-current failure of FCL. Therefore, it is very important to calculate the short-circuit electromagnetic force on the windings of saturated core HTS FCL and to analyze the displacements of each pancake coil and the influence of prestress on axial kinetic characteristics of the windings.

II. CALCULATION OF SHORT-CIRCUIT CURRENT AND ELECTROMAGNETIC FORCE

This paper carries out the numerical simulation for the performance of a designed three phase HTS FCL using a method combining 3-dimensional (3D) FEA and equivalent mathematic modal, which can achieve high accuracy for transient performance calculation. Because of the nonlinearity of the ferromagnetic core, the inductance of the HTS FCL is associated with the currents flowing through the AC windings and DC windings. The nonlinear inductance of the FCL is calculated using the energy perturbation method [4] based on FEA. The transient short current could be acquired from the solution of equivalent dynamic nonlinear model, using the characteristics of inductance versus current (L-I curve).

The computed transient current of FCL in both normal and three phase fault conditions are conformed through the measurement on the 380V prototype. Fig. 1 illustrates the measured and simulated currents, respectively. The transient currents of 35kV and 220kV FCLs are also calculated by using the same method. Fig. 2 shows the simulated current of 35kV FCL when three phase short circuit fault (the worst situation) occurs. Fig. 3 shows the simulated current of phase A of 220kV FCL. The figures of other two phases will be presented in the final paper.

Fig. 1. Comparison between the measured and simulated current of a 380V FCL: (a) Measured, (b) Simulated.

Fig. 2. Simulated current of a 35kV FCL

Fig. 3. Simulated current of a 220kV FCL

Numerical calculation is carried out based on the theory of finite element method, considering the saturation of the silicon sheet and the non-sine variations of the current. 3D transient electromagnetic field in the saturated core FCL under short-circuit condition is calculated, and then the distribution of electromagnetic field is obtained. Radial and axial electromagnetic forces are calculated by using the Lorentz formula. Based on the results, circumferential stress of each disk unit is calculated to check the strength of windings under short-circuit condition.

Figs. 4 to 7 show the electromagnetic force of 220kV FCL. More results and analyses about the electromagnetic force will be presented in the final paper.

Fig. 4. Distribution of radial force

Fig. 5. Distribution of axial force

Fig. 6. Transient electromagnetic force of the middle pancake coil

Fig. 7. Transient electromagnetic force of the bottom pancake coil

During the transient process of short-circuit, both short-circuit current and leakage magnetic field change continuously. Therefore, the short-circuit force, which is generated by the interaction between short-circuit current and leakage magnetic field, are a dynamic force actually. The calculation of dynamic force should consider these factors: the mechanical property of various insulation materials, inertia force, elastic force, and friction force which acts on the displacement of the structures. Combined with numerical calculation method, the relationship between prestress and peak dynamic force and displacement of each pancake coil are analyzed and the influence of prestress on axial kinetic characteristics of winding is revealed. The dynamic force and displacements of each pancake coil of elliptical and circular windings are compared and analyzed. The two types of modals are shown in Fig. 8. The calculated results of dynamic force and displacement of each pancake coil and their analysis will be presented in the final paper.

Abstract — In the international scientific community there is an increasing interest in the application of minimally invasive techniques to the treatment of primary and metastatic tumours. Among the possible techniques, RadioFrequency Ablation (RFA) is considered potentially successful. For the monitoring of ablative treatment, Electrical Impedance Tomography (EIT) arises particular interest for its low cost and good sensitivity to tissue electrical properties changes. In this paper, an adaptive ablation treatment based on EIT measurements is presented. Remarks for configuring the ablation electrodes system are proposed in order to optimize the distribution of power deposition, in particular minimizing the power delivered to the more sensible healthy tissues.

I. INTRODUCTION

RFA is a technique used in the field of medical oncology, for the treatment of primary and metastatic tumours, in particular when patients are not candidates for surgical resection [1]-[3]. RFA destroys pathological tissue by raising their temperature. To this purpose, a radio frequency alternating current (450–550 kHz) is injected into the tissue through needles inserted percutaneously, laparoscopically, or during surgery [1]-[3]. The system is completed with an adhesive return electrode to close the circuit and to allow the current flow through the patient. A current field is, therefore, created between the probe and a return electrode usually placed on the back of the patient. When the temperature of cells exceeds 45–50 °C, the denaturation of intracellular proteins and destruction of cell membranes occurs; furthermore if the temperature is higher than 90°C the carbonization of tissues is achieved. The success of the treatment, therefore, relies on the accurate prediction of the thermal field distribution in pathological tissues as well as in adjacent healthy tissue. The selectivity in the treatment is most important indeed, because of healthy tissues have not to be affected, and consequently their temperature must be kept below 42 °C [5].

The EIT is a non invasive imaging technique based on the identification of the complex admittivity profile inside a domain from measurements of electrical currents and voltages made on its boundary [6]-[10]. It has potential application in several fields such as geophysics, clinical diagnostics on human body, environmental sciences and non-destructive testing on materials. In particular, its clinical applications are intensively investigated because it exhibits some important advantages such as the absence of ionizing radiations,

portability and relatively low cost of the instrumentation [9], and a good time resolution, which makes it particularly suitable for continuous monitoring of patients [10]. In addition the suitability of the EIT for real time monitoring of the temperature rise in ablation treatments have been assessed [6]-[8]. In particular, it has been shown how a further improvement in EIT sensitivity could be achieved if using the RFA needle as a further electrode [6].

In this paper, the possibility of optimizing the distribution of Ohmic power deposited by the RFA treatments, minimizing the power delivered to sensible healthy tissues, is investigated. This is achieved by using a multiple return electrodes system, and designing an “optimal” current map starting from internal admittivity profiles, obtained using EIT measurements. In the following of this digest, an example of optimized ablation procedure will be presented, and some preliminary results will be briefly outlined.

II. PROBLEM FORMULATION

The temperature map actually achieved in internal tissues during a RFA treatment can be analysed using a coupled electrical and biothermal model [5]. Note that to be effective, RFA treatments require on one hand a localized temperature rise in cancerous tissue, but on the other hand safety issues must be taken into account in order to avoid unwanted damage of healthy tissues, causing eventually internal bleeding. For this reason any tool allowing to estimate and eventually drive the current density pattern in the patient’s body would be of great benefit, allowing to improve even state of the art RFA procedures.

In this paper a formulation of the problem based on the estimation of the tissues properties during the treatment based on the EIT is presented. Such a piece of information can be used to optimise the current path driven by the RFA equipment.

In order to include the therapeutical needs in the mathematical model of the RFA, a *target* distribution of power density P_T [W/m³] is defined, considering the physiopathological conditions of the subject to be treated. The target map P_T is such that the power delivered to the tumour region allows sufficient temperature rise for treatment, while keeping sensible tissues “protected” by preventing excessive temperature rises. As a matter of fact, the power density portraying the instantaneous situation in the coupled biothermal-electromagnetic model is $\sigma_m J^2$, J being the module

of the current density field, while σ_m is the electrical conductivity, eventually estimated in real time by the EIT. The most general scenario envisages the use of FEM/BEM discretization of the subject's body based on MRI pictures.

The treatment efficiency can be optimized by minimizing the weighted discrepancy $D(J, \sigma_m)$ between target and actual Ohmic power delivered to the internal of patient's body (which is described as a regular non homogeneous domain Ω):

$$D(J; \sigma_m) = \iint_{\Omega} \lambda(\mathbf{r}) \left\| \sigma_m(\mathbf{r}) J^2(\mathbf{r}) - P_T(\mathbf{r}) \right\|_{L^2}^2 d\Omega \quad (1)$$

where \mathbf{r} is the field point in Ω and λ is a weighting function accounting for different relevance of the tissues and for their sensitivity to temperature rises.

In the minimization of D , the control parameter is represented by the current density amplitude J , while σ_m represents a parameter which cannot be modified but, nevertheless, impacts on D , and must be consequently kept under control (e.g. using EIT measurement for its estimation).

The current density map is in turn "shaped" by adopting multiple return electrodes on the patients skin, connecting each to a different voltage or current source in the power supply system, and selecting the voltage/current sources amplitude able to minimize D .

In the full paper, the adaptive strategy for power distribution design will be illustrated in detail, while a simple example of application is presented here.

III. PRELIMINARY RESULTS

For the sake of simplicity, a 2-D domain Ω , representing the section of a patient's torso, has been considered in this study. A subdomain Ω_T representing the tumoral tissue and a subdomain Ω_p to be protected from temperature rise are defined, and a two return electrodes system has been considered in alternative to the standard single electrode one (see Fig.1). The total area of the two electrodes in the configuration (b) is equal to the area of the single return electrode of the configuration (a).

Comparisons between the total delivered power density, the power delivered in Ω_p and in Ω_T for the two different return electrodes configurations have been computed using a FEM model, and are reported in Table I. In addition, in Fig. 2 the Ohmic power density maps for case (a) and (b) are reported, limitedly to the region Ω_p . Note the different scale of delivered power density.

The simple example highlights how a careful design of the return path of the current can be importantly influence the selectivity of the treatment without affecting its effectiveness.

Abstract— In previous works, microfabricated permanent magnets were designed and fabricated for levitating picoliter water droplets in air. Manipulating levitating water droplets is a contamination-free alternative to digital-microfluidic systems on surface used in biotechnologies. Here, the possibility of adding dielectrophoretic (DEP) forces to control the position of levitating droplets along a magnetic groove is numerically evaluated. The diamagnetic forces are computed using CADES framework while the DEP forces are computed with Comsol Multiphysics™ (Finite Element Method). Errors made using the point dipole model and the 2D approximation are evaluated by comparison with the full 3D problem. Based on these results, an electric sequence for polarizing planar interdigitated ITO electrodes is proposed in order to provide a stable and accurate control of the droplets micropositioning along the gap.

I. INTRODUCTION

For the last twenty years, microfluidic and lab-on-a-chip devices have been widely investigated for biomedical or chemical applications. Miniaturization provides better sensitivity for molecular detection and reduces the volume of solvents and reactants handled. However, contamination phenomena raise significant issues for such small samples. Diamagnetic levitation above bulk magnets [1]-[2]-[3] or integrated micromagnets [3] have been investigated for providing a contactless handling of picoliter droplets. A “MEMS compatible” method to convey contactless some levitating droplets along a magnetic groove perpendicularly to the diamagnetic forces is presented. It combines diamagnetic levitation and dielectrophoresis (DEP). Corresponding computations are developed in this paper.

II. DIAMAGNETIC LEVITATION AND DIELECTROPHORESIS

A. Diamagnetic levitation

Water is a diamagnetic element which corresponds to a so weak negative susceptibility ($\chi_{\text{water}} = -9 \cdot 10^{-6}$ SI) that the demagnetization field can be neglected. Hence, under a non uniform magnetic induction \vec{B} , water droplets experiment a small repulsive force [1]-[2]:

$$\vec{F}_m = \iint_S \frac{\chi_{\text{water}}}{2\mu_0} B^2 d\vec{S} \quad (1)$$

Due to the favorable reduction scale laws in magnetism [4], water picoliter droplets can levitate above micrometric magnetic grooves. The grooves can be micromachined from bulk magnets (Fig. 1A) or fabricated by NdFeB sputtering

onto patterned silicon wafers [5]-[6] (Fig. 1B). The devices are then magnetized vertically ($1.2\text{T} < B_r < 1.4\text{T}$).

Fig. 1. Levitating droplets (30µm in diameter) within magnetic grooves above (A) bulk or (B) integrated NdFeB micromagnets [2],[3].

B. Dielectrophoresis

DEP is an electrical phenomenon which attracts (positive DEP) or repels (negative DEP) polarizable particles by applying a non uniform AC electrical field [7]. For the particular case of water droplets in air, only the positive (attractive) DEP is possible [8]. The electric field is obtained from Indium Tin Oxide (ITO) planar interdigitated transparent electrodes (10 µm wide, gap of 10 µm) deposited on a glass lid perpendicularly to the magnetic groove (Fig.2).

III. MICROSYSTEM MODELLING

A. Description of the microsystem

The DEP actuation of a 40µm diameter levitating droplet above a 50µm-deep and 50 µm-wide groove is presented (Fig. 2). The system is inspired from Honegger’s works [9] where a 45 µm thick microfluidic photopatternable silicone channel is bonded between two glass wafers where electrodes are deposited. Here, a 50 µm-thick magnetic layer sputtered on a patterned Si wafer replaces the bottom electrodes. The magnetic layer can be modeled by 55 µm-large rectangular parallelepiped magnets.

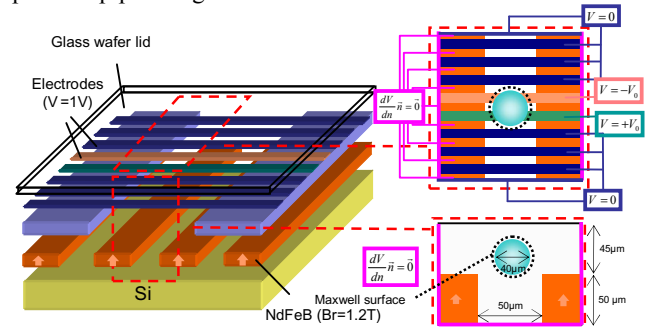

Fig. 2. Magnetic-DEP microdevice for the levitation and the translational transport of water droplets.

B. Forces Computation

The magnetic field created by the magnets is analytically computed in the CADES framework [10]. The diamagnetic forces are computed by integrating the magnetic energy over the droplet boundary (1).

The electric potential created by the interdigitated electrodes is determined by solving Laplace's equation, using the Finite Element Method with Comsol Multiphysics™. As for the DEP force, the dipolar approach commonly used is compared to the 2D and 3D Maxwell stress tensor methods applied on the computed electric field. Results show when droplet size (40 μm) is not negligible compared to the electrode dimensions (width = gap = 10 μm), the usual point dipole approximation and the 2D Maxwell stress tensor method reach errors around 100 % compared to the full 3D computation. The 3D Maxwell stress tensor method was thus selected for this study.

IV. NUMERICAL RESULTS

A. Force balance

According to the superposition principle, the vertical resultant force (\vec{F}_z) applying on a droplet is:

$$\vec{F}_z = \vec{P} + \vec{F}_{MAG} + \vec{F}_{DEP} \quad (2)$$

where \vec{P} is the droplet's weight, \vec{F}_{MAG} and \vec{F}_{DEP} are the vertical components of the magnetic force and of the DEP force, respectively.

The electrode voltage is tuned so the droplet remains in stable diamagnetic levitation while having the strongest horizontal actuation. Curves of Fig. 3 show that a droplet has a stable levitation height between 16 and 18 μm above the micromagnets for a voltage magnitude below 2.5 V.

Fig. 3. Vertical resultant force (F_z) vs. the height of the droplet: stable levitation ($F_z=0$ and $dF_z/dz < 0$) applies for a voltage inferior or equal to 2.5 V.

B. Voltage pulse sequence

To actuate droplets along the magnetic groove using DEP, two adjacent electrodes are polarized with a 180° phase shift (Figures 2 & 4). The magnetic force component parallel to the channel direction is negligible [8]. Therefore, in the horizontal direction, the droplet motion is governed by the DEP force. Conversely, the vertical DEP force magnitude (~1 pN, Fig. 4) is far weaker than the diamagnetic one (~100 pN range). The diamagnetic levitation height is thus not disturbed by DEP, and the droplet reaches a stable position just under the electrode pair. For a DEP force of 0.5 pN (1 V, 10 kHz), the droplet can move at ~70 μm.s⁻¹ due to the weak viscosity of

air. Finally, joule heating is negligible: evaluation of heating and power consumption will be discussed in the full paper.

Fig. 4. Horizontal and vertical DEP forces along the magnetic groove for a 40 μm droplet levitating at a 16 μm height.

V. CONCLUSION AND PERSPECTIVES

Computations show that a contactless DEP actuation of levitating micrometric water droplets in air in magnetic grooves is possible. This study raises some interesting questions about the models to use. Although the 3D Maxwell stress tensor is CPU consuming, the point dipole method appears to provide imprecise data. A multipolar approach may provide a satisfying compromise. Conversely, our semi-analytical diamagnetic force computations presently need an integration over the droplet boundary. Considering diamagnetic susceptibilities, a similar comparison with the point dipole and the multipole approaches could avoid using surface integration.

Compact Electromagnetic Bandgap Structures for Notch Band in Ultra-Wideband Applications

Mihai D. Rotaru and Jan K. Sykulski
 School of ECS, University of Southampton
 Highfield, Southampton, SO17 1BJ, UK
 mr@ecs.soton.ac.uk, jks@soton.ac.uk

Abstract — This paper introduces a novel approach to create notch band filters in the front-end of ultra-wideband (UWB) communication systems based on electromagnetic bandgap (EBG) structures. The design presented here can be implemented in any structure that has a microstrip in its configuration. The EBG structure is first analyzed using a full wave electromagnetic solver and then optimized to work at WLAN band (5.15-5.825GHz). Two UWB passband filters are used to demonstrate the applicability and effectiveness of the novel EBG notch band feature. Simulation results are provided for two cases studied.

I. INTRODUCTION

In recent years there has been a lot of interest in investigating electromagnetic bandgap (EBG) structures for various kinds of applications at microwave frequencies. EBG structures proposed over the past few years have been used primarily to enhance the functionality of antennas [1], but other applications – such as filters and baluns at microwave frequencies – have also been explored [2]. Moreover, the EBG structures have inherent features that can be used to reduce or suppress completely electromagnetic interferences (EMI) that can occur in electronic systems leading to electromagnetic compatibility (EMC) issues [3]. The EBG structures suppress the propagation of surface waves over specific frequency bands that directly depend on the dimensions and types of materials used to fabricate the EBGs. However, in this work we focus on a slightly different application of these structures. Consider the design of a notch band structure that can be used in ultra wideband (UWB) radio systems and can be easily integrated with microstrip circuitry fabricated with printed circuit board (PCB) technology. Since February 2002, when the Federal Communication Commission (FCC) released the 3.1-10.6GHz band for commercial communication usage, UWB has been receiving a lot of attention from both academia and industry. Unlike other existing wireless communication standards, which are narrowband, UWB has a very wide bandwidth, 7.5GHz wide to be precise. However, the UWB emission power is limited to a maximum of -41.3dBm/MHz therefore it can co-exist with other narrow band services that occupy the same spectrum. One such service is the 802.11a WLAN that is located at 5.15-5.45GHz and 5.725-5.825GHz. Recent work has shown that the effect of the 802.11a interference on UWB can be harmful and, depending on the probability of signal overlap and the relative distance between the two transceivers, the 802.11a interference can cause significant signal degradation of the attainable throughput of the UWB system [4]. Therefore it is very important to incorporate means that

can mitigate the effects of 802.11a in an UWB front end. Different types of structures for the physical layers and techniques for the MAC layers have been suggested recently. The previously proposed notch filter solutions are very specific to certain types of filters or antennas, therefore they cannot be easily integrated in a different design [5, 6, 7]. In this paper we propose a more general approach that can be implemented in any physical design that has at least a microstrip structure in its front end.

II. THE EBG STRUCTURE

As mentioned in the Introduction, EBG structures have been used for different types of applications in the past few years. The most popular mushroom like EBG structure was first introduced by Sievenpiper in 1999 [1]. The physical mechanism of the mushroom like EBGs can be explained by a simple equivalent LC parallel resonant circuit. However, more recently the EBG structures have been used to suppress the noise propagating in parallel plate waveguide structures, such as the power planes of high speed electronic systems. In this environment the equivalent circuit that can be used to explain the EBG behavior is somewhat different to the initial LC parallel resonant circuit used by Sievenpiper to explain the behavior of the EBGs in an open environment. Due to the EBG's proximity to the two metal planes in this set-up, the capacitances to the plane above and below the mushroom are much higher than the capacitance between the edge of the adjacent mushrooms. Therefore these capacitances will now dominate the response of the EBG structure.

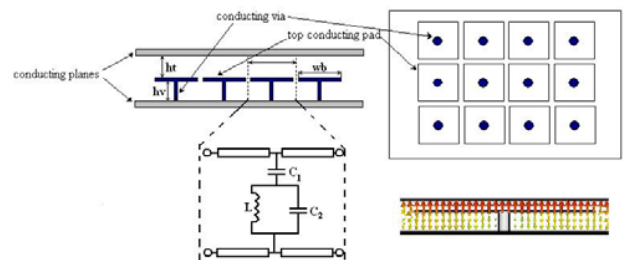

Fig. 1. EBG embedded between two metal planes and its equivalent circuit

In this configuration the EBG behaves like a stop band filter for the electromagnetic wave propagating in the parallel plate waveguide. The center of the stop band frequency and the bandwidth of the stop band are determined by C_1 , C_2 and L , where C_1 is the capacitance between the top conducting pad and the above metal structure, C_2 is the capacitance between the pad and the bottom metal plane and L is the inductance of the via connecting the bottom metal plane to the pad. The

capacitances of the structure C_1 and C_2 are determined by the size of the pad, the distance from the top and bottom planes and the dielectric material between the two planes. The inductance of the structure L is determined by the size of the via (length, diameter) but also by its position with respect to the center of the patch. As the distance between the two parallel plates is much smaller than the size in the xy direction, it can be assumed that the only mode travelling in this waveguide is a TEM mode. Therefore it is expected that, if the EBG structure is embedded within another wave guiding structure supporting a TEM mode, a similar response will be obtained. This has been confirmed through simulation of a microstrip line run above the EBG. As previously, the observed behavior can be explained by the circuit in Fig.1. The return loss of the microstrip routed above one mushroom has a zero at frequency f_1 and a pole at f_2 , where f_1 and f_2 are:

$$f_1 = \frac{1}{2\pi\sqrt{L(C_1 + C_2)}} \quad \text{and} \quad f_2 = \frac{1}{2\pi\sqrt{LC_2}} \quad (1)$$

Hence the stop band appears at the frequency f_1 . Another interesting behavior of this circuit is that the relative bandwidth of the circuit is proportional to $\sqrt{(C_1 + C_2)/L}$; therefore by controlling the size and the design of the EBG element one can tune frequency of the stop band as well as its bandwidth. This behavior has also been confirmed through numerical simulation.

The size of the EBG structure is critical when it has to be integrated into a practical design. Unfortunately the size of a mushroom EBG to be integrated into a practical substrate such as FR4 is quite large (4.4x4.4mm) if for example the 5.5GHz is chosen as the resonant frequency. Another drawback of the mushroom structure is the fact that its inductance is very small while C_1 and C_2 are much bigger; therefore the bandwidth of the stop band is relatively large and may not be useful for a notch filter application. A compact and novel EBG element based on small planar inductor is introduced to solve the above problem. The design and optimization of the size and shape of the inductor based EBG is done using a full wave simulation software. The numerical tool (CST-Microwave Studio) used for this work is based on Finite Integration Technique (FIT) [8]. Through this approach a much smaller EBG structure is obtained, only 2x2mm for a FR4 substrate. Moreover, the corresponding inductance is much higher while the two capacitances are much smaller. However, the design of such structure is not as straightforward as the design of a simpler mushroom structure as its total inductance and capacitances have to be computed through a rigorous three dimensional numerical model. The appropriate ratio between total capacitance and inductance of the structure has to be calculated carefully and an iterative process is necessary to obtain the optimum design.

III. UWB FILTERS WITH EMBEDDED EBG ELEMENT

Using the features described above one can design small structures with notch band characteristics that can be incorporated into existing designs without large and costly modifications. In this section two band pass filters that can be

used in UWB applications were modified to incorporate the notch band feature for the WLAN. All the following results were obtained through full wave simulation using CST Microwave Studio.

The first UWB filter studied here is based on the broadside coupling between a microstrip and a coplanar waveguide (CPW). The CPW is on the ground of the microstrip, while the two microstrip lines on the top surface are separated by a small gap. The second UWB filter has two coupled L-shaped microstrips on the top layer and a stepped impedance resonator (SIR) on a defected-ground structure (DSG) on the bottom layer. The UWB filters described above are considered to be built on different types of a substrate. The first design uses a dielectric substrate with a dielectric constant of 2.17 whereas the second filter has a substrate with a constant of 4.4 (FR4).

The simulations results in terms of the magnitude of the insertion loss ($|S_{21}|$) obtained from the full wave numerical solution are presented in Fig. 2. It can be observed that both designs have a sharp stop band feature in the WLAN band without serious degrading of the passband for the designs with the novel inductor based EBG implemented.

Abstract— This paper presents the use of the least-square support vector machines (LS-SVM) technique, combined with the finite element method (FEM), to evaluate the microwave properties of dielectric materials. The LS-SVM is a statistical learning method that has good generalization capability and learning performance. The FEM is used to create the data set required to train the LS-SVM. Numerical simulations demonstrate that the LS-SVM method can determine the permittivity of materials with a high accuracy.

I. INTRODUCTION

The problems of the determination of dielectric constant ϵ' and loss factor ϵ'' of dielectric materials are usually formulated and solved as optimization problems; so iterative methods are commonly used to solve this kind of problems. These methods involve solving a well-behaved forward problem in a feedback loop. Numerical methods such as finite element method (FEM) can be used to represent the forward process. However, iterative methods using a numerically based forward model are computationally expensive. In this situation the neural network (NN) and other machine learning tools such as support vector machines (SVM) are a good alternative to iterative methods [1].

SVM are a recent powerful machine learning method. They are developed on the basis of statistical learning theory. A lot of successful applications in nonlinear classification and function estimation have shown that SVM can handle high dimensional data with relatively few training samples and that they exhibit good generalization capability [2]. The SVM adjustment is obtained using complicated quadratic programming methods, which are often time consuming and difficult to implement. Least-squares support vector machines (LS-SVM) are reformulations of the standard SVM which lead to solve linear equations instead of a quadratic programming problem [3].

In this paper, we propose a new method for the evaluation of the microwave properties of dielectric materials (complex permittivity) from the admittance measured at the discontinuity plane of a coaxial open-ended probe. The method is based on the FEM and a LS-SVM scheme.

The FEM provides the data set required for the training of LS-SVM. A data set is constituted of input (complex admittance, frequency) and output (ϵ' , ϵ'') pairs.

II. LS-SVM FOR FUNCTION ESTIMATION

Given a training set $(x_k, y_k)_{k=1}^N$ with input data $x_k \in R^n$ and output data $y_k \in R$, the LS-SVM model for function

approximation has the following representation in feature space,

$$y(\mathbf{x}) = \mathbf{w}^T \boldsymbol{\varphi}(\mathbf{x}) + b \quad (1)$$

Here the nonlinear function $\boldsymbol{\varphi}(\cdot): R^n \rightarrow R^{n_k}$ maps the input space to a higher dimension feature space. b is a bias term and $\mathbf{w} \in R^n$ is the weight vector. The optimization problem is defined as:

$$\min \mathbf{J}(\mathbf{w}, \mathbf{e}) = \frac{1}{2} \mathbf{w}^T \mathbf{w} + \gamma \frac{1}{2} \sum_{i=1}^N \mathbf{e}_i^2 \quad (2)$$

Subject to the equality constraints:

$$y_i = \mathbf{w}^T \boldsymbol{\varphi}(x_i) + b + \mathbf{e}_i \quad i = 1, \dots, N \quad (3)$$

where the fitting error is denoted by \mathbf{e}_i . The hyper-parameter γ controls the trade-off between the smoothness of the function y and the accuracy of the fitting. This optimization problem leads to a solution,

$$y(\mathbf{x}) = \sum_{i=1}^N \alpha_i K(\mathbf{x}, x_i) + b \quad (4)$$

where α_i, b comprise the solution to the linear system obtained after constructing the Lagrangian and $K(\mathbf{x}, x_i) = \boldsymbol{\varphi}^T(\mathbf{x}) \boldsymbol{\varphi}(x_i)$ is the so-called kernel function. The most usual kernel functions are polynomial, Gaussian or sigmoid.

III. MEASUREMENT SETUP AND NUMERICAL METHOD

The characterization cell, called SuperMit, consists in a junction between a coaxial waveguide and a circular waveguide which is filled by the dielectric material. In order to study liquids, a coaxial window is inserted between the two guides (Fig. 1). The whole device is connected to an impedance analyzer.

Fig. 1. SuperMit measuring cell

The electromagnetic problem is solved by using the FEM. The problem is expressed in terms of the electric field \mathbf{E} which satisfies the following harmonic wave equation:

$$\text{curl} \left[-\frac{1}{i\omega\mu} \text{curl} \mathbf{E} \right] - i\omega\epsilon \mathbf{E} = 0 \quad (5)$$

ω is the pulsation, ϵ ($\epsilon = \epsilon_0(\epsilon' - i\epsilon'')$) and μ are the permittivity and the permeability, respectively. ϵ_0 is the permittivity of the free space. The meshing of the axially symmetric characterization cell is shown in Fig. 2.

Fig. 2. View of the meshed measurement cell

IV. IMPLEMENTATION OF THE LS-SVM

Two single-output LS-SVM corresponding to the two estimated quantities ϵ' and ϵ'' are used. The inputs of a LS-SVM are the values of the complex admittance (real part G , imaginary part B) and the measurement frequency (f).

The dataset is divided into three different sets training, validation and test set. The LS-SVMs were trained with 4500 learning examples.

In this study, radial basis function (RBF) kernels are used with LS-SVM,

$$K(\mathbf{x}, \mathbf{x}_i) = \exp \left(-\frac{\|\mathbf{x} - \mathbf{x}_i\|^2}{\sigma^2} \right) \quad (6)$$

where $\sigma > 0$ is a constant defining the kernel width.

It should be noted that predetermined parameters in LS-SVM algorithms with RBF kernel are γ and σ^2 , which are less numerous than those in standard SVM. A split-sample procedure [4] was used to train and test the LS-SVM under various hyper-parameter settings. To tune γ and σ^2 , a range of their values is scanned and optimal values of these hyper-parameters is the one corresponding to the minimum of the generalization error estimation obtained on the validation set.

V. EXPERIMENTAL RESULTS

Measurements have been carried out by using an impedance analyzer Agilent 4291A on an ethanol sample whose dielectric characteristics are known. The window coaxial is made of Plexiglas with a thickness of 0.82 mm and a dielectric constant of 2.7. The thickness of the sample under test is 13.8 mm. The coaxial guide is a standard APC7 ($a = 3.5$ mm, $b = 1.52$ mm). The measurement frequency band is from 1 MHz to 1.8 GHz. Hyper-parameters in LS-SVM for ϵ' , ϵ'' and root mean squared relative error (RMSRE) are given in Table I. In this case, the obtained results on the test set are quite good for both LS-SVM as shown in Fig. 3 and Fig. 4.

TABLE I
PARAMETERS IN LS-SVM WITH RBF KERNEL

Outputs	γ	σ^2	RMSRE (%)
ϵ'	$8.1113 \cdot 10^2$	1.5380	$3.6055 \cdot 10^{-1}$
ϵ''	$5.3367 \cdot 10^3$	0.3921	$5.8539 \cdot 10^{-2}$

Fig. 3. Comparison between LS-SVM output and real value of ϵ'

Fig. 4. Comparison between LS-SVM output and real value of ϵ''

The results obtained show clearly that the LS-SVM inversion agrees very well with the real ones.

VI. CONCLUSION

LS-SVM were presented and applied to inversion of microwave measurement data. The results indicate that LS-SVM could be used to microwave dielectric characterization. The applied data set at the testing stage of the LS-SVM demonstrates their abilities to perform identification with good accuracy. The validity of the proposed LS-SVM based inversion method is being assessed by comparing the results obtained using the proposed method with those obtained from a multilayer perceptron NN (MLP) and experiment.

Abstract— In this paper we compute the electromagnetic loads (forces, torques, Joule losses) on passive conductors of the ITER (International Thermonuclear Experimental Reactor) fusion device, currently under construction, following a disruption event, i.e. the sudden loss of magnetic confinement. An original integral formulation is used, able to automatically deal with complex topologies like the ones to be studied. Non-isotropic homogenized resistivities are used to take into account fine geometrical details. A suitable inverse problem is solved in order to compute the forcing terms.

I. INTRODUCTION

In devices for the controlled thermonuclear fusion, the plasma disruptions are associated to a sudden loss of magnetic confinement, which causes the magnetic and thermal energy stored in the plasma to be released to surrounding structures. The consequent electromagnetic forces and heat load have an impact on the operational lifetime of several components and in extreme cases seriously damage the integrity of the devices themselves. For this reason, the problem of the disruptions is of the major concerns for both existing and future fusion devices [1], and plays a fundamental role in the design of new experimental devices like ITER (International Thermonuclear Experimental Reactor), currently in the construction phase in Cadarache, France, which will be the biggest tokamak ever built.

To study this problem, we use an integral formulation of the eddy-currents equations [2], which is very advantageous in the description of fusion devices, since it is required to give a discretization only of the conducting structures, which are typically a small fraction of the overall solution domain in such devices. Moreover, it is possible to give separate discretizations of non-connected conductors, hence allowing easily a zooming approach. This integral formulation is able to deal automatically with complex geometries and topologies [3], like the ones arising for the present study.

II. NUMERICAL FORMULATION

We assume that no magnetic materials are present and that the conducting materials are linear, although possibly anisotropic. Integral methods are therefore well suited for this analysis. They are characterized by full matrices, but the number of unknowns needed to get a required accuracy is relatively small, as only the conducting region has to be meshed, and the regularity conditions at infinity are automatically taken into account. The results have been obtained using the CARIDDI code, based on an integral formulation in terms of two-component current density vector

potential [2]. The current density is expanded in terms of solenoidal shape functions with normal component zero on the boundary as $\mathbf{J}=\sum_k \nabla \times \mathbf{T}_k$, whose coefficients are determined applying Galerkin procedure in the time domain:

$$\{L\} d[I]/dt + \{R\} [I] = d[U]/dt \quad (1)$$

and:

$$L_{ij} = \frac{\mu_0}{4\pi} \int_{V_c} \int_{V_c} \frac{\nabla \times \mathbf{T}_i \cdot \nabla \times \mathbf{T}_j}{|\mathbf{x} - \mathbf{x}'|} dV dV' \quad (2)$$

$$R_{ij} = \int_{V_c} \nabla \times \mathbf{T}_i \cdot \eta \nabla \times \mathbf{T}_j dV \quad (3)$$

$$U_i = - \int_{V_c} \nabla \times \mathbf{T}_i \cdot \mathbf{A}_0 dV \quad (4)$$

where t is the time, η is the resistivity tensor, V_c is the conducting domain, and \mathbf{A}_0 is the magnetic vector potential due to the external sources (plasma and current driven coils).

III. PRELIMINARY RESULTS

The geometry of interest includes the following items:

- the blanket modules (BM), with the aim of shielding neutrons originating from nuclear reactions;
- the vacuum vessel (VV), made by two nested shells with port extensions and port plugs;
- the divertor, which must carry the heat load and particle flux.

The disruptive event to be represented is a so-called VDE (Vertical Displacement Event), in which the plasma experiences an unstable vertical axisymmetric evolution. This is originally represented by a variable number of moving toroidal filaments, each carrying a time-varying current, whose values have been computed by the DINA MHD code [4]. Several different VDEs will be considered, both upwards and downwards.

A. Equivalent filaments

We have given an equivalent representation of the VDE in terms of a given number of fixed filaments, located inside the plasma region. The waveforms of the current in each filament are obtained by imposing that:

- a) the multipolar expansion of the original plasma current density and of this set of filamentary currents is the same up to the sixth order;
- b) the flux and the flux time derivative at a given set of points of the two current distributions are the same.

The resulting algebraic system of linear equations (suitably normalized) is solved using the Tikhonov regularization. A typical result is reported in Fig. 1, showing a good agreement.

Fig. 1. Original current filaments (right) and relative error on magnetic flux over the green line using a set of fixed filaments

B. Equivalent anisotropic resistivity

The BM have a rather complex geometry: the front panel (FP) facing the plasma is made by a beryllium layer, followed by a copper layer and a stainless steel (SS) layer, each having a number of void channels inside. Further from the plasma, the shielding block (SB) is present, which is a volumetric SS structure with void channels, slits, pockets etc.

Figure 2 shows one typical example – around 20 different typologies of BM are present. While slits and pockets have been fully represented in the discretized model, the presence of channels has been taken into account via an an-isotropic equivalent resistivity. In particular, for each direction the void fraction α has been computed, and the resistivity has been enhanced of a factor $1/(1-\alpha)$. Whenever possible/applicable, we estimated the resistivity enhancement factor using the Clausius-Mossotti formula, or resorting to 2D simplified computations, as proposed in [5].

Meshes with three different levels of discretization have been produced for each BM. We have compared the power losses, forces and torques following a VDE, finding a good agreement (within around 10%). Moreover, in one single case also a mesh accounting for all geometrical details (including channels) has been considered, obviously with the reference bulk isotropic values of resistivity for each material. The agreement on the aforementioned parameters, as computed using the equivalent anisotropic resistivity, is around 15%.

C. Overall model

The overall discretized model has been successfully produced, including all the aforementioned geometrical features. The mesh is reported in Fig. 3, and is currently being used for quantitative computations of the overall electromagnetic loads due to disruptive events in ITER. As anticipated, the complex topology of the conductors is automatically treated.

Abstract — Relative movements of permanent magnets and conductors cause forces which can be used to study the material characteristics of the conducting object. The paper describes a fast technique to compute the forces acting on a permanent magnet using the finite element method. The proposed approach allows studying the possibilities of defect identifications in conductors if e.g., the Lorentz force eddy current testing technique is applied.

I. INTRODUCTION

Moving a permanent magnet above a conducting object or moving a conducting object in the vicinity of a permanent magnet causes induction of eddy currents in the object (Fig. 1). The interaction between the magnetic field of the permanent magnet and induced eddy currents leads to two types of Lorentz forces acting on the magnet, the first one which tries to stop the magnet (*drag* force) and the second one which lifts the magnet (*lift* force). In the paper, we consider the force calculations which are important in Lorentz force velocimetry [1] or a non-destructive material testing.

Fig. 1. Permanent magnet moving above conducting plate

II. DESCRIPTION OF METHODS

To solve above problem we have applied three approaches: (a) *transient* approach (TR), in which the global coordinate system is associated with the conducting plate and the permanent magnet is moving with a constant velocity \mathbf{v}_0 along x -axis, (b) *quasi-static* approach (QS), where the global coordinate system is associated with the permanent magnet and the conducting plate with a crack is moving with a constant velocity $-\mathbf{v}_0$ along x -axis, and (c) *fast quasi-static* approach (FAST), in which the global coordinate system is associated with the permanent magnet and the moving conducting plate contains no crack. In all analyzed cases, to avoid influence of edges effects, we have assumed that the moving magnet and the crack region are far away from the walls of the plate. Forces acting on the permanent magnet are

calculated indirectly, by calculating Lorentz forces acting on the plate (Newton's third law).

A. Transient approach (TR)

Assuming that the external current density \mathbf{J}^e equals 0, we have to solve the following equation [2]:

$$\sigma \frac{\partial \mathbf{A}}{\partial t} + \nabla \times \left(\frac{1}{\mu_0} \nabla \times \mathbf{A} - \mathbf{M} \right) = 0 \quad (1)$$

where \mathbf{A} is a magnetic vector potential and \mathbf{M} a magnetization vector defined as $\mathbf{B} = \mu_0(\mathbf{H} + \mathbf{M})$. To realize this approach, we define above the plate a rectangular region where the permanent magnet is moving (Fig. 2). In the movement region, the magnetization vector is defined as:

$$\mathbf{M} = M_0 f(x, z, t) \mathbf{1}_y, \quad (2)$$

$$f(x, z, t) = \mathcal{H}(x - x_0 - vt) - \mathcal{H}(x - x_0 - w - vt), \quad |z| \leq \frac{l}{2}$$

where $\mathcal{H}(\cdot)$ is the Heaviside step function, x_0 is the start position of the magnet, w is the width of the magnet, and v_0 is the velocity of the movement.

Fig. 2. Definition of material regions in a transient approach

In the numerical implementation, we have to take into consideration two facts: first, the finite element mesh in the movement region should be regular to fit the shape of the magnet (Fig. 3), and second, the time step used in a solution

Fig. 3. Sample finite element mesh with marked magnet position (2D, $t = 0$)

procedure should be chosen in such a manner that the position of the magnet coincides with the finite element mesh in the particular time.

B. Quasi-static approach (QS)

In the quasi-static approach, we have to solve the following equations:

$$\nabla \times \left(\frac{1}{\mu_0} \nabla \times \mathbf{A} - \mathbf{M} \right) - \sigma \mathbf{v} \times (\nabla \times \mathbf{A}) + \sigma \nabla V = 0 \quad (3)$$

$$\nabla \cdot [\sigma \mathbf{v} \times (\nabla \times \mathbf{A}) - \sigma \nabla V] = 0$$

Although, the quasi-static formulation is fully correct for problems without spatial material changes in the movement direction, i.e. for the plate without crack, we have applied it to find the limits of its application when the plate contains a crack (Fig. 4) [3].

Fig. 4. Configuration of the problem used in the quasi-static approach

The implementation of the quasi-static approach is much easier and gives the results faster as in the transient one. The only problem which we have to take into consideration is a proper finite elements size in the conducting region determined with the help of Peclet number ($Pe = v_0 \sigma \mu_0 \Delta x$) in order to avoid spurious solutions [4].

C. Fast quasi-static approach (FAST)

In the fast quasi-static approach, we solve (3) for the plate without crack. The presence of the crack is taken into account only in the force calculations where the region with the crack is simply eliminated from the integration loop (Fig. 5).

Fig. 5. Configuration used in the fast quasi-static approach

This kind of analysis is the fastest one because we have to solve the field problem only once and due to a suitable definition of the region with the possible crack position (e.g. by definition of several regions with different material codes) we receive the possibility to analyze various positions and shapes of the crack.

III. RESULTS AND DISCUSSION

We have realized all methods as Matlab® procedures using Comsol® as the FEM solver. In the digest, we present only sample 2D calculations of the drag force in the vicinity of the crack (Fig. 6). We can observe that the FAST approach gives results which are qualitatively closer to the transient approach than the QS approach even for high velocities. In the full paper we will present the results of 3D simulations as well as a detailed analysis of errors of the applied methods.

Fig. 6. Drag force distribution in the vicinity of crack ($w \times h = 5 \times 5$ mm) for different velocities

IV. CONCLUSIONS

The paper describes a fast technique to compute the forces acting on a permanent magnet that is moving relatively to a conductor. The proposed technique allows studying the velocity range in which the quasi-static approach can be used and thus, extensive transient FEM calculations can be avoided. The approach is very useful if the Lorentz force eddy current testing technique is applied to defect identifications in conductors.

Abstract — This paper presents a numerical approach, based on the Boundary Element Method, able to reconstruct the induced current and SAR distribution inside a human phantom from the knowledge of field quantities on the body surface. Some examples of application are reported and the parameters affecting the accuracy of the reconstruction are analyzed and discussed.

I. INTRODUCTION

Guidelines limiting human exposure to electromagnetic fields are set by the International Commission on Non-Ionising Radiation Protection (ICNIRP) [1]. Basic restrictions are established in terms of induced currents (up to 10 MHz), specific absorption rate (SAR) (between 100 kHz and 10 GHz), and incident power density (from 10 GHz to 300 GHz). In Europe, the directive EC 2004/40/EC “Physical Agents Directive” [2] will make the provisions of ICNIRP a legal requirement with respect to the exposure of workers to electromagnetic fields.

Artefact standards for SAR exist only within the frequency range 380 MHz to 6 GHz, while difficulties arise in the lower and higher frequency ranges. As a consequence, limitations to future use of high power radio-frequency in industrial and medical applications (e.g. plastic welding, induction furnaces, and Magnetic Resonance Imaging) may arise, particularly for frequencies below 380 MHz. Within this context, the EURAMET-iMERA project [3] aims at providing traceable metrology for SAR in the whole ICNIRP frequency range. In this work, we describe and discuss some results obtained in the aforementioned project, with specific attention to the development of models able to relate surface field measurements to SAR in human phantoms. This approach will provide a valuable tool for more accurately assessing work place exposures in the low frequency range.

The numerical simulations are based on an integral formulation (IE) of the electromagnetic field equations. In particular, the Boundary Element Method (BEM), which deduces the fields within a homogenous body from the surface values, seems to be tailored for the specific requirements. The results of simulations performed by BEM on a simplified version of the standard SAM phantom [4] are first compared with those provided by a commercial code based on Finite Integration Technique (FIT) [5]. The parameters affecting the reconstruction of induced currents and SAR starting from a limited set of surface field measurements are finally discussed.

II. MODELING APPROACH

In order to relate field quantities induced within the body to the fields measured on its surface, we derive an integral formulation of the complete Maxwell’s equations, assuming sinusoidal supply conditions with angular frequency ω :

$$\nabla \times \nabla \times \mathbf{E} = k^2 \mathbf{E} - i\omega\mu \mathbf{J}_s \quad (1)$$

$$\nabla \times \nabla \times \mathbf{H} = k^2 \mathbf{H} + \nabla \times \mathbf{J}_s$$

The field source is a known current density \mathbf{J}_s , distributed in a domain Ω_s . Considering the source and phantom sizes and the wavelengths at the considered frequency range, the near field assumption can be assumed and we refer to a magnetic field source. \mathbf{E} and \mathbf{H} are the phasors of the electric and magnetic fields. The complex propagation constant $k = \omega\sqrt{\mu\tilde{\epsilon}}$ depends on the magnetic permeability μ and the complex electric permittivity of the media $\tilde{\epsilon} = \epsilon' - i\epsilon''$. Here ϵ' is the dielectric constant and $\epsilon'' = \sigma/\omega$, where the equivalent electrical conductivity σ includes all material losses. The values of $\tilde{\epsilon}$ are given as a function of frequency. The medium is isotropic, so that vector \mathbf{E} and \mathbf{J} are always collinear.

By applying the Green vector identity over the phantom body (domain Ω), the integral form of (1) for the electric field (EFIE) within the considered body becomes [6]:

$$T(\mathbf{r})\mathbf{E}^{(1)} = -\sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(1)} \times \mathbf{E}^{(1)}) \times \nabla\psi^{(1)} ds - \sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(1)} \cdot \mathbf{E}^{(1)}) \nabla\psi^{(1)} ds + i\omega\mu^{(1)} \sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(1)} \times \mathbf{H}^{(1)}) \psi^{(1)} ds \quad (2)$$

The body surface $\partial\Omega$, separating the external region in air (volume 0) from the internal one filled by a weakly conductive medium (volume 1), is discretized into N triangles. In (2) the field quantities \mathbf{E} and \mathbf{H} are assumed to be constant on each triangle e ($e = 1, \dots, N$), $T(\mathbf{r})$ represents the singularity factor, the normal unit vector $\mathbf{n}^{(1)}$ points outward (toward volume 0) and ψ is the Green’s function satisfying Helmholtz equation. The electric and magnetic field values in the right-hand side are deduced from the external measured quantities (in volume 0) through the interface conditions. Relation (2) enables the computation of the value of $\mathbf{E}^{(1)}$ and $\mathbf{J}^{(1)} = i\omega\tilde{\epsilon}^{(1)}\mathbf{E}^{(1)}$ in any point inside Ω ; the local values of SAR are then deduced as $\Re(EJ^*)/\delta$, being δ the mass density of the media.

III. DISCUSSION OF RESULTS

The numerical model has been applied to the analysis of the homogeneous SAM phantom (see pictures in Fig. 2). In the results here reported, the phantom is exposed to the magnetic field generated by a small loop located laterally to the head, at a distance of ~ 4 cm. Assuming a working frequency of 100 MHz, the electric conductivity, relative permittivity and mass density of the SAM phantom are 0.33 S/m, 76 and 1000 kg/m^3 , according to average properties of muscle tissues [7].

In order to validate the proposed approach and verify its accuracy, the electromagnetic fields on the body surface are determined by a numerical solution of problem (1). For such a purpose, we add to the discretized relation (2) the magnetic field integral equation (MFIE) for the external volume:

$$T(\mathbf{r})\mathbf{H}^{(0)} = -\sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(0)} \times \mathbf{H}^{(0)}) \times \nabla \psi^{(0)} ds - \sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(0)} \cdot \mathbf{H}^{(0)}) \nabla \psi^{(0)} ds + i\omega \tilde{\epsilon}^{(0)} \sum_e \int_{\partial\Omega_e} (\mathbf{n}^{(0)} \times \mathbf{E}^{(0)}) \psi^{(0)} ds + \int_{\Omega_s} \mathbf{J}_s \times \nabla \psi^{(0)} dv$$

Following the BEM approach, a set of algebraic equations is then obtained by projecting Eqns. (2) and (3) along local coordinate systems, defined on each triangle by the normal and tangential unit vectors, and introducing interface conditions on the field quantities [6]. The system solution provides the electric and magnetic field on each surface triangle, effectively substituting the set of experimental values. The use of the numerical field solution allows us an easy investigation about the factors that affect the reconstruction of induced quantities and SAR within the body. Thus, we can verify the influence of the number of measuring points, of their distance from the investigation point and of the contributions of the single terms in (2) containing the electric and magnetic field components.

The induced currents flowing in the SAM phantom, together with the distribution of SAR are depicted in Fig. 1, making reference to a unitary supply current in the loop.

Fig. 1. Map of SAR distribution (values in mW/kg) over the central plane.

The corresponding induced electric field, along the investigation line A shown in Fig. 2, obtained by BEM approach are compared with those provided by a commercial code, based on Finite Integration Technique [5]. The same figure presents two additional curves obtained including for each evaluation point only the contribution within a given sphere of influence (having radius R). The results prove that

this simplifying assumption does not give rise to a satisfactory reconstruction of the induced field. More encouraging results are obtained neglecting the contributions of the normal component of the electric field on the body surface. The effect of the tangential components of \mathbf{E} and \mathbf{H} cannot be disregarded (see Fig. 3).

Abstract — This paper investigates a mutually reverse (MR) unit coil as a wheel detector which is more insusceptible to electromagnetic noise than conventional wheel detectors. We carry out the design optimization of the coil for the improvement of reception sensitivity by means of magnetic field computations.

I. INTRODUCTION

Recently, with the advancement of semiconductor devices, the wide spreading of railcars equipped with VVVF has become an issue due to the electromagnetic noises it creates. Therefore, the environment of the railway signaling system is deteriorating [1]. When developing new railway signaling devices, we need to consider the protection against noise. Especially, the noise reduction is indispensable in the case of wheel detectors, which are one of the railway signaling devices.

Thus, this paper deals with mutually reverse (MR) unit coil as a wheel detector, which is more insusceptible to electromagnetic noise than conventional wheel detectors. Unlike the conventional detector with only single receiving coil, in the MR wheel detector, two receiving coils are arranged one above the other. As the output, the difference of voltage which is induced in the two receiving coils is utilized. Therefore, the noise, i.e., magnetic field generated by the traction power converter of the railcar, is canceled by using two receiving coils, which results in the high accuracy of the wheel detector.

For the further improvement of reception sensitivity, we evaluate the performance and carry out the design optimization of MR wheel detector by using electromagnetic field computations.

II. INVESTIGATED MODEL

MR wheel detector is made up of a transmitting coil and two receiving coils, and a magnetic field from a transmitting coil which induces the voltage in receiving coils. When the wheel comes beside the detector, induced voltage of receiving coils is decreased by electromagnetic shielding effect due to eddy current generated in the wheel. The wheel detector judges the wheel presence based on the variation of signaling receive level.

In this paper, we analyze the MR wheel detector shown in Fig. 1. The current in transmitting coil is 500 mA, 33 kHz.

III. METHOD OF ANALYSIS

We adopt finite element method (FEM) using the magnetic vector potential A and electric scalar potential ϕ in analysis. We adequately utilize two kinds of mesh, i.e., the hexahedral and tetrahedral meshes [2]. Coils, wheel, and rail are independently divided with hexahedral elements. On the other hand, the tetrahedral mesh is applied to the air regions around both the coils and the wheel, which enables us to easily connect the meshes of each region mentioned above. This also makes it possible to easily displace the coils and wheel in the optimization procedure.

IV. ANALYSIS RESULTS

We compare the computational results with the measured value of signaling receive level. As a sampling rate, MR wheel detector judges signaling receive level at the points when the wheel comes right beside the receiving coils (0 mm), and when the wheel is in front or behind the receiving coils by 125 mm. And if signaling receive level is less than the threshold, the wheel is detected (Fig. 2). The wheel detector is more insusceptible as the attenuation of induced voltage in receiving coil becomes larger, which results in the prevention of false detection. First, we calculate signaling receive level in the following three cases, and compare the calculated values with the measured ones (TABLE I).

1. Static state (in case of no wheel)
2. When the wheel is located 125 mm away from the coils
3. When the wheel is located right beside the coils (0 mm)

The flux density distributions around the receiving coils in each case are shown in Fig. 3. In the case of no wheel, interlinkage flux of the lower receiving coil is decreasing more than that of the upper receiving coil due to the effect of eddy currents generated in the mounting hardware. Accordingly, we can obtain the obvious difference of signaling receive level between two receiving coils. On the other hand, flux density becomes parallel to the receiving coils when the position of the wheel is at 125 mm, resulting in the variation of signaling receive level. Additionally flux magnitude rapidly decreases when the wheel comes to the point of 0 mm due to the shield effect of the wheel. TABLE I shows that the calculated values of signaling receive level are well coincident with the measured ones.

Fig. 1. MR wheel detector (half model).

Fig. 2. Conceptual figure of wheel detector principle.

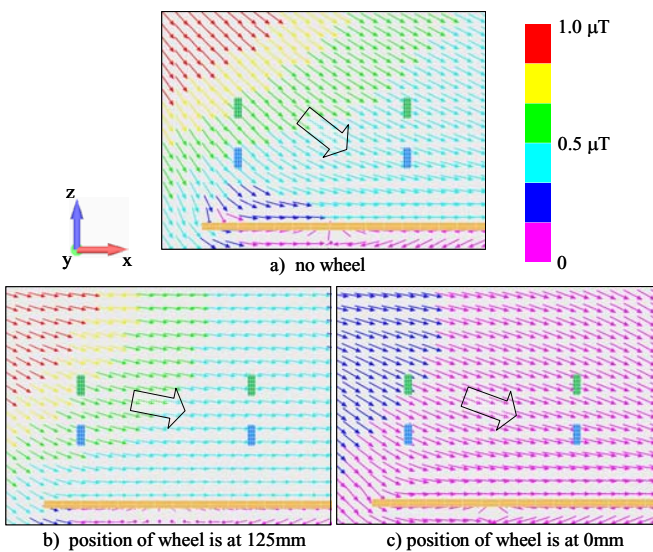

Fig. 3. Distributions of magnetic flux density.

TABLE I
COMPARISON BETWEEN MEASURED AND CALCULATED SIGNALING RECEIVE LEVEL

	Signaling receive level (dBV)		
	No wheel	Position of wheel	
		125 mm	0 mm
calculated	-43.26	-53.43	-63.01
measured	-44.89	-52.59	-63.09

V. IMPROVEMENT OF RECEPTION SENSITIVITY

In this chapter, as a design example, we carry out the layout optimization of receiving coils in the simulated wheel model so as to maximize the variation of signaling receive level. Considering the sizes of the coil case and mounting hardware, we assume the following constraint conditions for the receiving coils' position.

1. Distance between center of upper and lower receiving coils : 15-35 mm
2. Position of upper receiving coil : 80-105 mm
3. Position of lower receiving coil : 95-120 mm

Here, the coil position is defined as the distance between the top of the rail and the center of the coil.

The result of design optimization is shown in TABLE II. The layout optimization, taking account of the flux distributions effected by the wheel and mounting hardware, indicates the possible improvement of the reception sensitivity.

In the full paper, we will model the electromagnetic noise from the traction power converter, and investigate the design optimization of the receiving coils in detail.

TABLE II
IMPROVEMENT OF RECEPTION SENSITIVITY

	No wheel (dBV)	With wheel (dBV)	Variaton (dB)
Initial layout	-43.26	-62.25	18.99
Optimized layout	-41.07	-61.61	20.54

Abstract — The purpose of this contribution is to evaluate the feasibility, potential benefits and associated costs, of generalizing and improving finite element formulations used to model, analyze and simulate, the theoretical and practical operation and efficacy of internal myocardium defibrillation systems. The primary focus of this study addresses the issue of generalizing the finite element models to better represent the biological tissue anisotropies of the myocardium, for the purpose of simulating the bioelectromagnetic response to conventional internal defibrillation stimuli. From the electrical viewpoint, the dominant impact of the tissue anisotropy affects conductivity modeling. The critical goal of this research is to establish the importance of modeling myocardium conductivity anisotropy for predicting internal defibrillation performance, and to determine the quality and detail of the models required to yield operationally correct results. Full tensor anisotropy formulations suitable for representing individual myocardial fibre bundles and sheets are considered and evaluated against simpler models. It is shown that isotropic tissue models can overestimate defibrillation efficacy, while macroscopic anisotropy formulations are sufficient to predict accurate and reliable bioelectromagnetic responses, for a range of practical internal defibrillation case study applications.

I. INTRODUCTION

Ventricular fibrillation (VF) is a dangerous, unstable state of the heart in which the cardiac muscles of the ventricles tend to twitch or quiver in an unsynchronized and chaotic manner. VF is commonly linked to malfunctioning electrical activity of the heart, and usually yields abnormal contractions which prevent efficient distribution of blood and oxygen to the tissues. VF is responsible for about 300,000 deaths in the USA annually [1].

The most effective approach to resolve VF is using internal defibrillation, i.e. by applying electrical shocks directly to the heart via an implantable cardioverter-defibrillator (ICD). The performance and operational lifespan of an ICD is tied to both the placement of the electrodes surrounding the heart muscle, and the energy storage capacity of the batteries which power it. Optimizing ICD electrode design, configuration and discharge characteristics can play a vital role in increasing the reliability and safety of defibrillation, as well as in reducing the electric shock energies required, and increasing the ICD lifespan [1].

Until relatively recently, these issues were addressed largely based on practical clinical trial results, until the introduction of detailed thoracic and cardiac models facilitated computational simulations of heart defibrillation. These models are now used to optimize both electrode design and placement, and electrical stimulation strength and waveform, to improve the efficacy of

the defibrillation process [2], [3]. However, due to the lack of concrete conductivity data for the myocardium, finite element studies seldom attempt to represent the anisotropies associated with the highly fibrous and multilayered structure of the tissue, and the potential ramifications and impact of these aspects for practical internal defibrillation systems remain unclear [4], [5].

The defibrillation threshold (DFT) is conventionally defined as the minimum electrical stimulation required for a successful defibrillation result. While this specification is not unanimous, a widely held interpretation is the critical mass hypothesis [4]. This DFT stipulates that 75-90% of the myocardium should be raised to an average electric voltage gradient of 300-800 V/m, or more directly, exposed to an average electric current density of 70-200 A/m², for the duration of the stimulation, in order to achieve defibrillation [6]. It should be noted that higher tissue stimulation levels are also used in some applications, but they need higher capacity ICD energy storage sources, and render a greater risk of localized cardiac electrode-tissue damage. The critical mass hypothesis DFT is considered in this study.

The primary purpose of this contribution is to determine the potential advantages and related costs of generalizing the finite element formulations used to model, analyze and simulate the practical operation and efficacy of ICD systems, to account for the inherent electrical anisotropies of the myocardium tissues. At the cellular level, the myocardium consists of muscle fibres composed of co-aligned myocytes (muscle cells), organized in complex three-dimensional laminar structures (muscle sheets), which are oriented transversally to the heart walls [7], [8]. At the macroscopic level, sets of adjoining and similarly directed muscle sheets can be interpreted to represent averaged laminar muscle layers, which specify undulating and twisting preferred electrical conduction paths that transect the myocardium walls. In terms of macroscopic material conductivity modeling, these layers may be described using anisotropic conductivity tensors, with preferred conductivity directions aligned along the “flow” of the layers, which circulate azimuthally around the heart, and non-preferred conductivity directions oriented perpendicular to the muscle fibres. Other conductivity anisotropies also arise at sub-macroscopic levels, but they are operationally secondary.

An application-specific, recursive-refinement, second-order, isoparametric, tetrahedral, finite element formulation, with full tensor continuum conductivity modeling, for both macroscopic and sub-macroscopic analyses, is used in this study. The intent of this research is to establish the merits of using macroscopic anisotropy models for analyzing practical ICD performance.

II. ILLUSTRATIVE EXAMPLE AND RESULTS

A straightforward example that demonstrates the importance of modeling the anisotropic nature of myocardial conductivity for predicting ICD performance and efficacy is presented. The physical system geometry and finite element model for a basic, low-frequency ICD stimulation study are described by Fig. 1. In this case, two small rectangular patch electrodes are used to externally stimulate the lower mass of the left ventricle (LV) of the myocardium. Fig. 1 illustrates an exploded cut-away view of the LV tissue mass and the ICD electrode configuration.

Three sets of results are reported, for three mean equivalent LV tissue conductivity models: (i) isotropic $\sigma = 0.240\text{S/m}$; (ii) anisotropic with $\sigma = 0.48\text{S/m}$ along the fibres and $\sigma = 0.12\text{S/m}$ perpendicular to the fibres; (iii) anisotropic with $\sigma = 0.412\text{S/m}$ along the fibres, $\sigma = 0.206\text{S/m}$ perpendicular to the fibres and tangential to sheets, and $\sigma = 0.103\text{S/m}$ normal to fibre sheets. Sample LV wall field penetration plots are presented in Fig. 2.

In opposition with the conclusion of [9], the results in Fig. 3 indicate that using isotropic myocardium conductivity models in ICD DFT analyses can yield significantly different threshold predictions, compared to using anisotropic models. In fact, the isotropic model results over-estimate the anisotropic minimum DFT stimulation levels by 50-85%, in the 70-90% range of the LV tissue volume. This difference may be due to modeling the anisotropy of myocardial sheets – which was not done in [9]. In addition, Fig. 3 also indicates that it may not be necessary to model all the detail of the myocardial sheets to estimate useful DFT results; macroscopic anisotropy models may be adequate.

Fig. 1. Exploded cut-away view of the second-order, curvilinear, tetrahedral mesh for the lower portion of the LV (39,690 elements and 57,009 DOF). The cutout section illustrates the laminar structure of the myocardial wall; the ICD patch electrodes are shown in red (one on the cutout; one at the upper right).

Fig. 2. Normalized scalar electric potential solution plots for steady-current flow analysis over cutout section: (a) represents the homogeneous isotropic conductivity result [case (i)]; (b) represents the layers included anisotropic tissue response [case (iii)]. Both correspond to $\pm 1\text{V}$ electrode excitations. Note the sizable difference in potential field penetration into the LV free-wall.

Fig. 3. DFT results for the isotropic and anisotropic conductivity simulations: the curves describe the maximum average current density magnitude achieved per fractional volume of the LV myocardium; the knots indicate the minimum current density stimulation levels delivered to these partial LV tissue masses.

Abstract— The inductive method for measuring the critical current density in a high-temperature superconductor (HTS) has been investigated numerically. In the method, a HTS sample is exposed to the magnetic field which is generated by a small coil placed just above the sample. While applying an ac current $I(t)=I_0 \sin 2\pi ft$ in the coil, the 3rd-harmonic voltage V_3 induced in the coil is measured. In order to simulate the inductive method, I_0 - V_3 curves are numerically determined and the critical current density is estimated from their characteristics. The results of computations show that, for a HTS bulk, the accuracy of the inductive method is significantly influenced by the coil radius. In addition, for double-sided HTS films on an MgO substrate, the accuracy is strongly affected by the substrate thickness.

I. INTRODUCTION

The inductive method [1]-[3] has been widely used for measuring the critical current density j_c of a high-temperature superconductor (HTS) thin film since it was developed by Claassen *et al.* [1] Recently, Mawatari *et al.* [3] have improved the inductive method so that it can be applicable to the measurement of j_c in a HTS bulk. In the method, a HTS sample is exposed to an inhomogeneous ac magnetic field that is generated by an N_c -turn coil placed just above the HTS sample. While applying an ac current $I(t) = I_0 \sin 2\pi ft$ in the coil, the third-harmonic voltage $V_3 \sin(6\pi ft + \theta_3)$ is measured. On the basis of the measured values, $I_0 - V_3$ curves are obtained. In the inductive method, the value of j_c is estimated from the characteristics of the curves. However, their shapes differ remarkably depending on what type of a HTS sample is used: a bulk or a thin film. Hence, the j_c -estimation method for a bulk is widely different from that for a film.

By using the critical state model, Mawatari *et al.* analyzed the mechanisms of the V_3 generation to get the following formulas [2], [3]:

$$j_c^S = 2\pi f G_3 I_0^2 / V_3, \quad (1)$$

$$j_c^A = 2F_m I_\tau / b. \quad (2)$$

Here, j_c^S and j_c^A denote the value of j_c for a bulk and that for a film, respectively, and b is the thickness of a HTS film. Furthermore, G_3 and F_m are both constants determined only by the configuration of a coil and a HTS sample. In the inductive method, the value of j_c for a HTS bulk and that for a HTS film are estimated by using (1) and (2), respectively.

The purpose of the present study is to numerically investigate the applicability of the inductive method to a HTS bulk or to double-sided HTS films on a substrate. In particular, we elucidate the following two problems:

- 1) How is the inductive method for a HTS bulk affected by the experimental conditions?
- 2) Can the inductive method be applied to the j_c -measurement for double-sided HTS films on a substrate?

II. GOVERNING EQUATIONS

We assume that a HTS-sample shape is a disk of radius R and thickness b , and that a coil has a rectangular cross section of width W and height H . In addition, the coil is placed so that its symmetry axis may correspond to that of the HTS sample. Since these assumptions lead to the axisymmetric problem, we can use the cylindrical coordinate (r, θ, z) . In terms of the coordinate, the cross section of the coil is expressed as $D = \{(z, r) : |z - z_c| < H/2, |r - r_c| < W/2\}$.

Under the multiple-thin-layer approximation, the state of the shielding current density can be represented in terms of a vector-valued function $\vec{S}(r, t) \equiv [S_1(r, t), \dots, S_M(r, t)]^T$, where $S_p(r, t)$ is z -component of the current vector potential in the p th layer. In addition, the time evolution of $\vec{S}(r, t)$ is governed by the following integral-differential equations [4]:

$$\mu_0 \frac{\partial}{\partial t} \left(\hat{Q} + \frac{1}{\varepsilon} \hat{I} \right) \vec{S} + \frac{\partial}{\partial t} \vec{B} + \vec{E}_R = \vec{0}. \quad (3)$$

Here, \vec{B} and \vec{E}_R originate from the applied magnetic flux density and the electric field, respectively, and 2ε denotes the thickness of each layer. Moreover, \hat{I} is an identity operator, whereas \hat{Q} is the operator defined in [4]. For the J - E constitutive relation, the following power law is assumed:

$$\vec{E}_p = E(j_p) \hat{j}_p / |j_p|, \quad E(j) = E_C (j/j_c)^N, \quad (4)$$

where E_C denotes the critical electric field and N is a constant.

For the initial and the boundary conditions to (3), we assume $\vec{S}(r, 0) = \vec{S}(R, t) = \vec{0}$. The time evolution of the shielding current density can be determined by solving the initial-boundary-value problem of (3). By using the high-performance integration method [5], the authors recently developed an accurate numerical code for solving the problem.

III. NUMERICAL SIMULATION FOR HTS BULK

In the present section, we investigate the accuracy of the inductive method for a HTS bulk. To this end, two dimensionless quantities are defined as follows:

$$I_0^* \equiv I_0 / (j_c R b),$$

$$V_3^* \equiv V_3 / \left[2\pi f G_3 j_c (R b)^2 \right].$$

12. DEVICES AND APPLICATIONS

In terms of the above quantities, the relative error between j_C^S and j_C can be written as

$$\varepsilon_r = |1 - (1/k_0^*)^2|, \quad (5)$$

where k_0^* denotes a slope of a $I_0^* - (V_3^*)^{1/2}$ curve at the origin. As is apparent from (5), it is k_0^* that determines the value of ε_r . Hence, k_0^* can be used as a measure of the accuracy of the inductive method. Throughout the present section, the physical and the geometrical parameters are fixed as follows: $N_c = 400$, $f = 1$ kHz, $W = 1.2$ mm, $H = 1$ mm, $z_c = 0.75$ mm, $R = 10$ mm, $b = 0.4$ mm, $M = 10$, $N = 16$, $E_C = 1$ mV/m, and $j_C = 10$ MA/m².

Fig. 1. The dimensionless third-harmonic voltage V_3^* as functions of the dimensionless coil current I_0^* . The inset shows the dependence of the relative error ε_r on a coil radius r_c .

The $I_0^* - (V_3^*)^{1/2}$ curves are numerically determined for various values of r_c and are depicted in Fig. 1. We see from this figure that $k_0^* \cong 1.00$ for $r_c \leq 7.5$ mm and $k_0^* \cong 1.20$ for $r_c = 9.4$ mm. In other words, the relatively good accuracy is achieved for $r_c \leq 7.5$ mm, whereas the accuracy is drastically degraded for $r_c = 9.4$ mm. For the purpose of investigating these tendencies quantitatively, k_0^* is determined by applying the least-squares fitting to the $I_0^* - (V_3^*)^{1/2}$ curves and, subsequently, the relative error ε_r is evaluated by using (5). The results of computations are shown in the inset of Fig. 1. This inset indicates that, for $r_c \leq 7.5$ mm, the relative error slightly decreases with an increasing coil radius. On the other hand, for $r_c \geq 7.5$ mm, it drastically increases with r_c . This result suggests that there exists an optimum value of the coil radius.

IV. NUMERICAL SIMULATION FOR DOUBLE-SIDED HTS FILMS

As is well known, double-sided HTS films are generally grown on an MgO substrate and are frequently used for RF filter designs. In the present section, we numerically investigate whether the inductive method is applicable to the j_C -measurement of double-sided HTS films on an MgO substrate. Throughout the present section, the geometrical and the physical parameters are fixed as follows: $N_c = 300$, $f = 1$

kHz, $W = 1.25$ mm, $H = 3$ mm, $(z_c, r_c) = (1.56$ mm, 1.625 mm), $R = 10$ mm, $b = 500$ nm, $M = 1$, $N = 16$, $E_C = 1$ mV/m, and $j_C = 3.3 \times 10^3$ MA/m². Note that b does not denote the total thickness of a sample but the thickness of each film. In the following, the thickness of an MgO substrate is denoted by d .

The $I_0 - V_3$ curves are numerically determined for various values of d and are depicted in Fig. 2. Especially, for the case with $d = 5 \times 10^{-1}$ mm, the behavior peculiar to double-sided HTS films is observed. Just after I_0 exceeds the threshold current I_{T1} , V_3 abruptly develops. A further increase in I_0 will cause a monotonous increase in V_3 until V_3 reaches a plateau at $I_0 = I_{T2}$. Moreover, for the case with $I_0 > I_{T2}$, it increases again with I_0 . In other words, just after $I_0 = I_{T1}$ or just after $I_0 = I_{T2}$, the third-harmonic voltage rapidly develops with an increase in I_0 . Such a rapid increase in V_3 is attributable to the breakdown of the magnetic shielding behind either an upper film or a lower one. These tendencies are also observed in Saito's experiment [6]. In the following, the value of V_3 at $I_0 = I_{T2}$ is called an upper third-harmonic voltage. Fig. 2 also indicates that an upper third-harmonic voltage monotonously decreases with a decrease in d until it almost vanishes for the case with $d = 2 \times 10^{-2}$ mm. Hence, the equality $I_{T1} = I_{T2}$ is approximately satisfied for this case. This result suggests that, for $d \leq 2 \times 10^{-2}$ mm, the accuracy of (2) is deteriorated remarkably.

Abstract— In this paper an effective approach to generate specimen-specific finite element head models for bioelectromagnetic simulations is presented. The goal of the research is to develop a fast and automatic methodology for generation of such models.

The method uses a hybrid mixture of spatial transformation and image registration. The spatial transformation is used to transform the standard reference model, which was created with an elaborate manual segmentation, into individually fit model. The goal of this step is to morph the reference model to obtain the same external shape as the individual model. The image registration algorithm is then used to segment brain tissues, which are later put inside the skull. The final model is constructed of skull and skin obtained from morphing, and internal structure from image registration algorithm used for the brain.

I. INTRODUCTION

Numerical models in bioelectromagnetism created for the finite element method, need dividing the volume of the head into huge number of small elements, reflecting the size of the anatomical details.

The classical approach to the construction of such a model starts with obtaining a series of two-dimensional MRI scans. Each scan is then processed in order to improve the sharpness and the contrast between interesting tissues. Next step is a segmentation of images to extract boundaries between the different tissues. Next the voxelization follows in which the segmented cross-sections are combined into the 3D model. The 3D volume mesh is then generated by dividing each voxel into the relevant elements. In the final stage the reduction procedure decreases the number of elements and smoothes the model (see Fig. 1a).

Fig.1. (a) Head model generated from VH images [5] (b) External scan of the head made with Faro Laser ScanArm.

Some phases described above cannot be fully automated. The classical, semi-automatic approach becomes more painful with demand for even more realistic, patient-specific models of the human body. Individually tuned simulations could help to

design effective and possibly non-invasive configuration of medical devices for electromagnetic stimulation. However they need fast and robust procedure to create models based on individual features for certain patient [1]-[4].

The automatic segmentation of particular region depends on the medical imaging technique used to obtain data. It is quite easy to segment the brain tissues from MRI images. The skull can be more effectively segmented using CT data. There have been attempts to combine those techniques to improve the quality of models. Those algorithms however require additional effort like scaling and alignment of the models.

II. MORPHING APPROACHES

The new approach which is aimed to solve the presented problems emerged from methodology used in computer animation. It has already been used for relatively simple organs like bones and fingers, but we have adapted it to speed up creation of patient specific realistic head models.

The investigated morphing approach is based on works presented in [1]-[2] proposing two different methodologies but based on the same kind of idea. They start with fine discretized standard model and geometrical data of a target patient. These data can be based on some external measurements (see Fig.1b) or, preferably, on some medical imaging of the internal structure. Then the base model is morphed according to some criteria grounded in differences between the standard model and the target patient. The morphing can in principle be made on several levels—starting from the raw measurements (or images) up to the 3D discrete mesh. It is obvious, that morphing the mesh is the most difficult but as well the most wanted approach.

Several algorithms of the morphing were proposed. The most interesting from our point of view seems to be a combination of two methods: Automated Wrapping [1] and Volume Registration (VR) [2]. Automated wrapping was successfully applied to create individual model of bones. It needs relatively small amount of input data, but is not able to map the internal structure of the model. The VR method allows to obtain more accurate structured models, but it needs very fine input data. Authors of [2] have used tomography scans of the base patient and the target patient to obtain input data for the morphing criteria. Both scans were made in exactly the same device and same configuration. The morphing algorithm compared, pixel by pixel, scans of the base and target to calculate the morphing transformation. Obtaining similar input data for the head models seems to be extremely difficult if at all possible.

III. MORPHING IMPLEMENTATION

The basic technique assumes that we have a detailed model of sub-domains of a head. In this technique operator with help of a specialized software applies a stretch-shrink vectors set (see Fig.2). The set is then used by the algorithm to perform the morphing. This procedure can of course be automated.

Fig.2. Central point (CP) and Vectors (v_i) defining the stretch-shrink parameters for the algorithm.

In the proposed algorithm the domain is divided into the slices which are defined by a single central point (CP) and a set of vectors V_i . Each vector besides the direction and length has a location P_i . The slices are defined by the central point CP and two adjacent stretch-shrink vector locations P_i and P_{i+1} . Displacement of each vertex is defined by the two adjacent base vectors.

$$v_i = a_n r_n V_n + a_{n+1} r_{n+1} V_{n+1} \quad (1)$$

where

$$a_n = \frac{\langle x_i, P_{n+1} \rangle}{\langle P_n, P_{n+1} \rangle}, \quad a_{n+1} = \frac{\langle x_i, P_n \rangle}{\langle P_n, P_{n+1} \rangle} \quad (2)$$

$$r_n = \frac{|x_i|}{|P_n - CP|}, \quad r_{n+1} = \frac{|x_i|}{|P_{n+1} - CP|}$$

We can say that with the transformation defined by (1) and (2) the vertex is translated by the weighted sum of the adjacent base vectors V_n, V_{n+1} .

The presented transformation preserves the sub-domains from the base model in the morphed model. Proper definition of base vectors allows to adjust the external shape of the reference model to the current MRI image. In Fig.3 the reference and morphed models are presented. We can see that the external shape of the morphed model fits the shape of the subject, however the internal structure of the head differs.

Fig.3. Domains of the head before stretching-shrinking (a) and after execution of the algorithm (b).

To obtain the proper structure of the internal region we have removed the white matter obtained from the morphing (see Fig.4b) and added the white matter from image

registration algorithm. The image registration was performed with simple hence robust histogram-based method.

Fig.4. Domains of the head after stretching-shrinking (a) and with replaced white matter subdomain from image registration (b).

IV. CONCLUSIONS

The most crucial is the development of indicators, which will assess the quality (fidelity) of the derived model. This is due to the fact that the target model is unknown. These indicators should be based on measurements of the patient's head. The simplest indicators can be based solely on simple anthropometric measurements, but it can prove to be insufficient because of the complexity of a large numerical model. The morphing transformation which must be properly defined and needs large number of data can be automated what makes the method highly advantageous. Simple morphing is of course insufficient, because the shape of the outer surface of the head does not determine its internal structure. To obtain specific internal structure of the head the MRI scans can be used. The authors have used them as input data for image registration to get the internal structure. It was later put together with external domains (skin and skull) from morphing to obtain the complete subject specific model. In the authors opinion the proposed method can be fully automated. This will significantly reduce the time from data acquisition to patient specific model.

Modeling a “flying carpet” stable in both the positive and negative z-directions

Mikhail Kustov, Orphée Cugat, and Gilbert Reyne

Abstract — An original levitation device, stable in both the positive and negative z-directions is modelled and simulated. The device may be used either in the Earth gravity field or under weightless conditions. The semi-analytical modelling and optimization suite MacMEMS / CADES [1, 2] was used.

I. INTRODUCTION: DIAMAGNETIC LEVITATION DEVICES

Diamagnetic levitation of diamagnetic materials above permanent magnets is now being widely published [3-5]. Diamagnetic forces, in a variety of devices, can be used against gravity. However the vertical stability of such structures depends on the compensation between gravity and diamagnetic repulsion, which makes them usable in one orientation only and in the Earth's gravity field.

Fig. 1. describes a proposed +/-Z stable levitation device. The "flying carpet" is a 30 μm thick plate of highly oriented pyrolytic graphite (HOPG), coated with 20 nm of iron. The "base" element is a 50 μm thick permanent magnet film, magnetically patterned into stripes [6, 7].

The device is designed to be microfabricated. MEMS and microtechnologies are perfectly suited to the diamagnetic levitation [8], because diamagnetic effects improve with miniaturization: they become comparable to gravity around the sub-mm scale.

In the "traditional" diamagnetic levitating devices [9, 10], the permanent magnet base has two functions: on Earth, its main function is to provide lift against gravity, along the vertical (Oz) axis. Additionally, possible configurations in the Ox and Oy axes are very variable, allowing translations along Ox or Oy or both, or rotation around Oz, or even no freedom at all. Here in our example, the chosen stripe-like magnetization pattern allows one degree of freedom: Ox translation along the stripes.

II. NOVELTY: BI-DIRECTIONAL STABILITY ALONG OZ

However, these devices do not work upside-down nor in zero-gravity because the forces along Oz are purely repulsive. Our innovation is the addition of a 20 nm thin film of soft ferromagnetic material which is deposited onto the HOPG plate, on the far side from the magnets. This ferromagnetic layer generates an attraction force towards the base, which can stabilize the carpet along Oz if properly calculated: this is the topic of our paper.

Fig. 1: The array at the bottom is the permanent magnet film integrated on Si, magnetised in an up/down array (remanence B_r). The middle layer is the micro-layer of HOPG (susceptibility χ_{dia}). The stripe on top is the nano-layer of soft magnetic material (saturation magnetization M_s). All dimensions along

Ox-axis are much larger than those along Oy-axis.

Magnets: $b = h = 50 \mu\text{m}$, $B_r = 1.4 \text{ T}$, Graphite: $h_g = 30 \mu\text{m}$, $\chi_{\text{dia}} = -450.10^{-6}$; Soft film: $h_f = 20 \text{ nm}$, $d_f = 1 \mu\text{m}$, $\mu_0 M_s = 1 \text{ T}$

III. MODELING AND OPTIMIZATION OF THE DEVICE

The force acting between the array of magnets which generate magnetic fields and gradients, and the diamagnetic element of the carpet, is repulsive:

$$dF_z \approx \frac{1}{\mu_0} \left(\chi_x B_x \frac{\partial B_x}{\partial z} + \chi_y B_y \frac{\partial B_y}{\partial z} + \chi_z B_z \frac{\partial B_z}{\partial z} \right) dV = \frac{1}{2\mu_0} \left(\chi_x \frac{\partial B_x^2}{\partial z} + \chi_y \frac{\partial B_y^2}{\partial z} + \chi_z \frac{\partial B_z^2}{\partial z} \right) dV \quad (1)$$

with flux density $\mathbf{B} = (B_x, B_y, B_z)$, and susceptibility $\chi_{\text{dia}} < 0$.

On the other hand, the force acting on the ferromagnetic nano-layer attracts the carpet towards the array of magnets; equation (2) shows the approximate expression for the force acting on a volumetric unit of an isotropic magnetic element, in its saturated state with the saturation magnetization $\mathbf{M}_s = (M_{s_x}, M_{s_y}, M_{s_z})$:

$$dF_z \approx \left(M_{s_x} \frac{\partial B_x}{\partial z} + M_{s_y} \frac{\partial B_y}{\partial z} + M_{s_z} \frac{\partial B_z}{\partial z} \right) dV \quad (2)$$

Here we make the assumption that the nano-layer is fully saturated in the fashion shown on Fig. 1. Within the vertical displacement range of the carpet, the magnetic field produced by the permanent magnet array is enough to saturate this very thin soft magnetic film (permalloy, for example) in-plane almost everywhere except very small wall regions d_f where the Y-component of the external magnetic field is near zero (for

the worst case d_f is assumed to be $1\ \mu\text{m}$, when the flying distance is $9\ \mu\text{m}$). The possible interaction between these regions and the permanent magnet base is not taken into consideration because their volume is much smaller compared to the total volume of the ferromagnetic film. These assumptions allow us to use the semi-analytical modelling and optimization tools MacMMEMS / CADES.

As can be seen from (1) and (2) and illustrated on Fig. 2, the repulsive and attractive forces are functions of the partial derivatives of the different powers of magnetic field, therefore they decrease differently with the distance: this difference allows a compensation to happen at a fixed distance z_0 , which is extremely dependent on geometrical parameters and on the magnetic multipolar configuration of the base. Here, the flying carpet would levitate at a stable position $z_0 = 2.3\ \mu\text{m}$ above the base; this distance would decrease to $2.1\ \mu\text{m}$ if gravity is taken into account, and $2.5\ \mu\text{m}$ when upside-down (Fig. 3).

Fig. 2. Forces acting on the graphite layer, on the iron layer, and total force, versus the distance (airgap) between the levitating part and the magnet array (base).

Fig. 3 shows that the total magnetic force (both positive and negative) acting on the flying carpet is much higher than the gravity force ($1\ \mu\text{N}$ on Earth) within a $10\ \mu\text{m}$ distance range: this allows the system to withstand moderate accelerations of about $+5\ \text{G}$ before contact or about $-7\ \text{G}$ before separation.

The optimization aims at improving the allowed displacement range of the levitating body, with respect to the given specifications. Once the material is chosen, the physical and magnetic constants are fixed, thus only the geometrical dimensions of the system need to be optimized.

Optimizations were done in the CADES framework where sensitivities of constrained specifications to the geometric parameters were automatically computed from algebraic equations of the model. A sequential quadratic programming (SQP) algorithm was used in order to find the best solution for each of the three applications. One optimization with a standard PC takes about 10 iterations and less than 1 minute per iteration.

Fig. 3. Total magnetic force vs. airgap, compared with the gravity force.

This kind of devices could be used in micro-robotics, both on Earth and in space under low-gravity conditions, for transporting micro-objets and nano-particles, as well as for friction-less 3D micro-sensors (acceleration, rotation...) for example.

The experimental work on the flying carpet is presently in progress within the MINATEC facilities.

This work is financed by *Fondation Nanosciences* RTRA.

3D Voltage Driven Finite Element Analyses of Eccentric Rotor Positions of a Novel Hybrid Radial Active Magnetic Bearing

Erich Schmidt, Matthias Hofer

Institute of Electrical Drives and Machines, Vienna University of Technology, Vienna, Austria
erich.schmidt@tuwien.ac.at, matthias.hofer@tuwien.ac.at

Abstract – The paper discusses electromagnetic parameters of a novel arrangement of a permanent magnet biased radial active magnetic bearing with three poles. The control currents of the three poles produce a heteropolar distribution of the magnetic field whereas the permanent magnets cause a homopolar configuration of the magnetic field. Thus, 3D finite element analyses have to be used to accurately obtain the parameters such as inductances and electromagnetic forces. In order to finally using a position-sensorless control algorithm for the hybrid magnetic bearing, the dependence of the electromagnetic parameters on the rotor position is of great interest. Consequently, special attention will be given to the modelling of various eccentric rotor positions yielding a fast computation environment suitable for the prototype design.

I. DESIGN OF THE RADIAL MAGNETIC BEARING

Fig. 1 shows the cross section of the prototype of the hybrid active magnetic bearing with three poles. The three coils on the poles produce a heteropolar configuration of the magnetic field while the permanent magnets additionally inserted in the stator generate a homopolar distribution of the magnetic field [1]–[3]. The permanent magnets will act as the source of the bias magnetic field. Thus, the coil currents are used only as control currents reducing the overall size and therefore leading to a more compact design. Further, the number of the permanent magnets can be adopted in order to obtain a hybrid magnetic bearing with characteristics according to various applications.

II. FINITE ELEMENT MODELLING

The electromagnetic parameters of an active magnetic bearing can be calculated by means of analytical methods based on an assumption of designated paths of the magnetic field [4], [5]. With centered rotor positions, these results are quite accurate to predict the behaviour of the bearing. On the other hand, for non-centered rotor positions only numerical analyses will yield accurate results due to the more significant cross-coupling of the various magnetic paths [6], [7].

Fig. 2 shows the active parts of the stator including permanent magnets and stator coils of the finite element model. In order to obtain a fast modelling and solution environment for taking into account eccentric rotor positions, a sliding surface approach and a domain decomposition algorithm can successfully be applied [8]. For each concerned radial eccentric rotor

Fig. 1: Cross section of the stator of the permanent magnet biased radial active magnetic bearing with three poles, arrangement with four magnets

Fig. 2: Finite element model of the stator of the permanent magnet biased radial active magnetic bearing with three poles, arrangement with four magnets

position, only the air-gap region between the sliding surface and the rotor boundary has to be remeshed. Consequently, different numerical errors with respect to the angular rotor position are avoided.

III. SAMPLE ANALYSIS RESULTS – INDUCTANCES

The three control windings in the stator are star-connected, $I_1 + I_2 + I_3 = 0$. Therefore, the two axes approximation

$$\begin{pmatrix} I_x \\ I_y \end{pmatrix} = \begin{bmatrix} 2/3 & -1/3 & -1/3 \\ 0 & 1/\sqrt{3} & -1/\sqrt{3} \end{bmatrix} \begin{pmatrix} I_1 \\ I_2 \\ I_3 \end{pmatrix} \quad (1)$$

yields the flux linkages according to

$$\begin{pmatrix} \Psi_x \\ \Psi_y \end{pmatrix} = \begin{bmatrix} L_{xx} & L_{xy} \\ L_{yx} & L_{yy} \end{bmatrix} \begin{pmatrix} I_x \\ I_y \end{pmatrix} \quad (2)$$

Due to the symmetric arrangement of the three coil windings, the cross-coupling inductances $L_{xy} = L_{yx}$

are vanishing in the centered rotor position. But with an eccentric rotor position, in particular in the y -direction, the cross-coupling inductances are significant as shown with the full paper.

Fig. 3 and Fig. 4 show the inductances L_{xx} and L_{yy} in dependence on radial and angular position of the rotor eccentricity for the arrangement with four magnets. As these inductances directly depend on the eccentric rotor position, the presented novel radial active magnetic bearing shows a high suitability for a position sensorless control.

Fig. 3: Inductance L_{xx} versus radial and angular position of the eccentricity, arrangement with four magnets

Fig. 4: Inductance L_{yy} versus radial and angular position of the eccentricity, arrangement with four magnets

Accordingly, Fig. 5 and Fig. 6 show the transient current response obtained from the voltage driven analysis and from measurements resulting from applied voltage pulses suitable for the subsequent evaluation of the eccentric rotor position which is presented in detail with the full paper.

IV. CONCLUDING REMARKS

The paper discusses 3D finite element analyses of a prototype design of a permanent magnet biased radial active magnetic bearing with three poles. To obtain a fast analysis environment suitable for the initial design, the sliding surface method and a domain decomposition algorithm are used for analyzing in particular various eccentric rotor positions. In the full paper, the presented results are focussed on the inductances of the coil windings carrying the control currents, the electromagnetic forces acting on the rotor and the current gain provided by the bearing as the most impor-

Abstract— Contact of air circuit breaker (ACB) switches on or off the power supply. In this paper, a new type of contact is presented with double breakers for the ACB with permanent magnet actuator (PMA). 3-D finite element method (FEM) is employed to compute electro-dynamic repulsion force including Holms force and Lorenz force acted on static and movable contacts. The repulsion force is obtained for different number of contact, which value increases step by step from the outer contact to inner one. The contact of double breaker is manufactured according to our analysis results.

I. INTRODUCTION

Circuit breaker plays an important role in power system. In order to improve the circuit breaker reliability, new concept circuit breaker is developed with permanent magnet actuator (PMA) [1]-[4]. The proposed PMA offers many advantages such as low component counts and high reliability when compared with spring operated circuit breaker (SOCB) both vacuum circuit breaker (VCB) and air circuit breaker (ACB).

Compared with the conventional spring circuit breaker, the permanent magnet circuit breaker has much more key problem to be solved. Contactor parameter computation is indeed important to determine the ACB structure parameter. The author has proposed a method to compute the temperature of the ACB with spring actuator [5]. In this paper, a new type of contact is proposed with double breakers for the ACB with permanent magnet actuator (PMA). 3-D finite element method (FEM) is employed to compute electro-dynamic force between static and movable contacts. The computed results show that the repulsion force increases step by step from the outer contact to inner contact. In addition, the repulsion force is also computed for the contact arranged with permanent magnet and will be discussed in full paper. The contact of double breaker is manufactured according to our analysis results.

II. MATHEMATICS MODEL AND CONTACTOR ASSEMBLY

The static magnetic field method is used to compute electro-dynamic repulsion force. Since the eddy current has little effect on the electro-dynamic repulsion force, the static magnet field equation can be employed to solve current density and flux density distribution. Vector potential \mathbf{T} is served to calculate the current density

$$\mathbf{J} = \nabla \times \mathbf{T} \quad (1)$$

\mathbf{T} satisfies the governing equation

$$\nabla \times \left(\frac{1}{\sigma} \nabla \times \mathbf{T} \right) = 0 \quad (2)$$

The current constrain condition is

$$\oint_s \mathbf{T} \cdot d\mathbf{l} = I \quad (3)$$

If the current density \mathbf{J} is obtained, vector magnetic potential \mathbf{A} is employed to depict the flux density \mathbf{B}

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (4)$$

The whole area vector magnetic potential satisfies the following governing equation

$$\nabla \times \left(\frac{1}{\mu} \nabla \times \mathbf{A} \right) = \mathbf{J} \quad (5)$$

The contact force density f is calculated based on the relationship of current, magnetic field and electromagnetic force

$$\mathbf{F} = \int_V f dV = \int_V \mathbf{J} \times \mathbf{B} dV \quad (6)$$

where V is the contact volume. Electro-dynamic repulsion force of contacts uses the electrical bridge model, the Holms force and Lorenz force acting on the contactor can be computed in finite element method (FEM).

Fig. 1 shows the proposed contact for the ACB with PMA. The mechanical system mainly consists of the PMA, a rotating shaft, a cam and a movable contact.

Fig. 1. Assembly of the contact located on the ACB

III. FINITE ELEMENT ANALYSIS

Fig. 2 shows the parallel contact of the quarter model. The contact uses double breaker structure, mainly including static contact and movable contact. 3-D FEM is employed in analyzing the contacts. Fig. 2 shows the meshes of quarter model. The element number is 46539 and nodes are 53925, respectively. Fig. 3 shows the current density distribution including parallel and single contacts. It is noted that the maximum current density distribution is located on the contacts point.

(b)

Fig. 3. Current density distribution (a) parallel contacts (b) single contact

Fig.4 shows the magnetic field distribution. It can be found that the maximum magnetic field distribution is also located on the contact point.

Fig. 4. Magnetic field distribution

IV. ANALYSIS AND DISCUSSION

Fig.5 shows the computed results of electro-dynamic repulsion force. It can be observed that the repulsion force increase with the static contact number increasing from outer to inner. The maximum absolute increasing value reaches to 23.3%. Such result shows that the inner repulsion force is higher than that of the outer repulsion force and can be referenced as our ACB design. Fig.6 presents the contact matched with the ACB. In addition, the repulsion force is also computed for the contact arranged with permanent magnet and will be discussed in full paper.

V. CONCLUSION

3-D FEM is successfully to compute electro-dynamic force of double breakers contact for the ACB with PMA. The repulsion force is obtained for different number of contact.

Computed results show that the repulsion force increases step by step from the outer contactor to inner one. The maximum absolute increasing value reaches to 23.3%. The contact with the double breaker is manufactured according to our analysis results.

Abstract— This paper describes the 3-D finite element analysis of repulsion forces on current-carrying contacts of a relay for a hybrid electric vehicle. The mechanism of repulsion force generation is clarified in the analysis. Furthermore the model reduced repulsion forces is proposed.

I. INTRODUCTION

Efforts are under way worldwide to develop electric vehicles and hybrid electric vehicles in response to energy conservation and atmospheric pollution concerns. The vehicles are equipped with a high voltage battery over 100 V to drive some motors, and must be equipped with relays which can interrupt a large dc-current. Since the battery is moreover considered to be of a higher voltage as one way of improving energy efficiency, the relays are required and must improve a contact capacity. Under the circumstances, it becomes quite important to decrease the repulsion forces on current-carrying contact.

Recently, computer simulations are widely used in various engineering fields because of the significant improvement of computer performance, and can be applied to complex phenomena.

In the previous papers of repulsion forces on contact have been reported. Holm has computed the repulsion forces by the magnetic field analysis using simplified model of current-carrying contact [1]. In the model, two cylindrical terminals contact with its center, and it is assumed that the current flows radially through the spherical micro-contact. Therefore the influence of complex current distribution caused by the change of contact position on the repulsion forces has not been considered. Kawase and Ito have reported the repulsion force calculation by analyzing the current distribution using the 3-D finite element model, in which the contact part between two cylindrical terminals is modeled as the cylindrical micro-contact [2]. This report has clarified the influence of contact position and contact separation on repulsion forces, however, the reduction of repulsion forces has not been computed.

In this paper, we clarify the mechanism of repulsion force generation of relays for hybrid electric vehicles using 3-D finite element method (FEM), and propose the model improved repulsion forces.

II. ANALYSIS METHOD

A. Current Distribution Analysis

Since the distributions of current density vectors flowing in the contact are complicated, and analyzed by 3-D FEM using the current vector potential T as follows:

$$\operatorname{rot}\left(\frac{1}{\sigma}\operatorname{rot}T\right)=0, \quad J_0=\operatorname{rot}T, \quad \oint T \cdot ds=I \quad (1)$$

Where σ is the conductivity, J_0 is the current density, and I is the current.

B. Magnetic Field Analysis

The fundamental equations of the magnetic field can be written using the magnetic vector potential A and the current density J_0 as follows:

$$\operatorname{rot}(v\operatorname{rot}A)=J_0 \quad (2)$$

Where v is the reluctivity.

C. Calculation of Repulsion Forces

The magnetic force F on the current-carrying contact is computed as follows:

$$F=\int_V(J_0 \times B)dv=\int_V f dv \quad (3)$$

Where V is the volume of current-carrying part, B is the magnetic flux density, and f is the magnetic force density.

The repulsion forces between terminals can be calculated by the sum of z direction component of magnetic force density in each element.

III. ANALYZED MODEL AND CONDITION

Fig.1 shows the 3-D finite element mesh of relays for hybrid electric vehicles. This model consists of cylindrical stationary terminals, flat movable terminal, and cylindrical micro-contacts. The dc current flows through stationary terminals, contacts, and movable terminal while the coil is excited. The movable terminal is released from stationary terminals to interrupt the current by the restoring spring when the coil is not excited. The repulsion forces on contact are analyzed except the coil because of little influences. The diameter, height and conductivity of cylindrical micro-contact, which is thought to be the plastic deformation by the contact between micro-convexities of movable and stationary terminal, are 0.05 mm, 0.1 mm, and 6.0×10^7 S/m, respectively.

IV. ANALYZED RESULTS

Fig.2 shows the distribution of current density vectors and magnetic force density vectors, respectively. From the figure, the concentrations of current and magnetic force density are confirmed around contacts between movable and stationary terminals. It is considered that repulsion forces are decided by the flux density and the horizontal component of current near the contacts. Fig.3 shows the comparison of the computed repulsion force characteristics on current. The calculated results by Holm's equation are different from those by this analysis, showing the effectiveness of the 3-D FEM in the complex terminal shape model. The measured result of repulsion forces is about 4.5 N when the current of 2000 A is applied, then agrees well with computed ones. As a result, the validity of this method is confirmed.

Fig.4 shows the influence of contact position on repulsion forces. From this figure, the repulsion force at the center position is the lowest of y-direction change of contact position. This reason is thought that the horizontal component of current is increased as the contact position moves from the center position. The repulsion forces in x-direction change of contact position are decreased, as the contact is located at the inner side of relays. It is found that the influences of x- and y-

Fig.1 3-D finite element mesh of relays (1/2 region).

Fig.2 Distributions of current density vectors and magnetic density vectors.

Fig.3 Repulsion forces characteristics on current.

direction change of contact position on the repulsion forces are different.

Fig. 5 shows the distributions of magnetic force density vectors near the contact point. From this figure, the distributions of magnetic force density near the contact point seem to be almost the same. In addition, the repulsion forces are analyzed in detail. The movable terminal is separated in steps of 0.5 mm to clarify the influence of the contact position. Fig. 6 shows the distributions of repulsion forces on the movable terminal. It is found that the repulsion forces are generated not only near the contact but also on the center of movable terminal. From these results, as the contact is located at the inner side of relays, the reduced effect of repulsion forces is effective because the repulsion forces generated on the movable terminal are decreased. Furthermore the improved model of repulsion forces will be opened in the full paper.

Abstract— We have been studying an interior permanent magnet linear actuator for an artificial muscle. This actuator mainly consists of mover composed of permanent magnets, magnetic cores and a non-magnetic shaft, and a stator composed of 3-phase coils and a back yoke. In this paper, the dynamic analysis method under PID control is proposed employing the 3-D finite element method (3-D FEM) to compute the dynamic response and current response when the positioning control is active. As the results, computed results show good agreement with measured ones of a prototype.

I. INTRODUCTION

Generally, servo motors and air servo actuators have been used as driving sources of various parts of robots. Our humanlike robot (android) is composed of air servo actuators. These actuators have no backlash, but low response because of the pneumatic control. The authors therefore have been studying the direct drive electromagnetic linear actuator to solve the above problem. This actuator is expected to have long stroke, high response and large thrust using interior permanent magnets effectively, and shows higher dynamic performance as compared with the actuator using Halbach array of magnets [1], [2].

In this paper, we propose the dynamic analysis method for the actuator under PID control employing the 3-D FEM. This method is applied to compute the dynamic response and current response when the positioning control is active. The validity of the analysis is verified through the comparison with the measurement of a prototype. In addition, it is found that this actuator shows high response characteristics.

II. ANALYZED MODEL AND OPERATING PRINCIPLE

The cross-section of our linear actuator is shown in Fig. 1. The diameter and the length of this actuator are 20mm and 180mm respectively. The mover is mainly composed of permanent magnets, magnetic cores and a non-magnetic shaft. The magnetization of a magnet (NdFeB, Br=1.4T) is shown in Fig. 1. The structure of the mover can generate the high magnetic flux, especially effective radial component of flux along the outside of the magnetic core periodically. The stator is composed of 3-phase coils and a back yoke.

When these coils are excited, they are forced to move by Lorentz force. The mover is driven by the thrust as this reaction force while the stator is fixed. The mover is freely controlled by switching the 3-phase coil currents.

Fig. 1. Basic structure of an electromagnetic linear actuator

III. ANALYZED METHOD

A. Magnetic Field Analysis Coupled with Motion Equation

In this method, the equations of the magnetic field and the electric circuit are coupled, which are given by the magnetic vector potential \mathbf{A} and the exciting current I_0 as follows [3]:

$$\text{rot}(\nu \text{rot } \mathbf{A}) = \mathbf{J}_0 + \nu_0 \text{rot } \mathbf{M} \quad (1)$$

$$E = V_0 - RI_0 - \frac{d\Psi}{dt} = 0 \quad (2)$$

$$\mathbf{J}_0 = \frac{n_c}{S_c} I_0 \mathbf{n}_s \quad (3)$$

where ν is the reluctivity, \mathbf{J}_0 is the exciting current density, ν_0 is the reluctivity of the vacuum, \mathbf{M} is the magnetization of permanent magnet, V_0 is the applied voltage, R is the effective resistance, Ψ is the interlinkage flux of exciting the coil. n_c and S_c are the number of turns and the cross-sectional area of the coil respectively. And \mathbf{n}_s is the unit vector along with the direction of exciting current.

The motion of the mover is described as follows.

$$M \frac{d^2 z}{dt^2} + D \frac{dz}{dt} \pm F_s = F_z \quad (4)$$

where M is the mass of the mover, z is the displacement of the mover and D is the viscous damping coefficient. F_z and F_s is the z -axial component of the electromagnetic force and the dynamic friction force.

B. Consideration of Servo Controller

Fig. 2 shows the system configuration on the servo system. In target trajectory generator, the trajectory from start point to goal point is computed from position of goal point, maximum velocity and acceleration according to trapezoidal velocity role. The PID controller computed target torque (i_q^*) from the

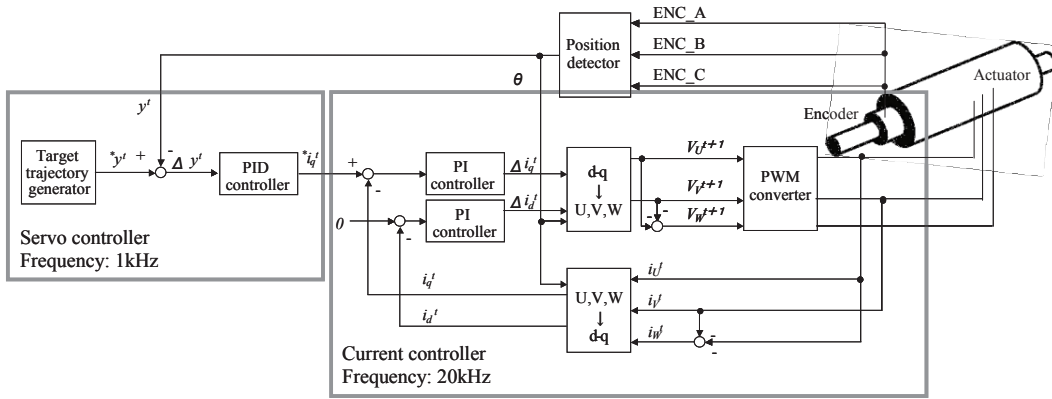

Fig. 2. System configuration of the servo system

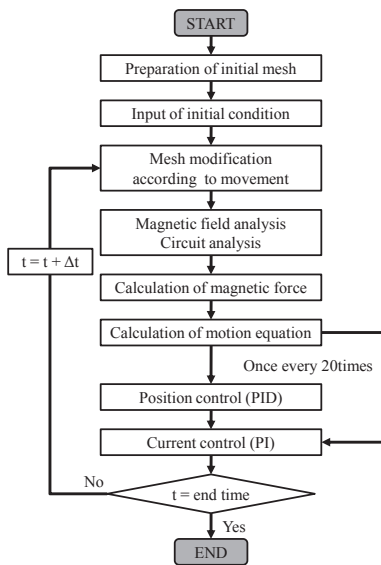

Fig. 3. Flowchart for dynamic analysis under PID control

difference ($\Delta y'$) between target position (y^*) and current position (y') from encoder (frequency: 1 kHz).

C. Consideration of Current Controller

Measured 3-phase currents (i_U^l, i_V^l, i_W^l) are transformed to field current (i_d^l) and torque current (i_q^l). PI control is adopted in the difference of field current and torque current (frequency: 20 kHz). These results are transformed inversely to next step voltage values ($V_U^{l+1}, V_V^{l+1}, V_W^{l+1}$).

Fig. 3 shows the flowchart for dynamic analysis under the PID control. The position control is adapted once every 20 times.

IV. RESULTS AND DISCUSSION

The dynamic performances of the actuator under PID control are computed while the mover moves from 0 to 3.2mm. Fig. 4 shows the computed time variations of position and U-, V-, W-phase currents. Fig. 5 shows the measured results of a prototype. As can be seen, both results of the time variations of position are in good agreement and this actuator shows high response characteristics. And, both results of the time

Fig. 4. Computed results

Fig. 5. Measured results

variations of U-, V-, W-phase currents are in good agreement qualitatively, however, the peak value of currents during rest and the current waveforms at the goal point are different. This is because the prototype has relatively large friction. In the final paper, the analyzed accuracy will be improved by taking into account of the dynamic friction in the computation.

Abstract – The shunt reactors are important components in the EHV/UHV (Eltra/Ultra High Voltage) power systems used for the voltage regulation issues. One of their important roles is to compensate the reactive power. Typically for such compensation the *fixed* shunt reactors are used. Alternative concepts introduced recently are the *controllable* reactors. Among various controllable reactors schemes, the orthogonal flux type controllable reactor is remarked for its low harmonics and fast response time. The *controlling* effect of orthogonal flux type controllable reactor is achieved by controlling the saturation level of the parts of the magnetic core (saturable reactor). In this paper we present an efficient approach for the simulation of such controllable reactors using Integral Equation Method (IEM). The key information when analyzing this kind of devices are the controllable reluctances. The paper demonstrates usage of IEM for the computation of the inductances as a function of the DC current changes depending on the saturation levels of the magnetic material. The results are compared with the calculation results based on equivalent magnetic circuit calculation model.

I. CONTROLLABLE REACTORS

Voltage regulation using shunt reactors is one of the key issues in the long power transmission lines. They are especially important when building the long distance power transmission lines for the EHV/UHV application, in which the line voltage is higher than 500kV. When the line is energized but not loaded or only loaded with a small current, there is a voltage rise along the line (the Ferranti-effect^[1]), Fig. 1. The overvoltage increases the stress of insulation level on the primary components or restriction of transfer capacity of the transmission lines, especially at the terminals.

Fig. 1: Illustration of the voltage dependency at the end of the line caused by the line capacitances

One solution for these problems is to employ the controllable reactor, which can regulate the bus voltage level and transmission capacity according to line's load level.

Till now, the references dealing with the reactor simulations are quite restricted and mostly limited to the FEM-based simulation of the *fixed* value shunt reactors, [2-4]. The basic principles and the design of the controllable reactor are discussed in [5].

In this paper we present a procedure for 3D IEM-based simulation of the orthogonal flux type controllable reactor. The simulation method provides accuracy analysis results to

accelerate the development procedure. The simulation results can also be used for calibration of the mathematic model. We discuss the main features and advantages of presented methodic for this type of simulations. The simulation results are compared with the calculation method on a simple geometry model.

II. MODELING OF THE CONTROLLABLE REACTOR

A. The magnetizing curve and its ideal model

The key problems when simulating this kind of devices are efficient treatment of the controllable *magnetic reluctances*. The “control” of the reluctances is achieved by the control of the saturation level of the “control discs” in the reactor's central limb. Fig. 2(a) shows the structure of controllable reactor with air-gaps between the control discs and uncontrolled discs. By adding air-gaps, the control range can be adjusted and thus decrease the total cost of the controllable reactor.

(a) The structure of controllable reactor (b) the control disc
Fig. 2: Structure of the controllable reactor with air-gaps between the discs

The main reactor coil is excited by the AC voltage. The control discs are excited by the auxiliary DC coils wound around each of them. The structure of the control disc is shown in Fig 2(b).

B. The magnetizing curve and its ideal model

The ideal magnetizing curve of the magnetic material can be expressed as:

$$B = B_m + \mu_0 H \quad (1.1)$$

Where $B_m = 1.91T$.

C. The Inductance calculation

The inductance of the controllable reactor can be estimated by the magnetic circuit theory and using (1.1).

III. SIMULATION OF THE CONTROLLABLE REACTORS

The simulation of the above phenomena is performed using IEM. As mentioned before, the major task is to calculate the changes of the inductance due to changes of the DC excitations around controlled discs.

A. IEM Formulation

The analysis of the non-linear problems in magnetostatic by IEM is performed using the improved procedure described initially in [6]. The magnetic field in any space point can be found as:

$$\mathbf{H} = \mathbf{H}^J + \mathbf{H}^M \quad (2.1)$$

where \mathbf{H}^J is a field component produced by the excitation current in free space and \mathbf{H}^M is a field produced by the magnetic charges. The first field component can be easily calculated by Bio-Savart law. For the calculation of the second one we use the formula:

$$\mathbf{H}^M = \frac{1}{4\pi} \oint_{S_J} \sigma_J \mathbf{K}_1 dS_J + \frac{1}{4\pi} \oint_{V_N} \rho_N \mathbf{K}_2 dV_N \quad (2.2)$$

where σ_J and ρ_N are the fictitious surface and volume magnetic charges, and \mathbf{K}_1 and \mathbf{K}_2 are the kernels of the type \mathbf{r}/r^3 . The surface charges are obtained by solving second Fredholm integral equation:

$$\sigma_I - \frac{\lambda_I}{2\pi} \oint_S \sigma_J G_1 dS_J = 2\lambda_I \mathbf{H}_I' \cdot \mathbf{n}_I + \frac{\lambda_I}{2\pi} \oint_{V_N} \rho_N G_2 dV_N \quad (2.3)$$

where G_1 and G_2 are the kernels of the type $\mathbf{r} \cdot \mathbf{n}/r^3$.

Here it important to stress the main features of IEM when solving the non-linear magnetostatic problem. In spite of the fact that it is necessary to mesh the volume of the non-linear magnetic parts, the number of unknowns for the non-linear problem is same as the number of unknowns for the linear one. This is due to the fact that the non-linear contribution (second term on the right-hand side of (2.3) appears just as the correction term and is calculated throughout the iteration procedure from the previous iteration. More detailed description will be given in the full paper.

B. Inductance calculation

The inductance calculation is based on the calculation of the flux density. For example, the self-inductance of the reactor coil can be calculated as:

$$L = \frac{1}{I_R} \int_{S_c} \mathbf{B} ds \quad (2.4)$$

where \mathbf{B} is a vector of magnetic flux density through the cross-section plane S_c positioned within the reactor coil.

IV. EXAMPLE

The above model of the reactor shown in Fig. 2 is used for the simulation.

Fig. 3: Flux distribution through the central limb; model a) with air-gaps. The flux through the control discs is at the saturation level and is circulating orthogonally to the direction of the AC flux.

The simulation is performed using BEM-based software package POLOPT for single- and multi-physics problems analysis. Fig. 3 shows the flux distribution through the central limb build of sequences of controlled and uncontrolled discs.

A. The magnetizing behavior of control disc

The AC side magnetizing curves under different DC magnetizing strength is obtained by POLOPT, as shown in Fig. 4, in which the red curves are calculation results by using Equation(1.1), and the blue markers are simulation results obtained by using POLOPT. The results imply that the ideal model can provide enough accuracy for engineering application.

Fig. 4 AC magnetic curves under different DC magnetic fields

B. The inductance of the controllable reactor

Fig. 5 shows the simulation results of the inductance of the controllable reactor, which is compared with calculation results.

Fig. 5 The inductance of controllable reactor: calculation and simulation results

More detailed analysis such as of inductance vs. different airgaps and the impact of the distribution of DC winding on the inductance value will be presented in the full paper.

Abstract — Inter-laboratory comparisons of Specific Absorption Rate (SAR) calculations sometimes show discrepancies between the results even for the case of simplified phone models. A possible cause could be an incorrect positioning of the device against the head. Two commercially available mobile phones with different antenna configurations are selected to evaluate the error induced by incorrect positioning. The SAM (Specific Anthropomorphic Mannequin) head phantom for which the positioning of the device is clearly defined by the standards is employed for the numerical simulations. Results show that deviations with respect to the reference positions may induce a few percent differences in the maximum 10°g averaged SAR values.

I. INTRODUCTION

The SAR (Specific Absorption Rate) conformity assessment of mobile phones is currently based on standardized measurement procedures such as IEEE1528 [1] and IEC62209-1 [2]. The SAM (Specific Anthropomorphic Mannequin) head-phantom filled with tissue equivalent liquid is employed for the SAR measurements of four intended use positions of the mobile phone: left/cheek, left/tilt, right/cheek and right/tilt. A rigorous measurement procedure is enforced – liquid verification, system validation, accurate positioning of the device, etc. – to ensure that the maximum averaged 10 g SAR value fits within less than 30 % uncertainty. The overall SAR compliance test of a mobile phone is time-consuming and costly. For instance, the compliance test of a dual-band mobile phone requires a full day using standard dosimetric test facilities.

Until recently, numerical dosimetry was approached to investigate power absorption in realistic head models using rather simplified phone models such as a quarter-wavelength monopole antenna mounted over a metallic box or a PIFA (Planar Inverted-F Antenna) over a PCB (Printed Circuit Board). The availability of fast computers at low cost and user-friendly electromagnetic software has paved the way for numerical simulations using more realistic phone models which account for the different components present in commercially available mobile phones: battery, camera, casing, display, support, etc. Obviously, the presence of such components – especially those having metallic elements – has a non-negligible impact on the SAR result. For example, the metallic frame usually present around the LCD (liquid crystal display) may modify the SAR distribution in the phantom.

Although the actual CAD (Computer-Aided Design) of the mobile phone may be sometimes available, the electromagnetic simulation is not straightforward. Indeed, such CAD models are initially developed for mechanical engineering purposes and most electromagnetic solvers cannot easily handle the complexity of the models. Furthermore, the presence of tiny elements or curvatures produces relatively high mesh densities which slow down the computational times. In fact, when using the Finite Difference Time Domain (FDTD) technique – which is nowadays commonly employed for SAR calculations – the mesh density of the mobile phone actually dictates the overall mesh with the SAM phantom i.e. the cell size may become much smaller than the typical recommended value of a tenth of the wavelength in the tissue equivalent liquid. To overcome this problem, it may sometimes be desirable to numerically reconstruct the phone model. By taking into account the relative electromagnetic importance of the different components of the mobile phone, simplifications of the model can be achieved. This methodology was applied to reconstruct the numerical model of a commercially available PIFA-based mobile phone which was validated using experimental data [3].

Even when the numerical simulations are feasible, the evaluation of the uncertainty associated to a given SAR calculation remains a critical issue. Usually the suitability of the mesh density employed for the numerical modeling is tested through a convergence analysis of the results. The initial high mesh density may then be relaxed to provide fast run times for efficient SAR calculations with the SAM phantom. A recent international comparison on SAR calculations found that one of the possible causes of discrepancy observed between the different participating laboratories could be due to the incorrect positioning of the handset with respect to the phantom [4]. When performing SAR calculations using inhomogeneous head models, the positioning error is expected to be amplified because of (i) the presence of irregularities along the surface of the head model and (ii) undefined standard reference points which help position the handset. To evaluate the uncertainty due to the positioning of the handset with respect to the head, two commercially available mobile phones are herein selected for SAR calculations. The SAM phantom for which the positioning of the handset is clearly defined by the standards is chosen for the numerical simulations.

II. NUMERICAL MODELING

Electromagnetic solvers based on time domain methods such as FDTD are usually employed for SAR calculations. Herein a commercial package of the TLM (Transmission Line Matrix) method is adopted [5]. The numerical models of the two reconstructed commercial mobile phones placed against the SAM phantom for the left/cheek position are shown in Figure 1 and 2, respectively. The first numerical phone model is a PIFA-based commercial mobile phone. A previous numerical study of this mobile phone showed that the results – return loss, total radiated power and SAR – obtained with the reconstructed model agree well with measurements [4]. The return loss data showed that some specific components of the mobile phone – for example, the speaker – can induce undesired resonances which cannot be easily accounted for by the numerical modeling. The total radiated power data showed that the losses of the mobile phone were consistent with the dielectric properties employed for the different components. The maximum averaged 10 g SAR values at 900 MHz and 1725 MHz were within the 30 % uncertainty level of the dosimetric test facility.

Fig. 1. PIFA-based commercial mobile phone (casing not shown) positioned against the SAM phantom.

The second model is another commercially available mobile phone with an external helicoidal antenna. For both numerical models, the PCB is modeled as a thin conducting plate i.e. the dielectric substrate and electronic circuits are not considered. The dielectric casing of the mobile phones (not shown in the figures) is drawn to have planar faces which enable a more accurate positioning of the device against the phantom (the actual casing of the devices are non-planar).

Fig. 2. Commercial mobile phone with external helicoidal antenna (casing not shown) positioned against the SAM phantom.

Both mobile phones are dual-bands and they can be operated at 900 MHz and 1725 MHz. The dielectric properties of the tissue equivalent liquid used at these two frequencies are provided in Table I. A first set of numerical simulations are performed for the four intended use positions which constitute the reference positions. Further simulations are undertaken for small deviations of the position of the mobile phones with respect to these four reference positions. For comparable results, the same mesh is applied for all the numerical simulations with a given mobile phone model.

TABLE I
DIELECTRIC PROPERTIES OF THE TISSUE EQUIVALENT LIQUID

Frequency [MHz]	Relative permittivity	Conductivity [S/m]
900	41.5	0.97
1725	40.0	1.40

III. RESULTS

Results show that for deviations of the position of the two mobile phones such that the distance between the antenna element and the tissue equivalent liquid is practically the same (e.g. 1 degree rotations in a plane parallel to the sagittal plane), the error in the SAR value is about 1 %. For other deviations of the position (e.g. 1 degree rotations perpendicular to the sagittal plane), the error in the SAR value is about 5 % for the PIFA-based mobile phone and 8 % for the mobile phone with the helicoidal antenna.

Abstract—In this paper equivalent circuits of inductive coupled radio frequency identification (RFID) antenna systems are extracted by means of the partial element equivalent circuit (PEEC) method. Each antenna impedance is analyzed separately regarding frequency dependent behavior including skin- and proximity effects as well as parasitic capacitances. In contrast to that, the inductive coupling between any two coils is computed for an arbitrary 3D spatial arrangement by a filamentary mutual inductance computation technique, allowing for fast spatial sweeps. Both models are combined to a single equivalent circuit that maintains the topology of mutually coupled inductances. The described approach is tested with a conventional reader transponder arrangement and compared with the full PEEC models.

I. INTRODUCTION

Inductive coupled RFID systems which are typically operating at the center frequency of 13.56 MHz are well described by equivalent circuits based on the transformer concept because of the dominance of inductive near field coupling [1]. In order to quantify the port impedances of the coil system for varying spatial arrangements different approaches can be applied. The most obvious but not necessarily most efficient approach would be to repeatedly simulate the complete system for each variation of the geometric parameters with a 3D full wave solver. A more flexible approach is to separate the calculation of the mutual antenna coupling from the location independent self impedances of the antennas. The combination of the separated models is recovered in the circuit representation. Therefore, it is necessary to ensure an equivalent circuit topology that inhibits the mutually coupled inductances as shown in Fig. 1.

A numerical method that is well suited for this task is the PEEC method [2]. The conducting regions are discretized leading to an equivalent RLC network representation with partial resistive, inductive and capacitive elements. These circuit elements are connected according to the Kirchhoff's laws and can then be analyzed via circuit solvers like SPICE.

II. PEEC MODELS

In order to compute the self impedances of spiral printed coils including skin- and proximity effects with the standard PEEC method, the conductor's volumes have to be subdivided in cross section. A common starting point is to choose the width of the outermost volume cell to be less or equal to the skin depth at the highest frequency of interest. Increasing the width of the volume cells towards the interior of the conductors reduces the discretization effort and reflects the decaying current distribution. The conductors of the tag antenna of the

Fig. 1. Equivalent circuit representation of two inductive coupled antennas.

model setup in Fig. 2 are subdivided into 9 segments in width and 3 segments in thickness leading to 756 unknown currents (Reader antenna: 132 unknown currents).

The consideration of capacitive effects requires an additional discretization of the conducting surfaces because the free charges are limited to the surfaces. It is sufficient to represent the thin conductors by a 2D approach [3]. Hereby, the simulation time is reduced and dielectrics can be easily included by adapting the Green's function [4]. For the model setup, the surface is discretized with 9 panels in width for the tag (11 for the reader) resulting in 504 (88) unknown surface charges. Using a mesh based circuit formulation [5] the port impedances can be calculated as presented for the tag antenna in Fig. 3.

For the calculation of the mutual coupling between multiple coils, the discretization level is reduced to a minimum taking only inductive effects into account. In detail, each straight conductor is modeled by a single filament (abbr. Fils) leading to $4N$ (N = number of turns) unknowns for each antenna. The mutual inductance can then be expressed as [1]

$$M = \sum_{\text{Fils coil } i} \sum_{\text{Fils coil } j} L_{ij}. \quad (1)$$

The partial inductances L_{ij} are computed analytically [6].

Fig. 2. Illustration of the test setup. A square reader antenna (substrate not visualized) is coupled to a multi turn tag antenna.

TABLE I
PARAMETERS OF FIG. 1 AND (2) FOR THE TEST SETUP IN FIG. 2.

	Reader	Tag
R	$R_{DC}=194 \text{ m}\Omega$ $f_R=939 \text{ kHz}$, $A_R=0.233$	$R_{DC}=1.64 \Omega$ $f_R=750 \text{ kHz}$, $A_R=0.185$
L	$L_{ext}=406 \text{ nH}$, $L_{int}=10.8 \text{ nH}$, $f_L=617 \text{ kHz}$, $A_L=-0.56$	$L_{ext}=5.38 \mu\text{H}$, $L_{int}=74.4 \text{ nH}$, $f_L=918 \text{ kHz}$, $A_L=-0.677$
C	$C_1=0.78 \text{ pF}$	$C_2=1.55 \text{ pF}$
R_p	$R_{p1} \rightarrow \infty$	$R_{p2} \rightarrow \infty$

III. EQUIVALENT CIRCUIT MODELS

The circuit element parameters of Fig. 1 are obtained by analyzing the frequency behavior of the coil impedances. While curve fitting techniques like vector fitting [7] are available without any a priori knowledge of the structures, a more physical approach for determining the equivalent network of spiral inductors is achieved by the following strategy: First, the partial matrix elements are calculated once. The parasitic capacitance is extracted by solving the system with and without capacitive effects at the frequency of interest. The difference in admittance reveals the capacitance C and eventually a parallel resistance R_p that is typically in the range of several $M\Omega$. The frequency dependent inductance and resistance are obtained by magnetic quasistatic evaluation without the capacitive cells. From the DC limit, the resistance R_{DC} and the total inductance $L_{ext} + L_{int}$ are obtained, the frequency dependent behavior is extracted by a curve fitting technique requiring the evaluation of a few frequency points only. Here, the frequency behavior of the resistance and inductance is chosen as follows

$$R(f) = R_{DC} \sqrt{1 + \frac{f^2}{f_R^2}}^{A_R}, \quad L(f) = L_{ext} + L_{int} \sqrt{1 + \frac{f^2}{f_L^2}}^{A_L}, \quad (2)$$

which allows to approximate the curves with a few design parameters (f_R , f_L , A_R , A_L , L_{int}). More details about the fitting technique will be presented in the final version of this paper. The computed parameters for the arrangement of Fig. 2 are given in Table I, the impedance curve for the tag antenna is shown in Fig. 3.

In the following, the mutual coupling is computed for both antennas for a varying spatial separation from 0 to 10 cm as presented in Fig. 2. For this setup the mutual port coupling is

Fig. 3. Tag antenna impedance. The error of the equivalent circuit with the parameters of Table I is well below 1% for the frequencies smaller than the resonance.

Fig. 4. Simulation results and error of the mutual impedance computed by the full PEEC model and the reduced circuit at 13.56 MHz. The error is again below 1% for all presented separations.

calculated in two different ways: The full PEEC models with a total unknowns of 1480 and the reduced circuit model with 6 fixed self impedance elements and 32 varying filaments for calculating the mutual inductance. Both techniques are best compared when visualizing the transmission behavior by the imaginary part of the mutual impedance Z_{21} which is shown in Fig. 4.

Design and Implementation of a High Frequency Flyback Converter Using New-developed Polymer-bonded Magnetic Cores

K. DING, K. W. E. CHENG, *Senior Member, IEEE*

Abstract—A novel polymer-bonded magnetic materials has been developed. The new magnetic material is composed of polymer matrices and special magnetic powder. By using the new materials, light weight, low cost and non-brittle magnetic cores of flexible shapes and different sizes can be made. To fully investigate the magnetic performance of the EI transformer, finite element analysis (FEA) has been applied. Based on the new-developed magnetic cores, 100Watt flyback power converter has been developed. The design guideline of how to use the new materials for power conversion has been given. PCB prototype and experimental results are provided to validate the feasibility of the application of the proposed novel materials for power conversion.

Index Terms—Polymer-bonded, Power conversion, finite element analysis, Flyback, Magnetic core.

I. INTRODUCTION

THE technology and engineering domains constantly set demanding requirements of magnetic materials. Materials such as Ferrites and Molybdenum Permalloy Powder (MPP) are famous for their low loss characteristics and high frequency operation, leading to wide applications in various fields. In particular, they are very popular for power conversion. One of the applications is the power converter which uses magnetic materials to construct inductors and transformers. The design of the magnetic device also depends on the permeability, loss factor and size and shape of the materials. Recently, polymer bonded magnetic materials have attracted a great deal of attention in the fields of magneto-electrics and magneto-optics. These materials are composed of polymer matrices and magnetic powders, which may be produced using traditional polymer processing methods[1-7]. Polymer bonded magnetic materials offer significant advantages over conventional materials[8, 9]. For example, polymer bonded magnetic materials can be molded more easily, lowering the cost of manufacturing and of quality control. Nonetheless, the polymer-bonded magnetic materials have not typically been applicable in power conversion. The outstanding work needed in the optimization and the permeability study has prevented developing the materials into a product.

K. DING, K.W.E.CHENG are with the Department of Electrical Engineering, Hong Kong Polytechnic University, Hong Kong, China (852-27666162 e-mail:eeecheng@polyu.edu.hk).

II. POLYMER-BONDED MAGNETIC MATERIALS FOR POWER CONVERSION

A. Development of Polymer-bonded Magnetic Material

A new polymer-bonded magnetic material has been developed in Hong Kong Polytechnic University. The new-developed material is produced by compounding from 10 weight percent of polyethylene resins (PE), 90% weight percent of a magnetic powder taken from NiZn Ferrite, and 15 weight percent (against magnetic powder) of Titanium (IV) Isopropoxide (C₁₂H₂₈O₄Ti) as a coupling agent. The developed materials and EI40 cores are shown in Figure 1

B-H Loop was measured by using EI40 shape cores. The Measured B-H loop of the material is shown in Figure 2.

B. Finite Element Analysis

To fully investigate the magnetic performance of the EI transformer, finite element analysis (FEA) has been applied. The purpose of FEA is to explore the magnetic flux distribution along the polymer and flux leakage can be calculated according to flux value from each finite element. Three dimensional model has been constructed to fully explore the magnetic characteristics. With current excitation of 1A from the primary coil, flux has been built up along the magnetic path as shown in Figure 3.

Figure 3: 3D flux distribution

A “3D cut” vertical to the arms of the transformer is performed along the finite element model. As can be seen from Figure 4 (a), most flux distributes along the E and I core respectively since the air region has a relatively large reluctance. For a precise numerical analysis, the flux from each element along the horizontal edge of one arm is selected according to its relative position to verify a negligible leakage flux. It can be seen from Figure 4 (b) that flux dominates along the polymer and diminishes rapidly along the air region. Similarly the flux plot along the vertical edge of one arm can be found in Figure 4 (c)

III. DESIGN AND IMPLEMENTATION OF A 100W FLYBACK CONVERTER

A. Flyback Converter

The flyback converter is one of the simplest topology isolated converter. Its basic circuit is shown in Figure 5. It only consists of coupled inductors, a transistor T, a rectifier diode D and filter capacitor C. The primary and secondary sides are isolated by a coupled inductor (some time is referred as a transformer). When transistor T is conducting, V_{in} is developed across the primary winding causing a linear increase in current as energy is stored in the coupled inductor increases[10].

Figure 5: Flyback converter

Table 1: Electrical specification of the polymer-bonded flyback converter

Description	Symbol	Min	Typ	Max	Units
Input					
Voltage	V_{in}	85	110	130	VAC
Frequency	f_{line}	47	50/60	64	Hz
Output					
Output Voltage	V_{out}		30		V
Output Ripple Voltage	V_{ripple}			200	mV
Output Current	I_{out}	0.1		3	A
Output Power	P_{out}			100	W
Switching Frequency	f_s		400		kHz
Efficiency	η		70		%
Ambient Temperature	T_{AMB}	0		85	$^{\circ}C$

Table 2: Effective Core parameters of an EI 40core

Symbol	Parameter	Value	Unit
V_e	effective volume	11100	mm^3
l_e	effective length	77.5	mm
A_e	effective area	143	mm^2

B. Design Guideline of 100Watt Flyback Converter by Using New-developed Magnetic cores

Table 1 shows the electrical specification of the 100Watt Flyback converter. EI40 core is selected for the development of the power converter, the parameter of the EI40 core is shown in Table 2. The maximum switching on time for the primary power transistor T will occur at minimum input voltage (85VAC) and maximum load (100Watt). For this development, it will be assumed that the maximum switching on time is 45% (Duty Ratio, D) of a total period of operation. The switching frequency is selected to be 400 kHz. So the period of the switching cycle is

$$T_s = \frac{1}{f_s} = \frac{1}{400 * 10^6} = 2.5 * 10^{-6} \quad (1)$$

The switching “on” time is:

$$t_{on} = DT_s = 1.125 * 10^{-6} \quad (2)$$

The absolute calculation of this voltage in practical application is difficult[11], as it depends on a number of factors which are not well defined. For this application, a fair approximation of the working value of V_s at full load will be given by using a factor of 1.3 times the RMS input voltage. So, at a line input of 85V RMS, the DC voltage V_s will be approximately

$$V_s = 85 * 1.3 = 110.5V \quad (3)$$

The effective area of the center leg of EI40 is $143mm^2$. The saturation flux density is 36mT shown in Figure 2(b), with operating frequency of 400 kHz, the maximum peak-to-peak ac

Figure 6: Transformer specification of the polymer flyback converter

(a) AC input: 85VAC, Upper: VDRain, 100V/div, 1us/div; Lower: IDrain, 1A/div, Operating Frequency 400 kHz, Power at 100W
(b) PCB prototype
Figure 7: Measured waveforms and PCB prototype of Polymer-bonded flyback converter

flux density B_{ac} is chosen at 26mT to provide a good working margin.

$$\Delta B_{ac} = 26mT \quad (4)$$

The primary turns can be calculated by:

$$N_p = \frac{V_s t_{on}}{\Delta B_{ac} * A_e} = 33.43 \quad (5)$$

The required output voltage for the main controlled line is 30V. Allowing for a voltage drop of 0.7V in the rectifier diode and 0.6V in interconnecting tracks and the transformer secondary, The voltage at the secondary of the transformer should be, say, 31.3V. Hence, the secondary turns would be

$$N_s = \frac{V_{out} N_p}{V_s} = \frac{(30+0.7+0.6) * 33}{110} = 9.39 \quad (6)$$

In this application, the turns of primary side is 33 and the secondary turns is 10. The transformer specification is shown in Figure 6. The measured experimental waveform and the PCB prototype are shown in Figure 7.

IV. CONCLUSION

Polymer-bonded magnetic materials are composed of polymer processing methods. Hence, it offers significant advantages over the conventional Ferrite. It is bonded with polymer and hence, there is an evenly distributed air-gap that is what we needed for high frequency power electronics. To fully investigate the magnetic performance of the EI transformer, finite element analysis (FEA) is applied. The purpose of FEA is to explore the magnetic flux distribution along the polymer and flux leakage can be calculated according to flux value from each finite element. Three dimensional model is constructed to fully explore the magnetic characteristics. With current excitation of 1 A from the primary coil, flux is built up along the magnetic path. By using the new-developed materials based magnetic core, a real application of 100Watt Flyback converter has been fully implemented. The design guideline of the

development for the flyback converter using the proposed materials has been illustrated. Experimental results show that the polymer-bonded magnetic cores can substitute the traditional ferrite in the applications for power conversion.

Abstract — The terminal current in voltage driven systems is an essential role for characterizing the pattern of electric discharge such as corona, breakdown, etc. Until now, to evaluate this terminal current, the Sato's equation has been widely used in the areas of high voltage and plasma discharge. Basically this Sato's equation was derived by using the energy balance equation and its final form described some physical meanings explicitly. To give more general abilities in Sato's equation, we, here, present a generalized approach by directly using the Poynting's theorem incorporating the Finite Element Method (FEM). When the magnetic field effect or the time-dependent voltage source should be considered, this generalized energy method can be easily applicable to those problems with any dielectric media such as gas, fluid, and solid. As an alternative approach, the integral Ohm's law resulting in small numerical distortions has an ability to be applied to multi-port systems. To test the generalized energy method and the integral Ohm's law, the results from two proposed methods were compared to those from the Sato's approach and an analytic solution.

I. INTRODUCTION

Calculation of the current flowing between any two electrodes during discharge simulation is important because the terminal current is often one of the only parameters that can be measured during actual breakdown testing. In high voltage discharge and plasma analysis, the Sato's equation has been widely used for calculating a terminal current [1]. The original Sato's equation was derived with an assumption that the applied voltage is constant in a gap. For many applications, however, it is necessary to calculate the terminal current considering time-varying applied voltages such as lightning impulse, rf, or pulsed input sources. To overcome this weakness, the original equation was expanded into a new version with including a time-dependent applied voltage [2]. This final form can be successfully applied to most of discharge problems. As in the arc simulation, however, when the magnetic field effect is significant, the calculating method for terminal current should be modified and generalized.

With the energy balance equation, here, we present a generalized method to calculate a terminal current by directly adopting the Poynting's theorem incorporating the Finite Element Method (FEM) which has been successfully applied to discharge analysis. In this approach, the global quantities such as energy and Ohmic dissipation were directly employed in the expression of Poynting's theorem with terminal quantities, current and voltage. This generalized energy method naturally covers the time-varying voltage sources,

magnetic field effect, and any dielectric media. In addition to this, the FEM gives more accurate global quantities such as energy and total power dissipation because the procedure of FEM follows the global energy minimization condition. This generalized energy method, therefore, is harmony well with the FEM.

As an alternative method, we also tested the integral Ohm's law, which can be applied to multi-port systems. The Sato's equation and the generalized energy method, however, can be applied to only a two-terminal electromagnetic system because it is difficult to separate the energy contributions for each port. Even though the integral Ohm's law has an ability to calculate a terminal current at each port, the result has some numerical distortions when we took a conductor surface as an integrating surface. To test two proposed methods, the results were compared to those from the Sato's equation and an analytic solution [3].

II. GOVERNING EQUATIONS AND FINAL SATO'S EQUATION

The general expression of governing equations for space charge propagation can be analyzed by using the hydrodynamic diffusion-drift model for the electron (N_e), positive ions (N_p), and negative ions (N_n) as [2]

$$\frac{\partial N_e}{\partial t} + \nabla \cdot (N_e \mathbf{V}_e - D_e \nabla N_e) = S + N_e \alpha |\mathbf{V}_e| - N_e \eta |\mathbf{V}_e| - N_e N_p \beta_{ep} \quad (1)$$

$$\frac{\partial N_p}{\partial t} + \nabla \cdot (N_p \mathbf{V}_p - D_p \nabla N_p) = S + N_e \alpha |\mathbf{V}_e| - N_e N_p \beta_1 - N_n N_p \beta_2 \quad (2)$$

$$\frac{\partial N_n}{\partial t} + \nabla \cdot (N_n \mathbf{V}_n - D_n \nabla N_n) = N_e \eta |\mathbf{V}_e| - N_n N_p \beta_2 \quad (3)$$

where t denotes the time, \mathbf{V}_e , \mathbf{V}_p , and \mathbf{V}_n the electron, positive and negative ion drift velocities, D_e , D_p , and D_n the electron, positive and negative ion diffusion coefficients, and α , η , and β the ionization, attachment, and recombination coefficients, respectively. S denotes the source term due to photoionization, and here its effect was neglected. To take the electric field effect, those continuity equations should be solved with the Poisson's equation simultaneously as

$$\nabla \cdot (-\epsilon \nabla V) = e(N_p - N_e - N_n) \quad (4)$$

where ϵ is the dielectric permittivity, e the electron charge, and V the electric scalar potential.

The expanded Sato's equation considering three carriers and a time-dependent applied voltage was expressed as [2]

$$I = \frac{1}{V_a} \int_{\Omega} \mathbf{J}_c \cdot \mathbf{E}_L dv + \frac{\varepsilon_0}{V_a} \int_{\Omega} \frac{\partial \mathbf{E}_L}{\partial t} \cdot \mathbf{E}_L dv \quad (5)$$

with

$$\mathbf{J}_c = e(N_p \mathbf{V}_p - N_e \mathbf{V}_e - N_n \mathbf{V}_n - D_p \nabla N_p + D_e \nabla N_e + D_n \nabla N_n)$$

where I is the external circuit current, V_a the applied voltage, \mathbf{J}_c the conduction current, \mathbf{E}_L the solution of Laplace's equation, ε_0 the dielectric permittivity in air, and $\int_{\Omega} dv$ a volume integral over the discharge space.

III. INTEGRAL OHM'S LAW AND GENERALIZED ENERGY METHOD FOR CALCULATING A DISCHARGE CURRENT

In general the terminal current is due to conduction current in a dielectric medium as well as displacement current due to the time rate of change of the surface charge on the electrodes as

$$I = \int_S \left(\mathbf{J}_c + \varepsilon \frac{\partial \mathbf{E}}{\partial t} \right) \cdot d\mathbf{a} \quad (6)$$

where \mathbf{E} is the total electric field intensity due to the applied voltage and space charge distributions, and (6) is known as the integral's Ohm's law.

By considering any general field within a volume, one realizes that the energy contained by that field must be distributed throughout space with a local energy density W at every point in the volume. Similarly, power dissipation can occur at every point within the volume at a rate P_d . The power flows with a density \mathbf{S} , the Poynting vector, so that the power crossing a surface S_a is given by $\int_{S_a} \mathbf{S} \cdot d\mathbf{a}$. With these field generalizations and quasi-static approximations, the power flowing into a volume Ω , enclosed by the surface S_a , can be expressed as

$$\sum_{i=1}^n V_i I_i = \frac{d}{dt} \int_{\Omega} W dv + \int_{\Omega} P_d dv \quad (7)$$

with $W = (1/2)\varepsilon \mathbf{E} \cdot \mathbf{E} + (1/2)\mu \mathbf{H} \cdot \mathbf{H}$ and $P_d = \mathbf{E} \cdot \mathbf{J}_c$

where V_i is an applied voltage at a terminal, I_i the corresponding current at that terminal, μ the magnetic permeability, and \mathbf{H} the magnetic field intensity.

It is important point out that it is only possible to use (5) and (7) to establish the current flowing into a volume when $n=1$, i.e., when the volume only has two terminals. On the contrary, the integral Ohm's law can be applied to a multi-port system when $n>1$.

IV. TERMINAL CURRENT IN PARALLEL PLANE ELECTRODES

To verify our numerical setup and compare with each other, first, we simplified our governing equations to one carrier

system in plane-plane 2-D XY geometry as shown in Fig. 1. The governing equations are the Poisson's equation and the charge conservation equations as

$$\frac{\partial N}{\partial t} + \nabla \cdot (N\mathbf{V}) = 0 \quad (8)$$

$$\nabla \cdot (-\varepsilon \nabla V) = eN \quad (9)$$

As we can see the Fig. 2, the energy approaches, the Sato's equation and generalized energy method, produced almost the same results as analytic solutions [3]. Even though the integral Ohm's law has an ability of measuring the terminal current on each electrode, it contained some numerical distortions where the value of space charge was high. In extended paper, tip-plane electrodes with the field emission condition, Fowler-Nordheim charge injection condition, will be presented and discussed in detail.

Fig. 1. The lower electrode at $x=0$ is a source of injected positive charge with mobility μ in the medium of permittivity ε . Here, ρ denotes charge density and A the linear injection coefficient.

Fig. 2. Terminal current profiles from the various methods. The analytic solution was evaluated by Zahn's approach in [3]. Here, the direct approach represents the integral Ohm's law.

Abstract—The paper offers a comparative study of numerical methods of analysis of electromagnetic fields. The focus is on the Finite Element Method (FEM) and Finite Integration Technique (FIT), but with the cell and equivalent network approaches also considered. It is shown how the approximate integrals describing coefficients of the FEM need to be derived for a mesh with parallelepiped elements to achieve consistency with FIT equations. The equivalence of FEM and FIT formulations for a triangular mesh in 2D is highlighted. The TEAM Workshops Problem No. 7 is used as an example for numerical comparisons. Edge values of magnetic vector potential A and nodal values of electric scalar potential V are used throughout.

I. INTRODUCTION

The finite element method (FEM) has established itself as the prime numerical technique for electromagnetic field computations, but some researchers prefer and promote the use of the finite integration technique (FIT) [1], the cell method (CM) [2] or the equivalent electric and magnetic networks (ENM) [3]. The similarities between CM, FIT and FEM were observed in [4, 5] and explored thoroughly in [6]. The main differences between the different approaches are related to the way in which space is discretised and equation coefficients set up, in particular the so-called ‘mass matrices’ of the FEM theory. [4]. The CM, FIT and ENM formulations rely on a discretisation which is equivalent to hexahedral FEM elements of 8 nodes and 12 edges (or curved rectangular parallelepipeds under cylindrical symmetry). The FEM mass matrices are non-diagonal, unlike the ones arising in CM, FIT and ENM. The purpose of this paper is to extend and enhance the previous comparative analysis of the methods. It is demonstrated that the CM, FIT and ENM equations may be considered a special case of the FEM formulation. The derived approximate integration formulae yield the equations equivalent (identical).

II. EQUATIONS OF FEM AND FIT

Both nodal elements using scalar potentials Ω , V and edge elements in terms of vector potentials A , T are considered. The FEM equations for scalar potentials correspond to the nodal equations of the edge network with branches coinciding with element edges (Fig. 1a) [6]. The permeances, conductances and capacitances forming the mass matrix may be found from

$$\Lambda_{i,j}^{(p,q)} = \int_{V_e} \mathbf{w}_{ei,j} \mu \mathbf{w}_{ep,q} dv, G_{i,j}^{(p,q)} + pC_{i,j}^{(p,q)} = \int_{V_e} \mathbf{w}_{ei,j} (\sigma + p\epsilon) \mathbf{w}_{ep,q} dv, \quad (1a,b)$$

where $\mathbf{w}_{ei,j}$, $\mathbf{w}_{ep,q}$ are interpolation functions of an edge element for the edges $P_i P_j$ and $P_p P_q$ respectively, $p=d/dt$, and V_e is the volume of the element. The FEM equations for vector potentials, on the other hand, represent loop equations of the

facet network, the branches of which cross the element facets. A portion of a network of a parallelepiped element is shown in Fig. 1b. The reluctances and impedances of the element model relate to the mass matrix elements and are described by

$$R_{\mu i,q} = \int_{V_e} \mathbf{w}_{fi} \mu^{-1} \mathbf{w}_{fq} dv, Z_{i,q} = \int_{V_e} \mathbf{w}_{fi} (\sigma + p\epsilon)^{-1} \mathbf{w}_{fq} dv, \quad (2a,b)$$

where \mathbf{w}_{fi} , \mathbf{w}_{fq} are interpolation functions of a facet element for the facets S_i , S_q [6].

The FEM mass matrices are non-diagonal; consequently so are the matrices of the equivalent network models. In the models of Fig. 1, the branches which are not perpendicular to each other will have a mutual coupling. Such couplings will also occur within the triangular 2D elements of Fig. 2. A model with mutual reluctances may be established using a facet model of a five sided prism [7].

Equations arising from the CM, FIT and ENM formulations may appear to be similar to those obtained from the FEM, but there is an important difference that they do not contain mutual couplings and thus the mass matrices are diagonal, for example

$$R_{\mu 5,5} = R_{\mu 6,6} = h_z / (2\mu h_x h_y), \Lambda_{i,i+4}^{(i,i+4)} = \mu h_x h_y / (4h_z) \quad (i=1,2,3,4), \quad (3a,b)$$

where h_y , h_x , h_z are dimensions as in Fig. 1b. In the reluctance model of a triangle $R_{\mu i,i} = h_i / (\mu s_i)$, with h_i and s_i shown in Fig. 2.

Fig. 1. Edge (a) and facet (b) model of element

Fig. 2 Reluctance (facet) model of triangle

III. DERIVING FEM EQUIVALENT TO FIT

From circuit theory it is well known that a three branch star with mutual couplings may be converted into an equivalent one without any couplings, as demonstrated by Fig. 2. This may be achieved by exploiting the condition $\sum \phi_i = 0$. It is therefore possible to start with different mass matrices for FEM and FIT and yet achieve identical matrix coefficients for both formulations. The above transposition, regrettably, does not apply to 3D systems. Notwithstanding, it is still possible to derive a FEM formulation which is equivalent to FIT by calculating the integrals (1) and (2) – required for setting up the mass matrix – using a simplified formula

$$\int_{V_e} f dv = V_e / 8 \sum_{i=1}^8 f(P_i), \quad (4)$$

which results in models free of mutual couplings, thus with coefficients the same as if obtained from FIT. Unfortunately, the procedure described by (4) is only successful – in terms of making the matrix diagonal – in the case of parallelepiped elements (it also works for curved rectangular parallelepipeds). The mass matrices of tetrahedral and five sided prism elements may be made diagonal only if complemented by additional assumptions regarding fluxes or currents; for example by imposing (or assuming) one of the facet flux or current densities in a tetrahedra to be negligibly small.

IV. EXAMPLE

The TEAM Workshops Problem No. 7 (Fig. 3) has been selected to illustrate the theoretical investigations [8]. The magnetic field and eddy current distributions have been calculated for a conducting plate with a hole, with the excitation provided by a multi-turn coil. An A - V formulation has been adopted with edge elements for the vector potential A and nodal elements for the scalar potential V . The bounded space has been subdivided into about 150 thousand elements, some 16 thousand of which were placed in the conducting region. The resultant system of equations corresponds to a reluctance-conductance network consisting of about half a million loop equations related to the magnetic network and 20 thousand nodal equations of the electric network. The relevant parameters for the FEM model were derived using (1) and (2), thus creating mutual conductances and reluctances. A block relaxation method, combined with incomplete Cholesky decomposition, has been used to solve the final system of equations. Table I shows example values of the flux and current densities at selected points P_1 and P_2 as marked in Fig. 3.

Fig. 3 TEAM Workshops Problem No.7

TABLE I
COMPARISON BETWEEN FIT AND FEM RESULTS

Method Quantity	FIT	FEM
Flux density in point P_1		
B_x [T]	-0.010689	-0.010747
B_y [T]	0.003581	0.003583
B_z [T]	0.008145	0.008165
Current density in point P_2		
J_x [A/m ²]	83275.85	83196.15
J_y [A/m ²]	1713894.52	1710454.18
J_z [A/m ²]	-39703.18	-39469.81

The values are given for an instant of time when the coil current was at its maximum (a 50Hz supply has been assumed).

For all points considered, the differences between the FIT and FEM results do not exceed 0.6% for flux density and 0.7% for current density, respectively. It appears therefore reasonable to conclude that the proposed approximation (4) – which leads to equations equivalent to the FIT method with a diagonal mass matrix – is perfectly acceptable without noticeable loss of accuracy. Moreover, the diagonal matrix is easy to invert, thus seeking edge values of A , representing loop fluxes in the model of Fig. 1b, may be conveniently replaced by an easier task of finding nodal potentials associated with element centres (nodes Q_i). In the case of diffusion problems the additional advantage of making the mass matrix diagonal is a possibility of applying explicit numerical schemes [4].

Abstract—A fast algorithm for transient analysis of grounding grids or above ground conductors is presented. The algorithm is based on the modified image theory and the Fast Multipole Method (FMM). Validation of the algorithm is achieved by comparison with other algorithm. The results show the flexibility, efficiency and accuracy of this algorithm.

I. INTRODUCTION

It is important to study the transient performance of grounding systems of substation for lightning surges in order to ensure the safety of personnel and prevent damage of installations. Three different analytical approaches have been used, which are based on circuit theory [1], transmission line theory [2] and electromagnetic field theory [3], respectively. Though the last approach is rigorist in theory, the presence of the lossy ground implies the computation of the slowly converging Sommerfeld integrals. The FMM [4] reduces the computational complexity from $O(N^2)$ to $O(N^{1.5})$, but it can't be used to evaluate electromagnetic fields if the Sommerfeld integrals are evaluated directly. The developed algorithm used the modified images to establish the EFIE and FMM to solve it. The remarkable efficiency and flexibility makes it possible to evaluate the lightning electromagnetic fields for grounding grid or overhead transmission lines.

II. FORMULATION

A. Modified Image Theory

Fig. 1. A grounding grid of substation

In Fig.1, a transient current is assumed to flow through the grounding grid, and every small segment of the grid can be expressed as a line current source. The influence of the interface is taken into account approximately by the modified images [5]. The electric field can be evaluated by means of the current sources and their images:

$$I' = \frac{j\omega\epsilon + \sigma - j\omega\epsilon_0}{j\omega\epsilon + \sigma + j\omega\epsilon_0} I = \Delta I \quad (1)$$

B. Electric Field Integral Equation

The EFIE for a lossless conductor is:

$$\mathbf{t} \cdot (\mathbf{E}^i + \mathbf{E}_1^s + \mathbf{E}_2^s) = 0 \quad (2)$$

where \mathbf{E}^i is the incident electric field, \mathbf{E}_1^s and \mathbf{E}_2^s are the scattered electric fields related with the current source and its

image, respectively. The subscript 1 indicates the variable or the parameter relative to the current sources and subscript 2 indicates that relative to the images. The scattered electric field can be evaluated by means of the Green function:

$$\mathbf{t} \cdot \mathbf{E}_j^s = \frac{1}{4\pi(\sigma + j\omega\epsilon)} \int_l I_l(\mathbf{r}_j') G(\mathbf{r}, \mathbf{r}_j') dl \quad j = 1, 2 \quad (3)$$

$$G(\mathbf{r}, \mathbf{r}_j') = [\nabla^2 - \gamma^2] \frac{e^{-\gamma|\mathbf{r}-\mathbf{r}_j'|}}{|\mathbf{r}-\mathbf{r}_j'|} \quad (3a)$$

$$\gamma = \sqrt{j\omega\mu(\sigma + j\omega\epsilon)} \quad (3b)$$

C. Method of Moment

The Galerkin method is employed to solve the EFIE (2) in the frequency domain. The longitudinal current is expanded as:

$$I_l = \sum_{n=0}^N I_n F_n \quad (4)$$

where I_n denotes the unknown coefficients to be determined, F_n is an expansion function which is expressed as:

$$F_n = \frac{\sinh \gamma(\Delta l - |l - l_n|)}{\sinh \gamma\Delta l}, \quad |l - l_n| < \Delta l \quad (5)$$

where $\Delta l = l_n - l_{n-1} = l_{n+1} - l_n$. The rigorous expression for the electric field of a sinusoidal dipole with unit amplitude is in a local cylindrical coordinate system illustrated in Fig.2:

$$E_{jzn} = \frac{1}{4\pi(\sigma + j\omega\epsilon)} \frac{\gamma}{\sinh \gamma\Delta z} \left(\frac{e^{-\gamma R_{j1n}}}{R_{j1n}} + \frac{e^{-\gamma R_{j3n}}}{R_{j3n}} - 2 \cosh \gamma\Delta z \frac{e^{-\gamma R_{j2n}}}{R_{j2n}} \right) \quad (6)$$

$$E_{j\phi n} = \frac{1}{4\pi(\sigma + j\omega\epsilon)\rho} \frac{\gamma}{\sinh \gamma\Delta z} \left(e^{-\gamma R_{j1n}} \cos \theta_1 + e^{-\gamma R_{j3n}} \cos \theta_3 - 2 \cosh \gamma\Delta z e^{-\gamma R_{j2n}} \cos \theta_2 \right) \quad (7)$$

Fig.2. Local coordinate system

The linear algebraic equations can be attained as follows:

$$Z_{N \times N} I_{N \times 1} = U_{N \times 1} \quad (8)$$

where the elements in $U_{N \times 1}$ are the mutual impedances between the dipoles and the incident monopoles, the element z_{mn} in $Z_{N \times N}$ is the mutual impedance between the dipoles m and n :

$$z_{mn} = \int_{l_n} F_m \mathbf{t} \cdot (\mathbf{E}_{1n} + \Delta \mathbf{E}_{2n}) dl \quad (8a)$$

D. Fast Multiple Method

Dividing the wire segments into M homogeneous groups, \mathbf{o}_j and \mathbf{o}_j' are the centers of groups \mathbf{m}_j and \mathbf{n}_j , respectively. Applying FMM, (8) can be rewritten as follows:

$$(Z^{near} + Z^{far})_{N \times N} I_{N \times 1} = U_{N \times 1} \quad (9)$$

The matrix element Z^{near} represents the interaction from nearby regions, evaluated by MoM, used the expression (8a), and Z^{far} represents the interactions from non-nearby regions. For the non-nearby regions, by applying the addition theory, the Green's function is rewritten as:

$$\frac{e^{-\gamma|r-r_j'|}}{|r-r_j'|} = \frac{e^{-jk|X_j+d_j|}}{|X_j+d_j|} \approx -\frac{ik}{4\pi} \int d^2\hat{k} e^{-ik \cdot d_j} T_j(\hat{k} \cdot \hat{X}_j) \quad (10)$$

where

$$\mathbf{r} - \mathbf{r}_j' = \mathbf{r}_{m_j n_j} = \mathbf{X}_j + \mathbf{d}_j = \mathbf{r}_{o_j o_j'} + (\mathbf{r}_{m_j o_j} - \mathbf{r}_{n_j o_j'}) \quad (10a)$$

$$\hat{\mathbf{k}} = (\sin \theta \cos \phi + \sin \theta \sin \phi + \cos \theta) \quad (10b)$$

$$\mathbf{k} = k\hat{\mathbf{k}} = \frac{\gamma}{i} \hat{\mathbf{k}} \quad (10c)$$

$$T_j(\hat{\mathbf{k}} \cdot \hat{X}_j) = \sum_{l=0}^L (-i)^l (2l+1) h_l^{(2)}(kX_j) P_l(\hat{\mathbf{k}} \cdot \hat{X}_j) \quad (10d)$$

$$L = kD + 2 \log(kD + \pi) \quad (10e)$$

where $\int d^2\hat{k}$ is the integral over the unit sphere, and $d_j < X_j$.

D is the maximum group size.

$$G(\mathbf{r}, \mathbf{r}_j') \approx -\frac{ik}{4\pi} \int d^2\hat{k} (\nabla^2 - \gamma^2) e^{-ik \cdot d_j} T_j(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}_j) \quad (11)$$

$$z_{mn}^{far} = \frac{-\gamma^3}{16\pi^2 (\sigma + j\omega\epsilon)} \int d^2\hat{k} V_m [T_1(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}_1) + AT_2(\hat{\mathbf{k}} \cdot \hat{\mathbf{r}}_2)] V_n \quad (12)$$

$$V_m = \int_{l_m} F_{m_1} (\nabla^2 - \gamma^2) e^{-ik \cdot \mathbf{r}_{m_1 o_1}} dl = \int_{l_m} F_{m_2} (\nabla^2 - \gamma^2) e^{-ik \cdot \mathbf{r}_{m_2 o_2}} dl \quad (12a)$$

$$V_n = \int_{l_n} F_{n_1} (\nabla^2 - \gamma^2) e^{ik \cdot \mathbf{r}_{n_1 o_1}} dl' = \int_{l_n} F_{n_2} (\nabla^2 - \gamma^2) e^{ik \cdot \mathbf{r}_{n_2 o_2}} dl' \quad (12b)$$

where V_m, T_j, V_n represents the matrix of aggregation, translation, disaggregation respectively. Because the conductors are divided symmetrically, T_j has a translational invariance and for the elements in different groups, when $\mathbf{r}_{m_j o_j}$ and V_m are the same, V_n also has the same nature. Furthermore, V_m, V_n are unchanged for the current sources and their images, and these properties reduce the computational complexity and the computer memory significantly.

In the case of lossy conductors, the boundary condition (2) needs to be modified as follows:

$$\mathbf{t} \cdot (\mathbf{E}^i + \mathbf{E}_1^s + \mathbf{E}_2^s) = Z_s I_1(r') \quad (14)$$

$$Z_s = \frac{\lambda_s}{2\pi a (\sigma_s + j\omega\epsilon_s)} \frac{J_0(\lambda_s a)}{J_1(\lambda_s a)} \quad (15)$$

where Z_s is the surface internal impedance, $\sigma_s, \epsilon_s, \mu_s$ are the conductivity, permittivity and permeability of the conductor, respectively, $\lambda_s \approx \omega^2 [\mu_s (\epsilon_s + \frac{\sigma_s}{j\omega}) - \mu (\epsilon + \frac{\sigma}{j\omega})]$, a is the radius of the conductor segment, J_0, J_1 are the first kind of zero and one order Bessel functions, respectively.

Once the current distribution along the conductors has been evaluated, the electric field can be calculated at any point by summing the contributions due to the currents in each segment.

III. NUMERICAL RESULTS

In order to examine the validity of the developed algorithm, we computed the longitudinal current along a wire placed horizontally in a lossy ground. It is assumed that the wire is excited by a sinusoidal current with unit amplitude of frequency $f=6.741\text{MHz}$. Fig.3 shows the current distribution along the wire calculated by the developed algorithm and by MOM directly, and the operation time for a different number of unknowns is given in Fig.4. It can be found the flexibility, efficiency and accuracy of this algorithm. The detailed results (including those calculated and measured) and analysis about grounding grids of the substation will be described in the extended paper.

Fig.3. Current distribution along the wire.

Fig.4. Operation time

IV. CONCLUSIONS

A fast algorithm is presented to compute electromagnetic field of a grounding grid. The method used the modified images to replace the ground effect, and utilized the FMM for solving the EFIE. The method can be used in analyzing lightning electromagnetic field problems of substation grounding systems or overhead transmission lines.

Overlapping Finite Elements for Arbitrary Surfaces in 3D

Guillaume Krebs¹, Stéphane Clénet^{1,2} and Igor Tsukerman²

¹L2EP/AMPT Lille, 8, Bd Louis XIV, 59046 Lille Cedex, France - stephane.clenet@ensam.eu

²Department of Electrical and Computer Engineering, The University of Akron, Akron, OH 44325-3904, United States - tsukerman@uakron.edu

Abstract— The overlapping method is usually employed to connect two surfaces or subdomains meshed separately. This method has been developed in 2D and in 3D for plane surfaces. The paper extends the overlapping method to arbitrary non-planar surfaces; this is accomplished by introducing new shape functions. The proposed method is compared with the classical overlapping method.

I. INTRODUCTION

The finite element method is a useful and reliable tool to study electromagnetic devices. 2D problems can be solved in seconds on today's personal computers. However, accounting for real 3D geometries involves complex mesh generators and solvers and can be very time consuming. Mesh generation can be simplified by relaxing the constraints on the mesh and connecting non-conforming surface meshes. This approach has many advantages. First, mesh propagation of a dense mesh into adjacent areas can be avoided. Second, for moving surfaces no re-meshing is required and the motion step is completely free. Finally, the decoupling of different subdomains can be taken advantage to parallelize the calculations.

Various methods have been proposed to connect two meshed surfaces. If the surfaces are in contact, interpolation, Lagrange Multipliers or the Mortar methods [1] are used. If the surfaces are separated by a constant gap, the overlapping method [2] can be applied and is very attractive because it leads to a sparse linear system of equations. However, if the surfaces to be connected are irregular (e.g. have ripples or bulges), the overlapping elements developed previously cannot be directly used. To overcome this problem, an extension of the overlapping method is proposed in this paper. First, the approach developed earlier is presented. The problems encountered for irregular surfaces are discussed. Modified shape functions are proposed in the overlapping element area. Finally, a test example for the new overlapping method is presented.

II. THE OVERLAPPING ELEMENTS DEVELOPED PREVIOUSLY

The overlapping method was originally introduced in [2] and afterwards independently in [3] for taking into account rotation of electrical machines in 2D. Then, it has been adapted in 3D for hexahedral meshes [4] and extended to tetrahedral elements and prisms [5]. We first review the construction of overlapping elements using the scalar potential formulation in magnetostatics as an example. If we denote the source field with \mathbf{H}_s , and the scalar potential with Ω , the magnetic field \mathbf{H} can be expressed by (1).

$$\mathbf{H} = \mathbf{H}_s - \text{grad}\Omega \quad (1)$$

On the computational domain D , the equation to solve is:

$$\text{div}(\mu(\mathbf{H}_s - \text{grad}\Omega)) = 0 \quad (2)$$

Where μ is the magnetic permeability. To solve (2), the scalar potential is approximated using nodal shape functions w_i ($i \in \mathcal{N}$ with \mathcal{N} the set of nodes) and \mathbf{H}_s using edge shape functions \mathbf{w}_i ($i \in \mathcal{E}$ with \mathcal{E} the set of edges). Applying the Galerkin method leads to a linear system $\mathbf{M}\boldsymbol{\Omega} = \mathbf{N}\mathbf{H}_s$ with \mathbf{M} an $\mathcal{N} \times \mathcal{N}$ matrix and \mathbf{N} is a $\mathcal{N} \times \mathcal{E}$ matrix with the following coefficients:

$$M_{i,j} = \int_D \mu \text{grad}w_i \cdot \text{grad}w_j d\tau \quad \forall i, j \in \mathcal{N} \quad (3)$$

$$N_{k,j} = \int_D \mu \mathbf{w}_k \cdot \text{grad}w_j d\tau \quad \forall k \in \mathcal{E} \text{ and } j \in \mathcal{N} \quad (4)$$

Here $\boldsymbol{\Omega}$ and \mathbf{H}_s the vectors of nodal values of Ω and of circulations of \mathbf{H}_s along the edges, respectively. In the overlapping method, one considers an area D_0 between the two surfaces S_1 that bounds a region D_1 , and S_2 that bounds D_2 , as shown in Fig. 1.a. D_1 and D_2 are two meshed subdomains of the domain D ($D=D_0 \cup D_1 \cup D_2$). Next, the nodes of each surface are projected on the other one. The projections create virtual nodes represented by asterisks in Fig 1.b and also virtual elements in the area D_0 . Two meshes M_1 and M_2 that overlap and are made of prisms are thus defined.

Fig. 1. Projection of the nodes in the non-meshed area .

The virtual nodes do not introduce new degrees of freedom; they are only used to define the shape functions associated with the nodal unknowns (see Fig 2.a). The problem is then to calculate the terms (3) on “overlapping elements” in D_0 . In [5], a methodology based on a common submesh of both meshes M_1 and M_2 is developed to retrieve the integration areas where numerical quadratures are applied to approximate the integral (3).

Fig. 2. Shape function associated to the node N_1 in the case of the standard overlapping method (a) and with the extended overlapping method (b).

III. NEW OF APPROXIMATION FUNCTIONS

When the meshed surfaces being connected are not planes (Fig.2.b), the elements are not prisms anymore. Consequently, the shape functions have to be modified. These functions must remain piecewise-differentiable and capable of approximating the solution of the problem accurately in D_0 .

To define a shape function associated with a node N_1 located on the surface S_1 (see Fig.3.a), let us consider the prism P obtained by extrusion of the facet f with vertices N_1, N_2 and N_3 . Let p be a point $p(x,y,z)$ in P . Let the projections of the nodes on the other surface S_2 be N_{11}, N_{22} and N_{33} . A volume V is then defined by the nodes $N_1, N_2, N_3, N_{11}, N_{22}$ and N_{33} . To calculate the nodal shape function at the point p , two projections of this point are required (e_0 on the surface S_1 and e_{00} on the surface S_2). Thus two distances, x_0 and x_{00} between p and e_0 and e_{00} can be defined respectively.

Fig. 3. Definitions of the nodes N_{11}, N_{22}, N_{33} and the distances x_0 and x_{00} (a) and one example of integration area in D_0 for the case of Fig.2 (b)

The value of the nodal shape function associated with node N_1 at the point p is then given by the expression (5).

$$w_{N_1} = \frac{x_{00}}{x_{00} + x_0} \frac{A}{S_{N_1N_2N_3}} \quad (5)$$

The variable A and $S_{N_1N_2N_3}$ are the areas of the triangles ($e_0; N_2; N_3$) and ($N_1; N_2; N_3$). If p is located on S_1 , x_0 is equal to zero, w_{N_1} is equal to the ratio of A and $S_{N_1N_2N_3}$. The function w_{N_1} is so continuous through the surface S_1 . Now, if p is located on the surface S_2 , one can easily check that the value of the shape function is equal to zero. The prolongation of the nodal shape function w_{N_1} in D_0 insures the continuity of the function at the interfaces between D_0 and D_1 and D_0 and D_2 and so on the whole domain D . Once all the shape functions are defined, the calculation of the integral in (3) is carried out in the same way as in [5].

IV. APPLICATION

The case studied involves a coil inside a mobile air box, see Fig.4. The coil is placed above a metal plate with a corrugated surface (sinusoidal shape). We aim at calculating the variation of the flux linkage through the coil as a function of position. In order to implement the standard and the extended overlapping methods, the gap between the mover and the metal is divided into two regions. Region 1 is between two plane surfaces. The remaining part defines region 2. If region 1 is not meshed, the standard overlapping method can be used. The new extended version is employed with the two areas 1 and 2 unmeshed. In fig. 5, we show the field distribution in the overlapping area. The flux linkages calculated with the classical and extended overlapping methods are close and equal to $1.4 \mu\text{Wb}$ and $1.44 \mu\text{Wb}$, respectively. Details of the simulation will be provided in the extended paper at the conference.

Abstract—A method for implementing divergence constraints in the finite element method is given. This method yields a linearly independent, sparse set of constraints for a mesh of brick elements. The solutions for the resonant frequencies of a cubic cavity are in good agreement with the exact values, and there are no spurious modes.

I. INTRODUCTION

A vector field, such as the electric or magnetic field, can be uniquely determined from its curl, divergence and appropriate boundary conditions [1]. In light of this, several methods have been developed for implementing divergence constraints in the finite element method [2]–[5]. Konrad [2] specifies divergence constraints for a single curvilinear brick, while Kobelansky and Webb [3] provide a method for deriving global basis functions that are divergence free. Both of these methods reduce the size of the curl matrices and preclude the existence of spurious modes, but neither method can, in general, preserve the sparsity of the curl matrices that is necessary for solving large problems. Cendes and Wong [4], [5] construct a mesh that allows for smooth interpolation of random data. This mesh enables the divergence constraints to be implemented inside of the mesh elements and across their boundaries.

The earliest paper on edge elements is due to Nedelec [6]. This method does not constrain the divergence of the field, but rather ensures that the null space of the curl operator is modeled accurately. Tangential continuity conditions at tetrahedra boundaries are explicitly enforced but normal continuity conditions are not. This method does not eliminate spurious modes, but instead guarantees that they are static and thus can be characterized by their frequency. Advantages and disadvantages of edge elements are discussed further by other authors [7]–[9].

The method introduced in the present paper enables divergence constraints to be imposed within brick elements and across their interfaces. This is accomplished using a mixture of cubic Hermite splines and second order Lagrange interpolation polynomials. This method models the divergence of the field with second order accuracy on the interior of the brick elements and enables the divergence to be a continuous function across element boundaries. Spurious modes in eigenvalue problems are eliminated when the divergence constraints are imposed.

II. BASIS FUNCTIONS

In many cases the divergence of the field is a continuous function, including the specific case where the divergence is zero everywhere. One way to guarantee that the finite element approximation of the divergence will be a continuous function is to require that $\partial E_x/\partial x$, $\partial E_y/\partial y$ and $\partial E_z/\partial z$ are each continuous functions. For a mesh comprised of brick elements, this can be accomplished by using a mixture of cubic Hermite splines, H_i , and second order Lagrange interpolation polynomials, L_i , within each brick.

$$E_x(x, y, z) = \sum_{i=0}^3 \sum_{j=0}^2 \sum_{k=0}^2 \alpha_{ijk} H_i(x) L_j(y) L_k(z) \quad (1)$$

$$E_y(x, y, z) = \sum_{i=0}^3 \sum_{j=0}^2 \sum_{k=0}^2 \beta_{ijk} H_i(y) L_j(x) L_k(z) \quad (2)$$

$$E_z(x, y, z) = \sum_{i=0}^3 \sum_{j=0}^2 \sum_{k=0}^2 \gamma_{ijk} H_i(z) L_j(x) L_k(y) \quad (3)$$

In the expansion above, x , y , and z are local coordinates for a given brick, which means that they are translated and scaled so that they are each between 0 and 1. In what follows, the single index of the Lagrange polynomials corresponds to the nodes $L_0(0) = 1$, $L_1(\frac{1}{2}) = 1$, and $L_2(1) = 1$ and the single index of the Hermite splines correspond to nodal values $H_0(0) = 1$, $H'_1(0) = 1$, $H_2(1) = 1$, and $H'_3(1) = 1$, where primes denote derivatives. Different field components have nodes that are located in different positions, as shown in fig 1. Each node in the figure corresponds to a value of the field component and a value of its derivative.

To illustrate that $\partial E_x/\partial x$ is continuous using these basis functions, consider its continuity across each face of a brick. For points that are on the surfaces $x = 0$ and $x = 1$,

$$\frac{\partial E_x}{\partial x}(0, y, z) = \sum_{j=0}^2 \sum_{k=0}^2 \alpha_{1jk} L_j(y) L_k(z) \quad (4)$$

and

$$\frac{\partial E_x}{\partial x}(1, y, z) = \sum_{j=0}^2 \sum_{k=0}^2 \alpha_{3jk} L_j(y) L_k(z), \quad (5)$$

respectively. Thus, continuity of $\partial E_x/\partial x$ can be enforced explicitly by equating α_{1jk} and α_{3jk} from adjacent bricks.

Fig. 1. Field component nodes

On each of the other four faces, $\partial/\partial x$ is a derivative that is tangential to each face and so continuity of $\partial E_x/\partial x$ is automatically satisfied if E_x is continuous everywhere on each face. This does not depend on using Hermite splines and it is also true using the standard nodal basis functions for tetrahedra [10]. Similar arguments hold for establishing the continuity of $\partial E_y/\partial y$ and $\partial E_z/\partial z$. Note that using the basis functions above, $\partial E_x/\partial y$, for example, is not guaranteed to be continuous across the face $y = 0$.

III. DIVERGENCE CONSTRAINTS

The derivatives of cubic Hermite splines can be expressed as a linear combination of second order Lagrange polynomials. Thus it is possible to expand the divergence of the field within a given brick using only polynomials of the latter type.

$$\nabla \cdot \mathbf{E}(x, y, z) = \sum_{i=0}^2 \sum_{j=0}^2 \sum_{k=0}^2 d_{ijk} L_i(x) L_j(y) L_k(z) \quad (6)$$

The divergence equation yields 27 linearly independent constraints per brick. A relatively simple set of equations is obtained if (6) is evaluated at the nodes of the Lagrange polynomials. In this case, the constraint at a given corner, for example, involves only coefficients corresponding to nodes at that corner. Furthermore, the constraints at a given corner due to different bricks are identical. These results would not be obtained if third order Lagrange polynomials were used in place of cubic Hermite splines. Similar results hold for the constraints at the midpoint of each edge and at the center of each face. Consequently, a linearly independent set of constraints over the entire mesh may be obtained using constraints from each corner, edge and face in the mesh, as well as constraints from the center of each brick. These constraints are implemented by eliminating coefficients in the curl matrices, resulting in modified curl matrices of reduced dimension. As a result of using the set of constraints described above, the number of non-zero elements in the modified curl matrices is less than the number of non-zero elements in the original curl matrices. A detailed explanation is omitted due to lack of space.

IV. CAVITY PROBLEM

Consider an empty cubic cavity with sides of unit length. The cavity modes are obtained by minimizing the functional

$$\mathcal{F}(\mathbf{E}) = \iiint_V \left[\frac{1}{\mu} (\nabla \times \mathbf{E})^2 - \omega^2 \epsilon \mathbf{E}^2 \right] dx dy dz \quad (7)$$

TABLE I

subject to the constraint $\nabla \cdot \mathbf{E} = 0$ and the boundary condition $\hat{n} \times \mathbf{E} = 0$. The eigenvalues obtained with an $8 \times 8 \times 8$ mesh are shown in table I along with the exact values obtained analytically. There are no spurious modes.

V. CONCLUSION

A method for implementing divergence constraints in the finite element method has been discussed. The divergence constraints are linearly independent and sparse. In the description given above, a uniform mesh, similar to that used in the finite difference time domain method [11], is required. This work has already been extended for refined meshes with non-uniform brick size and for inhomogeneous objects. The divergence is modeled to second order accuracy and does not necessarily have to be zero or continuous. The divergence constraints can be implemented in a wide variety of problems, not just eigenvalue problems. The method is being extended to include non-brick elements.

Abstract—An algebraic multigrid algorithm based on element agglomeration is proposed for linear systems coming from edge-element discretizations. The edge prolongation operator satisfies commutativity and energy-minimization properties. Robustness is illustrated on 2D numerical examples.

Multigrid methods are beyond the most performing linear system solvers and these solvers are a key point in finite element method libraries. Here, we focus on the discretization on a triangular mesh with the lowest order edge element of

$$\operatorname{curl} \delta \operatorname{curl} \mathbf{U} + \gamma \mathbf{U} = \mathbf{f} \text{ on } \Omega \subset \mathbb{R}^2, \quad (1)$$

which gives rise to a linear system $Ax = f$. As solver we propose an Algebraic MultiGrid (AMG) algorithm which keeps a good efficiency with non-smooth functions δ and γ and with unstructured triangulations. The coarsening process is based on *element agglomeration*. A *low-energy* edge prolongator satisfying a *commutativity property* [1] is obtained from the solution of local linear systems. Numerical examples demonstrate the robustness of our method.

I. COMPONENTS OF THE ALGORITHM

A. Levels

Starting from an initial fine grid partitioned into triangles, we build a hierarchy of generalized meshes $\tau^h = (\mathcal{D}^h, \mathcal{A}^h, \mathcal{S}^h)$. $\mathcal{D}^h = \{D_i^h\}_{i \in I_{\mathcal{D}^h}}$ is a family of open polygons we call elements. On the finest mesh they are the original triangles. $\mathcal{A}^h = \{A_i^h\}_{i \in I_{\mathcal{A}^h}}$ is a family of open one-dimensional manifolds we call edges. $\mathcal{S}^h = \{S_i^h\}_{i \in I_{\mathcal{S}^h}}$ is a family of single points we call vertices. The coarsening procedure which builds a generalized mesh $\tau^H = (\mathcal{D}^H, \mathcal{A}^H, \mathcal{S}^H)$ from a generalized mesh $\tau^h = (\mathcal{D}^h, \mathcal{A}^h, \mathcal{S}^h)$ must satisfy constraints defined in [2], [3]. Moreover, any edge in family \mathcal{A}^H is a connected path of edges belonging to \mathcal{A}^h and has two different endpoints which are vertices in \mathcal{S}^H (Fig. 1). From the family

Fig. 1. Example of a coarse mesh τ^H builds from the finest mesh τ^h .

of generalized mesh $\tau^h = (\mathcal{D}^h, \mathcal{A}^h, \mathcal{S}^h)$, we define a family of oriented simple graphs. For each vertex S_p^h of \mathcal{A}^h a node p is created and 2 separate nodes p, q are connected by an arc each time an edge of \mathcal{A}^h has S_p^h and S_q^h as endpoints. An arc starts from a node p to a node q if $p < q$. The arc-node incidence matrices denoted G^h can be viewed as discrete gradient operators on the meshes.

B. Prolongation operator properties

For each couple of generalized meshes (τ^h, τ^H) , τ^H being obtained from τ^h by a coarsening procedure, we give us a nodal prolongator P^{nod} with a prescribed non-zero pattern and with all row sums equal to 1. We build then an edge prolongator P^{edg} with a prescribed non-zero pattern and with low-energy columns $(P^{\text{edg}})^e$, $e \in I_{\mathcal{A}^h}$. It must also satisfy a node-edge commutativity property [1]: $P^{\text{edg}}G^H = G^hP^{\text{nod}}$. The energy function on a mesh τ^h is defined by

$$g(x^e, e \in I_{\mathcal{A}^h}) = \sum_{e \in I_{\mathcal{A}^h}} \|x^e\|_{K^h}^2 = \sum_{e \in I_{\mathcal{A}^h}} (x^e)^t K^h x^e \quad (2)$$

where K^h is a sparse symmetric definite positive matrix. For its non-zero pattern we require that $K_{i,i'}^h = 0$ if both edges A_i^h and $A_{i'}^h$ do not belong to the interior of the closure of the same element. Such a property is satisfied on the finest mesh by the finite element matrix A .

To define the non-zero pattern of the nodal prolongator P^{nod} and the edge prolongator P^{edg} we mimic the situation in geometric multigrid on nested meshes:

- If S_p^h belongs to the interior of the closure of an element of \mathcal{D}^H , $P_{p,n}^{\text{nod}} = 0$ if S_n^H does not belong to its boundary.
- If S_p^h is an endpoint of an edge of \mathcal{A}^h included in edge A_e^H of \mathcal{A}^H with endpoints $S_{n_k}^H$, $k = 1, 2$; if $S_p^h = S_{n_k}^H$, $P_{p,n}^{\text{nod}} = 0, \forall n \neq n_k$, else $P_{p,n}^{\text{nod}} = 0, \forall n \neq n_1, n_2$.
- If edge A_i^h of \mathcal{A}^h is included in edge A_e^H of \mathcal{A}^H , $P_{ee'}^{\text{edg}} = 0, \forall e' \neq e$ (Fig. 2(a)).
- If edge A_i^h of \mathcal{A}^h is included in the interior of the closure of an element of \mathcal{A}^H , $P_{i,e}^{\text{edg}} = 0$ if A_e^H is not included in its boundary (Fig. 2(b)).

C. Solution of the constrained minimization problem

An element D_a^H of \mathcal{D}^H being fixed, we denote by $\{A_i^h\}_{i \in I_{\text{int}}}$ (resp. $\{A_i^h\}_{i \in I_{\text{bound}}}$) the family of edges of \mathcal{A}^h included in the interior of its closure $\overline{D_a^H}$ (resp. included in

Fig. 2. A coarse element D_a^H . Coarse edges are in wide lines ($m = 3$). Coarse vertices are large bullets. Arrows indicate prolongation.

its boundary), $A_{e_1}^H, A_{e_2}^H, \dots, A_{e_m}^H$ the path of the edges of \mathcal{A}^H included in its boundary. This path defines on the coarse graph an elementary cycle of nodes denoted $n_1, n_2, \dots, n_m, n_1$.

Let A_i^h of \mathcal{A}^h with starting point p and ending point q . Two different cases have to be considered :

- 1) If $i \in I_{\text{bound}}$, then A_i^h is included in an edge A_e^H of \mathcal{A}^H (Fig. 2(a)). The non-zero entries of row i of P^{edg} are settled by the commutativity property since it writes

$$P_{i,e}^{\text{edg}} = P_{i,e}^* \text{ with } P_{i,e}^* = P_{p,n}^{\text{nod}} - P_{q,n}^{\text{nod}} \quad (3)$$

and S_n^H the starting endpoint of A_e^H .

- 2) If $i \in I_{\text{int}}$ (Fig. 2(b)) the commutativity property writes

$$\begin{aligned} \epsilon_{n_k}(e_{k-1})P_{i,e_{k-1}}^{\text{edg}} + \epsilon_{n_k}(e_k)P_{i,e_k}^{\text{edg}} \\ = P_{p,n_k}^{\text{nod}} - P_{q,n_k}^{\text{nod}}, \quad \forall k \in \llbracket 2; m \rrbracket, \end{aligned} \quad (4)$$

where $\epsilon_{n_k}(e)$ denotes 1 (resp. -1) if n_k is the starting point (resp. ending point) of the arc e .

We deduce that the non-zero entries of row i of P^{edg} are defined up to a real constant θ_i as follows :

$$\begin{aligned} P_{i,e_k}^{\text{edg}} = \epsilon_{n_k}(e_k)P_{i,e_k}^* + \theta_i \epsilon_{n_k}(e_k) \\ \text{with } P_{i,e_k}^* = \left[\sum_{l=2}^k P_{p,n_l}^{\text{nod}} - \sum_{l=2}^k P_{q,n_l}^{\text{nod}} \right]. \end{aligned} \quad (5)$$

It can be proved that the prolongator with the lowest energy is obtained with the values θ_i , $i \in I_{\text{int}}$ solution to a local linear system :

$$K^{D_a^H} \theta = K^{\overline{D_a^H}} b,$$

where $K^{D_a^H}$ (resp. $K^{\overline{D_a^H}}$) is the matrix obtained from the matrix K^h by keeping the entries $K_{i,j}^h$, $i, j \in I_{\text{int}}$ (resp. $K_{i,j}^h$, $i \in I_{\text{int}}, j \in I_{\text{int}} \cup I_{\text{bound}}$). b is given by:

$$b_i = -\frac{1}{m} \sum_{k=1}^m \epsilon_{n_k}(e_k)P_{i,e_k}^*, \quad i \in I_{\text{int}} \cup I_{\text{bound}}.$$

II. NUMERICAL RESULTS

The robustness of the method with parameters δ and γ is illustrated using examples of [4]. The domain is simply a unit square and Dirichlet boundary conditions are enforced.

In our strategy (Aggl. in the tables), coarse elements are obtained by double-pairwise agglomeration of elements. The results obtained by our method are compared with the Reitzinger and Schöberl (RS in the tables) strategy [1]. The

comparison is based on the convergence rate σ_{est} in energy norm: $\sigma_{\text{est}} = (\text{er}_k^t \text{Aer}_k / \text{er}_0^t \text{Aer}_0)^{1/(2k_f)}$ with er_k the error at the k -th iteration and k_f the iteration where the stopping criterion is reached. The smoother is a symmetric version of this proposed in [5] in a geometric multigrid context ((pre-, post-) smoothing steps in the tables).

For the homogeneous case in Table I, the two-grid convergence rate is quasi-independent of the size of the problem for both methods but the convergence rate of our method is better than for RS method and should lead to an optimal multigrid strategy. Moreover, increasing the number of pre- and post-smoothing steps significantly improves the convergence rate for the agglomeration. This behavior is confirmed in Table II and Table III for oscillating and discontinuous δ coefficients and two-grid and multigrid solver respectively. For this example, $f = C(2 + \sin(40\pi x))^2(2 + \cos(40\pi y))^2$ with $C = 10$ in $]0, 0.5[\times]0, 0.5[$, 10^4 in $]0.5, 1[\times]0, 0.5[$, 10^{-1} in $]0, 0.5[\times]0.5, 1[$ and 10^2 in $]0.5, 1[\times]0.5, 1[$.

Abstract — A robust numerical method based on 2-D mixed finite elements - finite volumes (FE-FV) allows the solution of diffusion problems in superconducting (SC) materials. The proposed approach handles the strong nonlinearity of the E(J) constitutive power law of high temperature superconductors (HTS). The method is tested in the case of a SC cylinder under a sinusoidal transport current. The current density distributions as well as the AC losses are computed. Comparisons to a FE analysis that uses the magnetic field as state variable show the validity of the proposed approach. It can be seen that the proposed method is very stable even for large n-values for which the FE method doesn't converge.

I. INTRODUCTION

The constitutive power law is widely used to characterize high temperature superconductors. It is written as:

$$J = J_c (E / E_c)^{1/n} \quad (1)$$

where J is the current density, E the electric field, E_c the critical electric field, J_c the critical current density and n the power law exponent. $n=1$ corresponds to a normal conductor and $n=\infty$ represents the critical state model suggested by Bean.

Finite element methods are widely used to compute the magnetic field distribution in superconductors using different formulations [1, 2]. Unfortunately, the use of (1) leads to numerical oscillations and convergence problems for high n-values (typically for $n>50$).

We propose a mixed FE-FV discretization of the electric field diffusion in HTS materials. This approach is shown to be robust for n values up to 200. It has been successfully used in solving nonlinear diffusion-convection-reaction equations in porous media [3].

II. PRINCIPLE OF THE METHOD

We set $u=E/E_c$, $\beta(u)=J/J_c$, and $c=\mu_0 J_c E_c$.

The superconductor has a vacuum magnetic permeability μ_0 . In 2D Cartesian problems, J and E are scalar quantities having only one component in the z direction. The SC domain is noted Ω and its boundary Γ .

Using Maxwell equations and the constitutive law (1), the problem to solve is:

$$\begin{cases} c \frac{\partial \beta(u)}{\partial t} - \Delta u = 0 & \text{in } \Omega \\ \vec{\nabla} u \cdot \vec{\nu} = C_b(t) & \text{on } \Gamma \end{cases} \quad (2)$$

The boundary condition on Γ results from the variation of the magnetic field according to Faraday's law:

$$C_b(t) = E_c^{-1} (\partial B_y / \partial t, -\partial B_x / \partial t) \cdot \vec{\nu} \quad (3)$$

B_x, B_y are respectively the x, y components of the flux density and $\vec{\nu}$ is the outward normal vector on Γ .

The method exposed here exploits the duality of the FE and FV meshes as well as the footbridge operators. It is applied to the weak formulation of (2) in the time interval $[t_p, t_{p+1}]$:

$$\begin{aligned} \int_{\Omega} c \frac{\beta(u^{p+1}) - \beta(u^p)}{\Delta t_p} \varphi d\Omega - \int_{\Omega} \vec{\nabla} u^{p+1} \cdot \vec{\nabla} \varphi d\Omega \\ - \int_{\Gamma} \vec{\nabla} u^{p+1} \cdot \vec{\nu} \varphi d\Gamma = 0 \end{aligned} \quad (4)$$

Where φ are a set of FE base functions and u^p is the solution at instant t_p and Δt_p the time step.

A. FV mesh construction

From a triangulation of Ω , the FV partition is obtained as shown in Fig.1.

Fig. 1. Association of each node of the FE mesh to the cells of the FV mesh: we link the centers of gravity of two contiguous triangles through the vertex of their common edge.

(a) The nodes N_i correspond to the middle of the edges

(b) The nodes N_i correspond to the center of the cells D_i

B. Footbridge operators

Let u^{FE} and u^{FV} be the respective solutions of the FE and FV approaches. The footbridges operators $\pi_{EV} (\pi_{EV}(u^{FV}) = u^{FE})$ and $\pi_{VE} (\pi_{VE}(u^{FE}) = u^{FV})$ between the FE and the FV approximation spaces are well described in [4]. They are defined as:

9. Numerical techniques

$$\int_{\Omega} |\pi_{EV}(u) - u|^2 d\Omega = \min_{w \in FE} \int_{\Omega} |w - u|^2 d\Omega \quad (5)$$

$$\int_{\Omega} \pi_{VE}(u) \varphi d\Omega = \int_{\Omega} u \varphi d\Omega \quad (6)$$

The basis functions of the FV approximation space are obtained from the indicatrix functions of each cell of the FV mesh.

The first order FE base functions φ_i are constructed on the nodes N_i of the FE triangulation. Each of them can be prolonged to the corresponding FV cell. In so doing, we obtain another FE space approximation. Using the footbridge operators (5) and (6), we prove that $u^{FE} = u^{FV}$ [4].

C. Numerical scheme

The numerical discretization of the Laplacian operator is well established using the FE method whereas it is not adapted to the strong nonlinearity of the β term. Instead, we use the FV method to deal with this nonlinear term:

$$\int_D \frac{\beta(u^{p+1}) - \beta(u^p)}{\Delta t_p} dD = \frac{\beta^{p+1} - \beta^p}{\Delta t_p} D \quad (7)$$

Where D is the surface of a FV cell and β^p is the mean value of $\beta(u^p)$.

Hence, using the footbridge operators, we combine FE-FV methods to take advantage of both of them in the same numerical scheme.

In the FV method, the flux $\Phi_{i,j}$ between two adjacent cells i and j must be continuous. The mixed numerical scheme is justified if the diffusion on a FE node is equal to the convection in the FV cell. This leads to:

$$\underbrace{\int_{D_i} \text{div}(\vec{v}u) dD_i}_{FV} = \underbrace{\int_{\Omega} \vec{v}u \cdot \vec{\nabla} \varphi_i d\Omega}_{FE} \quad (8)$$

To ensure the equality in (8), the $\Phi_{i,j}$ are constructed from the mass matrix coefficient $S_{i,j}$ of the FE discretization as follows:

$$\sum_{j \neq i} |D_i \cap D_j| \Phi_{i,j} = - \sum_j S_{i,j} u_j \quad (9)$$

If we define $S_{i,i} = - \sum_{j \neq i} S_{i,j}$, the local conservation property of the FV formulation is ensured.

For the internal FV cells, the discrete problem is written as:

$$c \frac{\beta_i^{p+1} - \beta_i^p}{\Delta t_p} D_i = \sum_j S_{i,j} u_j^{p+1} \quad (10)$$

and for the boundary cells, we write:

$$c \frac{\beta_i^{p+1} - \beta_i^p}{\Delta t_p} D_i = \sum_j S_{i,j} u_j^{p+1} + |\Gamma_i| C_b^{p+1} \quad (11)$$

The obtained nonlinear system of algebraic equations is solved using a Newton-Raphson method.

III. APPLICATION EXAMPLE

We consider a SC cylinder having a radius of 1.5 mm. The SC material is characterized by $n=25$, $J_c=14.15$ A/mm² and $E_c=10^{-4}$ V/m.

The cylinder is submitted to a sinusoidal transport current $i(t)=I_{max} \cdot \sin(2\pi ft)$ ($f = 0.5$ Hz and $I_{max} = 40.8$ A). B_x, B_y used in the boundary condition (3) are obtained by Ampere's theorem.

We have compared in Fig.2, the instantaneous self field losses obtained by the FE-FV method and these issued from a pure FE method based on H-formulation [2]. The agreement is good.

However, for $n=200$ the FE method didn't converge. In this case, the average AC losses obtained by our method are 0.024W/mm. The Bean formula gave 0.028 W/mm which seems to validate the FE-FV method in the case of strong nonlinearity.

Abstract — Several methods of a posteriori error estimation and adaptive refinement controlling in finite element analysis of 3D steady state eddy current field is researched in this paper. An improved Z-Z method is proposed. The numerical models of TEAM Problem 7 and 21A are used to verify the validity of the method presented.

I. INTRODUCTION

The finite element (FE) analysis of 3D steady state eddy current fields plays an important role in performance evaluation of electrical devices and non-destructive testing with eddy current detection. The complicated configuration and very small skin depth of the metal parts in the calculated region make the effective FE analysis rather difficult. The a posteriori error estimation and adaptive mesh generation provide an efficient approach for dealing with the problem. Some researches have been done regarding these subjects. A comparison between complementary algorithm and energy method applied to eddy current detection was presented in [1]. The residual method used in a posteriori error estimation of eddy current field analysis [2] was described by [3] and [4]. Ref. [5] employed Z-Z method [6] in the eddy current analysis of moving conductors. In this paper, a posteriori error estimation and adaptive mesh refinement using the Z-Z method are described and improved for the 3D eddy current field analysis using the pair of magnetic vector potential A and electric scalar potential ϕ .

II. GOVERNING EQUATIONS IN COMPLEX DOMAIN

According to [7], a 3D steady state eddy current field boundary value problem can be expressed as

$$\text{in } \Omega_1 : \begin{cases} \nabla \times \nu \nabla \times A - \nabla \nu \nabla \cdot A + j\omega\sigma A + \sigma \nabla \phi = \mathbf{0} \\ \nabla \cdot (-j\omega\sigma A - \sigma \nabla \phi) = 0 \end{cases} \quad (1)$$

$$\text{in } \Omega_2 : \nabla \times \nu \nabla \times A - \nabla \nu \nabla \cdot A = \mathbf{J}_s \quad (2)$$

with certain boundary conditions under the sinusoidal excitation, where Ω_1 and Ω_2 denote the eddy current region and non-eddy current region respectively. Based on the theory of electromagnetic field the magnetic flux density and electric field intensity are given by

$$\mathbf{B} = \nabla \times \mathbf{A} \quad (3)$$

and

$$\mathbf{E} = -j\omega \mathbf{A} - \nabla \phi \quad (4)$$

III. A POSTERIORI ERROR ESTIMATION FOR NODE-FINITE ELEMENT ANALYSIS OF EDDY CURRENT FIELD WITH POTENTIAL PAIR OF A - ϕ

The Z-Z method was proposed aiming at the second order elliptic equations, and it is proved that the method is also efficient for the a posteriori error estimation of FE Analysis for non-elliptic problems. However, there are not many papers applying this method to the eddy current field analysis. Considering the principle of Z-Z [6] and the property of eddy current field boundary value problems, the a posteriori error estimation is given by

$$\eta_e = c_1 \|\mathbf{B}^* - \mathbf{B}_h\| + c_2 \|\mathbf{E}^* - \mathbf{E}_h\| \quad (5)$$

where \mathbf{B}_h and \mathbf{E}_h express the calculated value, \mathbf{B}^* and \mathbf{E}^* for the recovery value of the flux density and electric field in an element respectively, c_1 and c_2 denote the constants related to the size of the element, and $\|\bullet\|$ expresses the energy norm. In some paper only the first term in (5) is used when carrying out the a posteriori error estimation using the Z-Z method. It is not complete for analyzing of the eddy current case. Based on the numerical experiments by the authors, if the second term of (5), which is closely related to the electric current density, is neglected in the eddy current region, the computational precision of eddy current losses can not be ensured easily, especially for the case of skin depth less than 1 mm.

Furthermore, equation (5) provides the a posteriori estimation of the discretization error in the whole solved region, but does not directly give the evaluation of the computational precision for the eddy current losses, in which the engineers are interested. Therefore, when determining the criterion for the end of adaptive iterations, the eddy current losses should be used directly.

\mathbf{B}^* and \mathbf{E}^* are obtained through the Least Square Fitting (LST) in the patch of elements based on the Z-Z method [6]. In our case, the LST is used only at the boundary and the interface of different materials, with the Inverse Distance Weighting (IDW) method applied to the recovery calculation of \mathbf{B}^* and \mathbf{E}^* in the patch of elements. This method proposed is called Combined IDW with Least square fitting (CIL) in the following text. It is obvious that the computation effort of the CIL method is much less than the original Z-Z method.

IV. COMPUTATION RESULTS AND ANALYSIS

To verify the method presented in this paper, the TEAM Workshop problem 7 and Problem 21A are used as the examples. Fig. 1 shows the comparison of the error estimation versus the node number using the Z-Z method, CIL approach and uniformed refinement for the adaptive FE analysis of Problem 7. The x - and y -axis are both in logarithmic scale. Fig. 2 and Fig. 3 are the initial mesh and the mesh of fifth adaptive refinement respectively. It can be seen from Fig. 1 that the Z-Z method and CIL approach have the similar convergent property. Compared with the uniformed refinement, Z-Z and CIL methods are of higher computational efficiency. Taking the mesh refinement of Fig. 2 and Fig. 3 into account, it is concluded that the Z-Z and CIL methods can be used as the error indicator for the adaptive FE analysis of 3D eddy current fields.

The eddy current losses versus the node number of the TEAM Workshop Problem 21A with the adaptive mesh refinement controlling of Z-Z, CIL and CIL* method respectively are shown in Fig. 4, where CIL* expresses the method of CIL including only the first term of (5). In view of the complex governing equations, the relative permeability of the steel plate in Problem 21A is assigned approximately as a constant of 1000. According to the measured value of 9.28W [8] and comparing the loss curves with the three methods in Fig. 4, it is seen that for the problem with small skin depth, like Problem 21A, using (5) to fulfill error estimation is appropriate, while the computation without the second term of (5) will result in relatively large computational deviation of the eddy current loss.

Fig. 1 A posteriori error versus the node number of TEAM Problem 7

V. CONCLUSIONS

The Z-Z method used in the FE analysis of 3D steady state eddy current field is described, and a more efficient method of CIL is proposed in this paper. The issues how to apply the Z-Z and CIL method to conduct the mesh refinement are researched. The numerical models verify the validity of the method proposed.

Auto adaptive interface treatment for the EFGM in electromagnetic problems

Carlos A. S. J. Gulo*, José Márcio Machado[§], Gleber Nelson Marques*

Abstract—The interpolating Element Free Galerkin Method (EFGM) combined with the domain truncation technique has been shown to be an easy and efficient technique for treating physical discontinuities in the Poisson’s equation. A good accuracy for this approach is achieved when the material interfaces lines are properly refined. This work describes an auto adaptive algorithm for handling the refinement process of such interfaces.

Index Terms—Galerkin method, interface treatment, auto adaptive algorithm.

I. INTRODUCTION

THE EFGM [1] is an attractive meshfree method for solving partial differential equations (pde) whose applications have been reported in the specialized literature of many fields of science and engineering, e.g. computational mechanics [1] and electromagnetism [2], magnetohydrodynamic (mhd) [3], quantum physics [4] and recently plasma simulations [5].

The EFGM theoretical foundations rely on the idea of constructing a functional basis composed by the so called (EFGM) shape functions. These shape functions are constructed from a local Moving Least Square (MLS) approximation performed on the discretization points, and provide the required functional basis for the well-known Galerkin discretization procedure for solving pde’s. Different from the Finite Element Method (FEM), the standard approach of the EFGM [1] does not provide interpolating EFGM approximations. In this case, additional techniques must be used for enforcing the prescribed boundary conditions as well as the material interface conditions for a correct physical description of the phenomenon and for avoiding spurious oscillations.[6]

Naturally the requirement of such techniques is undesirable due to: 1) the increasing of the total number of unknowns caused by most used techniques, e.g. Lagrange Multipliers and Penalty methods, and 2) the loss of the positive definite character of the stiffness matrix in the final linear system [7], [6]. The interpolating EFGM-domain truncation approach proposed in [8] completely avoids the use of these additional techniques at the cost of carefully take care about the boundary lines, specially the material interface ones. Depending on the complexity of the device geometry, an iterative procedure of inspecting approximations near the material interfaces of the domain may take place and become a boring and time-consuming task.

[§] José Márcio Machado is with São Paulo State University, São José do Rio Preto, São Paulo (email: jmarcio@ibilce.unesp.br). * Carlos A. S. J. Gulo and Gleber Nelson Marques are with Mato Grosso State University, Alto Araguaia, Mato Grosso (email: sander@unemat.br and gleber.nmarques@gmail.com).

[†]The authors thank FAPEMAT for the project financial support (Grant n. 002.229/2007).

This paper describes an auto adaptive algorithm for treating material interface conditions by using the interpolating EFGM together the modified domain truncation technique [6].

A. The interpolating EFGM approach

Suppose we are interested in solving the Poisson’s equation for the unknown function $u(x)$ in a domain containing material interfaces. Consider a set of discretization points at which the approximation $u^h(x)$ will be performed. To each node is associated a weight function $w_l(x)$ whose support defines the nodal influence domains. Starting from a local MLS approximation whose coefficients are determined by the minimization of a weighted L_2 norm of the error between the local MLS approximation and the nodal variables u_l , one can obtain the EFGM shape functions $\phi_l(x)$:

$$\phi_l(x) = \sum_j^m p_j(x) \left(A^{-1}(x) B(x) \right)_{jl}, \quad (1)$$

often found in the following expansion:

$$u^h(x) = \sum_l \phi_l(x) \cdot u_l. \quad (2)$$

The matrices \mathbf{A} and \mathbf{B} are defined as usual [1], [6], [2]. Our code implements the consistency approach for avoiding the inversion of matrix \mathbf{A} . [9]

The interpolating character of the EFGM approximation can be obtained by defining singular weight functions $\tilde{w}_i(x)$:

$$\tilde{w}_i(x) = w_i(x) / (1 - w_i(x) + \varepsilon), \quad (3)$$

where the parameter ε is a prescribed precision for the singularity, and the truncated Schwarz function was chosen as $w_i(x)$ [6]. Since the interpolating condition is satisfied only punctually at the nodes, a more refined discretization along the boundaries and interfaces can provide a correct global and local description of the phenomenon.[6]

B. Treatment of the interface conditions

The presence of material interfaces in electromagnetic problems leads to field discontinuities. Since the proposed approximation inherits the continuity of the Schwarz function, the state variable approximation and its derivatives will be continuous and differentiable functions. Thus, additional techniques must be used for obtaining a correct description of the physical field discontinuity.

We use the modified domain truncation technique for interpolating EFGM formulation [6], where the influence domains

of the nodes localized at a specified material are truncated across material interfaces. This means that nodes localized in a specified material sub-domain S_1 will only participate in the approximation of evaluation points belonging the same material, S_1 . The discontinuous approximations of each material sub-domain are connected by the nodes distributed along the material interfaces which participate in the approximation of points belonging to both materials. No Lagrange multipliers are required due to the interpolating character of the approximation. It can be mentioned that the error for computing the field near the interface is an increasing function of the magnitude of the physical discontinuity and decrease for more refined discretizations. [6]

C. Auto adaptive algorithm for treating interface conditions

We take as a reference problem the computation of a stationary electric field involving different conductor materials, however, the procedures here developed can be applied for computing stationary fields associated to the Poisson's equation in inhomogeneous media. From theory the physical discontinuity of the normal component of the electric field crossing the material interface of two conductors, is given by

$$\sigma_1 E_{1n} = \sigma_2 E_{2n}, \quad (4)$$

from which we can estimate a mean local error near the interface for a set of arbitrary test points distributed parallel and very close, δ , the interface line as show in Fig.1

Fig. 1. Distribution pattern of interface test-points

Lets $x_{t1}^{S1}, \dots, x_{tk}^{S1}$ be the interface test-points belonging material S_1 and, correspondingly $x_{t1}^{S2}, \dots, x_{tk}^{S2}$ be the ones belonging to material S_2 . Similarly, let $E_{t1}^{S1}, \dots, E_{tk}^{S1}$ and $E_{t1}^{S2}, \dots, E_{tk}^{S2}$ be the computed normal field component at the interface test-points. If $\hat{E}_{t1}^{S2}, \dots, \hat{E}_{tk}^{S2}$ are the theoretically expected values at the test points $x_{t1}^{S2}, \dots, x_{tk}^{S2}$ algebraically obtained from (4), then the mean relative local error in the approximation of the normal field component at the specified interface test-points can be defined as:

$$E_I = \sum_{t_i=t_1}^{t_k} \left| \frac{E_{t_i}^{S2} - \hat{E}_{t_i}^{S2}}{k \cdot \hat{E}_{t_i}^{S2}} \right| = \sum_{t_i=t_1}^{t_k} \left| \frac{E_{t_i}^{S2} - \left(\frac{\sigma_{S1}}{\sigma_{S2}} E_{t_i}^{S1} \right)}{k \cdot \hat{E}_{t_i}^{S2}} \right|. \quad (5)$$

By using the above defined interface error we propose an auto adaptive algorithm as follows:

1) After the preprocessing stage of the simulation, e.g., the device design and physical specifications, generate the sets of test-points for each material interface of interest;

- 2) Compute the approximation at the given discretization nodes;
- 3) Compute the component of the electric field normal to the material interface line for all the interface test-points;
- 4) Compute the mean relative errors E_I (5) for each set of interface test-points;
- 5) For each interface, compare its E_I (5) with a prescribed interface precision ε_I , and, if ($E_I \leq \varepsilon_I$) :
 - a) then, the prescribed precision has been achieved for this interface, consider next interface;
 - b) else ($E_I > \varepsilon_I$), refine the discretization nodes along this interface and consider next interface;
- 6) If the number of discretization nodes has changed (this means that step 5.b was executed) then return to step 2.

The fast h -convergence of the EFGM has already been demonstrated in previous works for stationary electric [6], magnetic fields [8] as well as in scattering problems [2], which have encouraged a software engineering for including new object-oriented classes of such auto adaptive algorithms in our EFGM code.

II. FINAL DISCUSSION AND FURTHER DEVELOPMENTS

The auto adaptive algorithm proposed in this work is based on the error estimative obtained from the physical interface conditions theoretically expected. It automates an iterative process of inspecting the approximation errors near physical discontinuities. This work has being developed in the context of the LExVE (Laboratory for Virtual Experiences in Engineering) research project associated with the LEVSOFT system [10]. A rigorous analysis of the performance and robustness of the proposed algorithm, is being carried out and will be further reported.

Abstract— This paper deals with the volume integral formulation of the eddy current problem in terms of the electric vector potential. Its aim is to present a simple topological algorithm for finding the additional degrees of freedom required in the discretization of a multiply connected region when using edge elements. The algorithm is completely automated and it is based, as other previous approaches, on the application of the spanning tree technique on the edge element based topological graph defined on the boundary surface of the conducting domain.

I. INTRODUCTION

In several numerical formulation of the eddy current problem, the field in the vacuum region is conveniently expressed in terms of the magnetic scalar potential. However this potential may become multi-valued when the source region is multiply connected. For this case, it is necessary to introduce suitable cuts for making the domain simply connected or, more rigorously, loop-free. This topic has draw considerable attention [1-4] and several automatic algorithms for finding cuts have been already proposed.

In this respect, our problem is different because it involves the topological treatment on the surface corresponding to the boundary of the eddy current region. The integral formulation we deal with is written in terms of the eddy current density vector whose solenoidality is assured by expressing it as the curl of the electric vector potential \mathbf{T} . The uniqueness of \mathbf{T} is imposed on the discrete by adopting edge elements shape functions and by imposing the tree-cotree gauge condition [5-6]. When the conducting region is multiply connected, a set of boundary edges may not be the boundary of a simply connected patch lying on the boundary of the conductor. For this reason the boundary condition assuring that the current density does not flow outside the domain cannot be imposed by zeroing the tangential component of \mathbf{T} on the boundary. As a matter of fact the circulation of \mathbf{T} on a closed line lying on the boundary may be related to current loops inside the domain. The main ideas behind the proposed approach have been already discussed in previous papers [6-8]. In these cases the *nonlocal* additional degrees of freedom were automatically obtained in an algebraic way as the columns spanning the null space of the incidence matrix relating fluxes across elementary boundary faces and edges lying on the boundary. In this paper, we present a much simpler approach that exploits the spanning tree technique applied to the topological graph made of boundary facets (nodes) and edges for automatically finding these *nonlocal* DOFs. The underlying idea of *nonlocal* basis functions was also discussed by Kettunen in [9]. In that frame, he pointed out that “these nonlocal functions can be rather

easily found once the representative Σ and γ of the equivalence classes are known. (In many cases – although not always – it is easy to say what the Σ and γ cuts are. The difficulty is to detect them automatically)”.

II. THE INTEGRAL FORMULATION

The reference geometry which we deal with is made by a multiply connected domain, with several feeding electrodes on its boundary. We solve the eddy current problem using the integral formulation described in [5-6]. Expressing the electric field as

$$\mathbf{E} = -\frac{\partial \mathbf{A}}{\partial t} - \nabla \phi \quad (1)$$

and using the Biot-Savart law for calculating the magnetic vector potential \mathbf{A} , the Ohm’s law, imposed in the weak form gives:

$$\begin{aligned} & \text{find } \mathbf{J} \in Q \text{ such that} \\ & \int_{\Omega} \mathbf{w} \cdot \eta \mathbf{J} dV + \int_{\Omega} \mathbf{w}(\mathbf{r}) \cdot \frac{\partial}{\partial t} \int_{\Omega} \frac{\mathbf{J}(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|} dV' dV + \int_{S_e} \phi \mathbf{w} \cdot \hat{\mathbf{n}} dS = \\ & - \int_{\Omega} \mathbf{w} \cdot \frac{\partial}{\partial t} \mathbf{A}_0 dV, \quad \mathbf{w} \in Q \end{aligned} \quad (2)$$

where $Q = \{ \mathbf{q} | \nabla \cdot \mathbf{q} = 0, \mathbf{q} \cdot \hat{\mathbf{n}} = 0 \text{ on } \partial\Omega \setminus S_e \}$ and S_e is the surface of all the electrodes. In order to guarantee that $\mathbf{J} \in Q$, we impose $\mathbf{J} = \nabla \times \mathbf{T}$ in Ω , where the uniqueness of \mathbf{T} is assured by a two component gauge condition [5]

III. THE NUMERICAL FORMULATION

The conducting domain is discretized in a number of finite elements, such that each electrode is approximated by a set of boundary mesh facets. The vector potential \mathbf{T} is expressed in terms of edge element shape functions \mathbf{N}_k as $\mathbf{T} = \sum_k I_k \mathbf{N}_k$, so that $\mathbf{J} = \sum_k I_k \nabla \times \mathbf{N}_k$. The gauge condition is directly imposed on the shape functions by giving a tree-cotree decomposition of the mesh and retaining only the degrees of freedom associated with the edges of the cotree. The internal edges of the co-tree are retained with no additional manipulation. On the other hand, a special treatment is required for the n_c active edges belonging to the boundary $\partial\Omega$ of the conducting domain Ω , in order to force $\mathbf{J} \cdot \hat{\mathbf{n}} = 0$ over $\partial\Omega$ [6-8].

In a simply connected region without electrodes, boundary condition $\mathbf{J} \cdot \hat{\mathbf{n}} = 0$ can be easily imposed, by forming the tree firstly connecting boundary nodes with boundary edges and then zeroing the cotree edges belonging to the boundary. As a

matter of fact in this case any line integral on a closed line made by edges lying on the boundary represents a current flux crossing a surface which lies on the boundary.

IV. MULTIPLY CONNECTED REGIONS

With reference to a multiply connected region, we firstly discuss the case in the simpler hypothesis that the boundary of the conducting domain is without electrode facets. We propose the following procedure to find the nonlocal additional DoFs required. The procedure is repeated for each separate piece.

We firstly supply few definitions:

- Dual vertex: facet
- Dual edge: edge
- Dual graph: the graph made by considering the facets as vertices and the edges as edges. Notice that, by definition, any edge connects two vertices (facets in this case)
- Degree: the degree of a vertex is the number of edges connected to that vertex
- Leaf: a leaf is a vertex of degree 1

Procedure

1. Form a tree by firstly connecting boundary nodes with boundary edges;
2. Select the cotree edges on the boundary $\partial\Omega$;
3. Form the facets-edges dual graph for all the edges of cotree on $\partial\Omega$;
4. recursively remove all the leaves. In this way, the closed loops left are made by sets of edges that are candidates to represent the nonlocal additional DoFs;
5. form the tree-cotree decomposition of the dual graph obtained at points 3-4;
6. any cotree edge of this dual cotree close a loop that represents an additional DoF.

As a matter of fact, the edges of any additional DoF produce zero flux across the boundary facets (on the primary graph) and assure the possibility of having a flux different from zero, associated to proper closed paths on the boundary having one edge of this DoF as the only active edge.

In the presence of the electrodes the procedure should be modified as follows:

1. Form the tree by connecting first boundary nodes with boundary edges for every electrode surface; then continue as in the step 1 of the previous procedure;
2. by construction any contour of any surface of the electrodes presents a unique edge belonging to the cotree; identify the facet of the electrode associated to this edge;
3. when building the dual graph (point 3 of the previous procedure), connect all the facets previously identified (point 2) to a common fictitious dual vertex.
4. execute points 3-6 of the previous procedure.

However, as already remarked in previous papers, only a part of these nonlocal basis functions are related to net current fluxes circulating inside the conducting region, whereas others would be related to current fluxes across surfaces external to

the conductor. The last ones are redundant because inside the conducting region they are linear combinations of the other degrees of freedom. On this basis, their selection can be obtained with the same algorithm already described in [8].

V. AN EXAMPLE

The procedure is here illustrated with reference to the torus shown in fig. 1a. The cotree edges are drawn as red arrows in the same figure. In fig. 1b the dual graph is shown with the leaves sequentially removed marked in green. The remaining facet marked in blue are also shown in fig. 1.c. Finally in fig. 1.d, the two nonlocal DoFs are drawn in blue and red, respectively. Only the DoF marked in red is associated to a current flux circulating inside the conducting region.

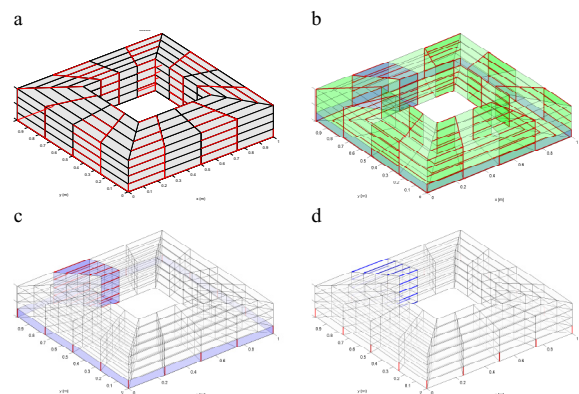

Fig. 1. a: the conducting domain and the co-tree edges on $\partial\Omega$; b: the dual graph with in green the removed leaves; c: the dual graph after removing the leaves. d: the non local additional DoF s; Only the DoF marked in red is associated to a current flux circulating inside the conducting region.

Abstract—This paper presents finite element analysis of time-harmonic eddy current problems using the complex adjoint variable method (C-AVM). In the sensitivity analysis as well as optimization based on FE analysis of time-harmonic eddy current fields, response and objective functions are often real-valued functions, while unknown variables for the FE analysis are complex. When the AVM is applied to such problems, the real-valued functions must be differentiated in terms of the complex variables. However, such differentiation cannot be defined because the Cauchy-Riemann equation does not hold. In this paper, the C-AVM is introduced to overcome this difficulty, and is applied to sensitivity analysis and optimization.

I. INTRODUCTION

The adjoint variable method (AVM) has widely been applied to various problems in computational electromagnetism to compute sensitivity of response functions, and derivative of objective functions in optimization problems and inverse problems. It is the advantage of AVM that computational cost for computation of derivatives of the response (or objective) function in terms of parameters little grows as the number of the parameters increases.

In AVM, the adjoint equation must be solved before the computation of the derivative. The right-hand-side vector in the adjoint equation is the derivative of the response function in terms of the unknown variable of the field analysis. When time-harmonic eddy current fields are analyzed using finite element method (FEM), the unknown variables are complex. On the other hand, the response functions are often chosen as real valued functions which represent, e.g., energy, loss and magnitude of magnetic induction. In such cases, the derivative cannot be defined because the Cauchy-Riemann equation cannot hold in general. The similar situation can also be found in other cases such as microwave problems including complex permittivity or permeability, magnetic field analysis based on the effective permeability, and so on.

In this paper, the complex AVM, referred here C-AVM, will be introduced by adequate modification of the conventional AVM and be applied to sensitivity analysis of time-harmonic eddy current fields.

II. COMPLEX ADJOINT VARIABLE METHOD

Let us consider a quasi-static electromagnetic field governed by

$$\text{rot}(\nu \text{rot} \mathbf{A}) + j\omega\sigma\mathbf{A} = \mathbf{J}, \quad (1)$$

where \mathbf{A} and \mathbf{J} are vector potential and current density, ν , ω and σ are the reciprocal of magnetic permeability, angular frequency and conductivity. The edge-based finite element method applied to (1) yields a system of linear equations

$$[K]\mathbf{a} = \mathbf{b}, \quad (2)$$

where $[K] \in \mathbb{C}^{E \times E}$, $\mathbf{a} \in \mathbb{C}^E$, $\mathbf{b} \in \mathbb{R}^E$ and E denotes the number of edges in the finite element mesh. The entities of $[K]$ and \mathbf{b} are given by

$$\begin{aligned} K_{ij} &= \int_v (\nu \text{rot} \mathbf{N}_i \cdot \text{rot} \mathbf{N}_j + j\omega\sigma \mathbf{N}_i \cdot \mathbf{N}_j) dv, \\ \mathbf{b}_i &= \int_v \mathbf{N}_i \cdot \mathbf{J} dv, \end{aligned} \quad (3)$$

where \mathbf{N}_i denotes the vector basis function for the edge-based element.

Now let assume that the electromagnetic field depends on design parameters $\mathbf{p} = [p_1, p_2, \dots, p_n]^t$, which are, for example, shape and material parameters. In this situation, we can write $\mathbf{a} = \mathbf{a}(\mathbf{p})$. Moreover, let us consider the numerical evaluation of sensitivity $\partial W / \partial p_k$, $k = 1, 2, \dots, n$ for a real valued function $W(\mathbf{a}(\mathbf{p}))$ against parameter changes. In real situations, the function W would express quantities such as electromagnetic energy, loss, and magnitude of magnetic induction. In order to evaluate the sensitivity, we employ the AVM where the adjoint equation to (2),

$$[K]\bar{\mathbf{a}} = \frac{\partial W}{\partial \mathbf{a}} \quad (4)$$

must be solved to obtain the adjoint variable $\bar{\mathbf{a}}$. However, the right-hand-side of (2), which is the differentiation of the real-valued function in terms of the complex variable, cannot be defined because it is not guaranteed the function W satisfies the Cauchy-Riemann differential equation

$$\begin{aligned} \frac{\partial W^{\text{re}}}{\partial a_m^{\text{re}}} &= \frac{\partial W^{\text{im}}}{\partial a_m^{\text{im}}}, \\ \frac{\partial W^{\text{re}}}{\partial a_m^{\text{im}}} &= -\frac{\partial W^{\text{im}}}{\partial a_m^{\text{re}}}, \end{aligned} \quad (5)$$

which is equivalent to

$$\frac{\partial W}{\partial a_m^*} = 0, \quad (6)$$

where $m = 1, 2, \dots, E$ and the suffixes re and im denote real and imaginary parts.

To overcome this difficulty, we consider the modified adjoint equation

$$[K]\bar{\mathbf{a}} = \frac{\partial W}{\partial \mathbf{a}^{\text{re}}} - j \frac{\partial W}{\partial \mathbf{a}^{\text{im}}} \quad (7)$$

in stead of (4). Note here that the right-hand-side of (7) only contains the differentiation of W in terms of real variables. The equation (7) is further modified to

$$\begin{bmatrix} K^{\text{re}} & -K^{\text{im}} \\ K^{\text{im}} & K^{\text{re}} \end{bmatrix} \begin{bmatrix} \bar{\mathbf{a}}^{\text{re}} \\ \bar{\mathbf{a}}^{\text{im}} \end{bmatrix} = \begin{bmatrix} \partial W / \partial \mathbf{a}^{\text{re}} \\ -\partial W / \partial \mathbf{a}^{\text{im}} \end{bmatrix}, \quad (8)$$

where the first and second equations of (8) correspond to the real and imaginary parts of (7). For simplicity, we define the variables

$$\begin{aligned} \boldsymbol{\alpha} &= [\mathbf{a}^{\text{re}}, -\mathbf{a}^{\text{im}}]^t, \\ \bar{\boldsymbol{\alpha}} &= [\bar{\mathbf{a}}^{\text{re}}, -\bar{\mathbf{a}}^{\text{im}}]^t, \end{aligned} \quad (9)$$

then (8) becomes

$$\begin{bmatrix} K^{\text{re}} & K^{\text{im}} \\ K^{\text{im}} & -K^{\text{re}} \end{bmatrix} \bar{\boldsymbol{\alpha}} = \frac{\partial W}{\partial \boldsymbol{\alpha}}. \quad (10)$$

We write the matrix in the left-hand-side of (10) as $[\tilde{K}]$, which is symmetric.

Moreover, we divide (2) into real and imaginary parts to obtain

$$\begin{bmatrix} K^{\text{re}} & K^{\text{im}} \\ K^{\text{im}} & -K^{\text{re}} \end{bmatrix} \begin{bmatrix} \mathbf{a}^{\text{re}} \\ -\mathbf{a}^{\text{im}} \end{bmatrix} = \begin{bmatrix} \mathbf{b} \\ \mathbf{0} \end{bmatrix}. \quad (11)$$

Rewriting (11) using $\boldsymbol{\alpha}$ and $[\tilde{K}]$, we have

$$[\tilde{K}]\boldsymbol{\alpha} = \tilde{\mathbf{b}}, \quad (12)$$

where $\tilde{\mathbf{b}} = [\mathbf{b}, \mathbf{0}]^t$. By differentiating (12) in terms of the parameter p_k , we have

$$[\tilde{K}] \frac{\partial \boldsymbol{\alpha}}{\partial p_k} = -\frac{\partial [\tilde{K}]}{\partial p_k} \boldsymbol{\alpha}. \quad (13)$$

Multiplying $\bar{\boldsymbol{\alpha}}^t$ to both sides of (13) and taking its transpose, we obtain

$$\left(\frac{\partial \boldsymbol{\alpha}}{\partial p_k} \right)^t [\tilde{K}] \bar{\boldsymbol{\alpha}} = -\boldsymbol{\alpha}^t \frac{\partial [\tilde{K}]}{\partial p_k} \bar{\boldsymbol{\alpha}}. \quad (14)$$

Substitution of (12) into (14) yields

$$\frac{\partial W}{\partial p_k} = -\boldsymbol{\alpha}^t \frac{\partial [\tilde{K}]}{\partial p_k} \bar{\boldsymbol{\alpha}}, \quad (15)$$

which gives the sensitivity. Moreover it can be shown that

$$\boldsymbol{\alpha}^t \frac{\partial [\tilde{K}]}{\partial p_k} \bar{\boldsymbol{\alpha}} = \text{Re} \left(\mathbf{a}^t \frac{\partial [K]}{\partial p_k} \bar{\mathbf{a}} \right). \quad (16)$$

Hence, it is concluded that (15) can be expressed as

$$\frac{\partial W}{\partial p_k} = -\text{Re} \left(\mathbf{a}^t \frac{\partial [K]}{\partial p_k} \bar{\mathbf{a}} \right). \quad (17)$$

which will be used in our sensitivity analysis. The similar sensitivity expression as (17) has been obtained for the microwave circuit problem [1].

III. NUMERICAL RESULTS

The present method is applied to the sensitivity analysis of a system of non-destructive testing, shown in Fig.1. In this model, the alternative current of 100 [AT] flows along the coil at 10 [kHz]. The aluminum plate, whose conductivity is set to 36×10^6 [S/m], contains a rectangular flaw. The sensitivity dB/dh in the magnetic induction B measured at point p against the thickness h of the flaw is computed using the present C-AVM and numerical differentiation $\Delta B/\Delta h$. The thickness h is set to 1 [mm]. The whole system including the air region is subdivided into 102,580 tetrahedral elements with 123,555 unknowns. The derivative $\partial[K]/\partial p_k$ in (17) is computed using finite difference. The numerical results are summarized in TABLE I. It is clear that the finite difference $\Delta B/\Delta h$ approaches dB/dh computed by C-AVM as Δh decreases.

TABLE I
COMPARISON OF RESULTANT SENSITIVITY

method	C-AVM	finite difference		
Δh [mm]	-	0.02	0.01	0.005
dB/dh	0.01297	0.01209	0.01214	0.01279

IV. CONCLUSIONS

In this paper, C-AVM has been presented and applied to sensitivity analysis. The sensitivity obtained by C-AVM is shown to be accurate. In the long version, sensitivity analysis containing more parameters will be presented. Moreover, identification of flaws based on C-AVM will be discussed.

New Method Analysis of Non-rotating Magnetoacoustic Tomography with Magnetic Induction

Yang Zhang¹, Guoqiang Liu¹, Baodong Bai², Dexin Xie²

¹ Research Department of Frontiers, Electrical Engineering Institute of Chinese Academy of Sciences, China

² School of Electrical Engineering, Shenyang University of Technology, China

Abstract—A new image reconstruction method of magnetoacoustic tomography with magnetic induction (MAT-MI) is described. It breaks through some illogical supposes that the existing methods applied and can improve the spatial resolution of the image available. Besides it can avoid rotating the static magnetic field which is very difficult to come true in application, therefore the development of MAT-MI technique can be promoted greatly. To test the validity of the new method, a test model is analyzed, and the availability of the method is demonstrated.

I. INTRODUCTION

Magnetoacoustic tomography with magnetic induction (MAT-MI) is bring forward by B He etc. in 2003. It is the combination of Electromagnetic tomography (EMT) and ultrasonic tomography, so it combines the good contrast of EMT with the good spatial resolution of ultrasonic tomography^[1]. Compared with other electromagnetic tomography techniques, MAT-MI has several unique features. Firstly, it has no shielding effect, that is it will not be affected by the low-conductivity layer of the tissue at/near the surface of the human body. Secondly, for the eddy current which produces the Lorentz force distributes throughout the imaging body, so the ultrasonic waves which take valid information of magnetic parameter character are abundant accordingly, and this is the main reason why the spatial resolution of MAT-MI is good^[2].

Image reconstruction algorithm is the key problem of MAT-MI, but the existing algorithms are not perfect. They either need to adopt some illogical approximate hypothesis which will decrease the quality of the reconstructed image greatly, such as looking the time varying impulse as a step one and supposing the distribution of object is piecewise, or need to rotate the static magnetic field which is very difficult to come true in application, and these baffle the improvement of MAT-MI greatly. Therefore new image reconstruction algorithms of MAT-MI technique are needed especially.

Refer to the reconstruction method of magnetic resonance electrical impedance tomography (MREIT) which apply the single component of magnetic induction intensity to reconstruct the distribution of electromagnetic parameters^[3], the author bring forwards a new image reconstruction method of MAT-MI technique. Through substituting the single component of the divergence of Lorentz force density, the new method can not only break through the illogical supposes, but also can avoid rotating the static magnetic field and solve the choke point of MAT-MI. Besides, the method applies the transient field analysis method to take into account the electromagnetic effect produced by the time-varying excitation. Therefore, it can

improve the trueness of the image, and can also promote the development of MAT-MI effectively.

II. FORMULATIONS

For MAT-MI, the object is in a static magnetic field and a time-varying magnetic field. The time-varying magnetic field induces an eddy current in the object. Consequently, the object will emit ultrasonic waves through the Lorentz force produced by the combination of the eddy current and the static magnetic field. The ultrasonic waves are then collected by the detectors located around the object. Then, through the image reconstruction the image which can reflect the tissue's electromagnetic parameters can be reconstructed.

The process of image reconstruction is very important, and this process can be divided into two steps. In the first step, the divergence of Lorentz force's density distribution will be reconstructed from sound pressure through the analysis of sound field reverse problem. In the second step, the distribution of electromagnetic parameters will be reconstructed from the divergence of Lorentz force density through the analysis of electromagnetic field reverse problems. The first step can be accomplished with the back-projection algorithm, and it is mature comparatively. The second step is more challenging. To avoid rotating the static magnetic field, in the new method we apply the method of substituting the single component of the divergence of Lorentz force density. Beside, to improve the trueness of the image reconstruction, we apply the transient field analysis method to take into account the effect of the time-varying excitation.

Because the reverse problem of electromagnetic field is based on the forward one, so at first the formulations of forward problem will be introduced.

A. Forward problem of electromagnetic field

The field equation system with $A-\phi, A$ formulations with the Coulomb gauge can be given as:

$$\begin{cases} \nabla \times \frac{1}{\mu} \nabla \times A = -\sigma \left(\frac{\partial A}{\partial t} + \nabla \phi \right) \\ \nabla \cdot \left[\sigma \left(\frac{\partial A}{\partial t} + \nabla \phi \right) \right] = 0 \end{cases} \quad (1)$$

Where, A is the magnetic vector potential with or without ϕ , the electric scalar potential, μ and σ are the magnetic reluctivity and conductivity respectively.

In the forward problem of electromagnetic field, the known quality is the distribution of σ , and the calculating target is the divergence of Lorentz force density $\nabla \cdot (\vec{J} \times \vec{B})$.

To ensure the symmetrical characteristics of equation coefficient matrix, φ is introduced, where $\phi = \frac{\partial \varphi}{\partial t}$, and the matrix form of the transient field equation can be given as

$$[K]\{A\} + [D]\frac{\partial}{\partial t}\{A\} = \{F\} \quad (2)$$

Where, K, D are coefficient matrices of the field equation, and F is the known quantity matrices of source.

Formulation (2) can be solved by Runge-Kutta methods, and according to the corresponding relation, B and J can be calculated, and then the divergence of Lorentz force density $\nabla \cdot (\vec{J} \times \vec{B})$ at each time step can be obtained accordingly.

B. Inverse problem of electromagnetic field

In the inverse problem of electromagnetic field, the known quality is the divergence of Lorentz force density $\nabla \cdot (\vec{J} \times \vec{B})$, and the calculating target is the distribution of σ .

Through calculating we find that comparing with the static magnetic field the time-varying magnetic field and the magnetic field produced by the eddy current is small enough to be neglected, so the divergence of Lorentz force density can be regarded as $\nabla \cdot (\vec{J} \times \vec{B}_0)$.

$$\nabla \cdot (\vec{J} \times \vec{B}_0) = \vec{B}_0 \cdot (\nabla \times \vec{J}) = \vec{B}_0 \nabla \times \vec{J} \Big|_z \quad (3)$$

For B_0 is a constant we known, so $\nabla \times \vec{J} \Big|_z$ can be obtained.

Besides formulation (1), σ and A also satisfy the following equation,

$$\left(\nabla \sigma \times \frac{\partial \vec{A}}{\partial t} \right) \Big|_z + (\nabla \sigma \times \nabla \phi) \Big|_z + \sigma \nabla \times \frac{\partial \vec{A}}{\partial t} \Big|_z = -\nabla \times \vec{J} \Big|_z \quad (4)$$

Through iterative calculating between formulation (1) and (4), the distribution of σ can be reconstructed.

III. APPLICATION

To verify the availability of the new method, a test model is analyzed. There are two coils and a conductive object which composed by 16 blocks with different conductivity in the model. The subdivision of the model is shown in Fig.1. When an impulse current which the max value is 98.71A and the actuation duration is 5.2us is added to the coils, a transient changed magnetic field will be induced accordingly, and in the conductive object area the magnetic field is homogeneous spatially. Magnetic induction intensity B together with the eddy current J and Lorentz force density $J \times B$ are calculated. The curves of the calculated results of 3 sample points are shown in Fig.2-4, and the image of σ distribution is shown in Fig.5.

Fig.1 Subdivision of the model

IV. CONCLUSION

A new image reconstruction algorithm of MAT-MI is presented in this paper. Through substituting the single component of the divergence of Lorentz force density, the problem of rotating static magnetic field can be solved availably, therefore the application of MAT-MI technique will be promoted. Besides, the transient magnetic field analysis is used to take into account the effect of the time-varying excitation, and accordingly the quality of image can be improved effectively. A test model is analyzed to test the availability of the new method. The detailed comparison of the numerical results with the measured ones will be described in the full paper.

Abstract—The performance of a magnetic brake is calculated by a cross-sectional model where stator and air-gap are discretized by finite elements whereas the nonlinear ferromagnetic rotor is discretized by spectral elements in order to guarantee a sufficient resolution of the thin eddy-current layers.

I. INTRODUCTION

Magnetic brakes and solid-rotor induction machines generate eddy currents in their rotors, which on their turn cause an accelerating or braking torque. Many devices have a rotor which is uniform in the direction of motion. Then, an Eulerian formulation may be more convenient than a Lagrangian formulation [1]. Eulerian formulations, however, suffer from spurious oscillations of numerical nature when high velocities are applied. These can be suppressed by upwinding, possibly in combination with adaptive mesh refinement. Nevertheless, FEs are cumbersome for resolving the thin eddy-current layers arising at high speeds, especially when a higher accuracy is required, e.g., when high saturation levels are attained in the eddy-current layer. In this paper, the rotating rotor is discretized by spectral elements (SEs), which is embedded in an overall FE model.

II. EULERIAN FORMULATION AND FE DISCRETIZATION

Here, the motional eddy currents are simulation by a time-harmonic, Eulerian magnetoquasistatic formulation in terms of the magnetic vector potential \mathbf{A} :

$$\nabla \times (\nu \nabla \times \mathbf{A}) - \sigma \mathbf{v} \times \nabla \times \mathbf{A} + j\omega \sigma \mathbf{A} = \mathbf{J}_s \quad (1)$$

with ν the reluctivity, σ the conductivity, ω the angular frequency, \mathbf{v} the velocity and \mathbf{J}_s the applied current density. In the standard 2D FE discretization

$$\underbrace{(\mathbf{K}_{fe} + \mathbf{L}_{fe} + j\omega \mathbf{M}_{fe})}_{\mathbf{A}_{fe}} \mathbf{u}_{fe} = \mathbf{f}_{fe}, \quad (2)$$

\mathbf{K}_{fe} , \mathbf{L}_{fe} and \mathbf{M}_{fe} are the discrete counterparts of the operators in (1), \mathbf{f}_{fe} are the discretized applied currents and \mathbf{u}_{fe} is a vector of the degrees of freedom (DOFs) for the z -component A_z of \mathbf{A} . The solution of (2) may turn out to be inaccurate when the FE mesh does not resolve the *motional skin depth* $\delta_m = \nu/(\sigma|\mathbf{v}|)$ [1]. Then, the solution may exhibit spurious oscillations which, on their turn, hamper the error-estimation and adaptive-mesh-refinement procedure [2]. Typically, an upwinding technique is applied to overcome this problem [3]. The simplest scheme consists of adding *artificial diffusion*, i.e., increasing ν such that locally the expected motional skin depth exceeds the mesh size. The slightly better *streamline diffusion*

Fig. 1. Convergence of a FE model with uniform mesh refinement, a FE model with error-controlled adaptive mesh refinement and a combined FE-SE model with uniform mesh refinement.

technique adds an anisotropic diffusion term only along the direction of motion. The *streamline-upwind Petrov-Galerkin* (SUPG) technique does not change the model but applies modified test functions for discretization [4]. The convergence of discretization error for a FE-SUPG model with several error-controlled refinement strategies is shown in Fig. 1.

III. SE DISCRETIZATION

The moving part of the model is a hollow cylinder with inner radius r_1 and outer radius r_2 . For such a regular domain, a superior convergence of the discretization error is expected when orthogonal functions are used for discretizing A_z [5]–[7]. The (r, θ) -domain $[r_1, r_2] \times [0, 2\pi[$ is mapped onto the (s, θ) -domain $[-1, 1] \times [0, 2\pi[$ by $s = \frac{1}{e_m} \ln \frac{r}{r_m}$ with $r_m = \sqrt{r_1 r_2}$ the mean radius and $e_m = \ln \sqrt{r_2/r_1}$ a form factor. The corresponding mapping of (1) reads

$$\frac{1}{e_m^2} \frac{\partial}{\partial s} \left(\nu \frac{\partial A_z}{\partial s} \right) + \frac{\partial}{\partial \theta} \left(\nu \frac{\partial A_z}{\partial \theta} \right) - \sigma \omega_m r^2 \frac{\partial A_z}{\partial \theta} = 0 \quad (3)$$

with ω_m the angular velocity. The z -component of the magnetic vector potential is discretized by Chebyshev polynomials $T_q(s)$ in s -direction and harmonic functions $e^{-j\lambda\theta}$ in θ -direction, i.e.,

$$A_z(s, \theta) = \sum_{q \in \mathcal{Q}} \sum_{\lambda \in \Lambda} \alpha_{q,\lambda} T_q(s) e^{-j\lambda\theta} \quad (4)$$

where $\alpha_{q,\lambda}$ are the DOFs and \mathcal{Q} and Λ denote the set of orders of the Chebyshev polynomials and the harmonic functions,

Fig. 2. FE mesh (stator and air gap) and SE grid (rotor) discretizing a four-pole magnetic brake.

respectively. In practice, a tensor-product grid combining the Chebyshev-point distribution along s with an equidistant distribution along θ is constructed (Fig. 2). The values for A_z at the grid points serve as DOFs \mathbf{u}_{se} in the formulation. The collocation of the residual of (3) at the grid points leads to the matrix formulation

$$\underbrace{(\mathbf{L}_s \mathbf{M}_\nu \mathbf{L}_s + \mathbf{L}_\theta \mathbf{M}_\nu \mathbf{L}_\theta - \sigma \omega_m \mathbf{R}^2 \mathbf{L}_\theta)}_{\mathbf{A}_{se}} \mathbf{u}_{se} = 0; \quad (5)$$

$$\mathbf{L}_r = \frac{1}{\epsilon_m} \mathbf{D}_s \otimes \mathbf{I}_{|\Lambda|}; \quad \mathbf{L}_\theta = \mathbf{I}_{|\Omega|} \otimes \mathbf{D}_\theta, \quad (6)$$

The matrix factors in (5) and (6) mimic the operators in (3). The Kronecker products in (6) resemble the tensor-product grid structure. \mathbf{D}_s and \mathbf{D}_θ are fully populated first-order differentiation matrices along the s - and θ -direction respectively [8]. \mathbf{R} and \mathbf{M}_ν are diagonal matrices with the radii and reluctivities at the collocation points. The exponential convergence behavior of this SE formulation has been shown in [7]. The Newton linearization of (5) will be documented in the full paper.

IV. COUPLING

Both formulations are coupled at the circular rotor-air-gap interface Γ (Fig. 2). A partial FE model is built by omitting the rotor part and imposing homogeneous Neumann boundary conditions at Γ . The DOFs allocated at nodes of Γ are selected by the operators \mathbf{Q}_{fe} and \mathbf{Q}_{se} respectively. The coupled system of equations reads

$$\begin{bmatrix} \mathbf{A}_{fe} & \mathbf{0} & \mathbf{Q}_{fe}^T \\ \mathbf{0} & \mathbf{A}_{se} & -\mathbf{Q}_{se}^T \\ \mathbf{Q}_{fe} & -\mathbf{Q}_{se} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \mathbf{u}_{fe} \\ \mathbf{u}_{se} \\ \mathbf{v}_{lg} \end{bmatrix} = \begin{bmatrix} \mathbf{f}_{fe} \\ \mathbf{0} \\ \mathbf{0} \end{bmatrix} \quad (7)$$

where \mathbf{v}_{lg} contains n_Γ Lagrange multipliers corresponding to the n_Γ nodes at Γ . The third row of (7) imposes the continuity of A_z , which is equivalent to the normal continuity of the magnetic flux density. The terms $\mathbf{Q}_{fe}^T \mathbf{v}_{lg}$ and $-\mathbf{Q}_{se}^T \mathbf{v}_{lg}$ can be interpreted as surface currents at Γ , which cancel out each other and, hence, ensure the tangential continuity of the magnetic field strength. It would be possible to eliminate the DOFs at one side of Γ at the expense of a fill-in in \mathbf{A}_{fe} or \mathbf{A}_{se} . Here, however, the saddle-point system (7) is kept in order to preserve the different structure of both matrices. The coupled system of equations is solved by the Bi-Conjugate

Fig. 3. Magnetic flux lines for the results of (a) the linear comparative simulation and (b) the nonlinear simulation at a velocity of 100 rad/s.

Gradient Stabilized (BiCGStab) method [9] and preconditioned by incomplete LU-factorization. The convergence of the discretization error for the coupled method is demonstrated in Fig. 1. The convergence order is determined by the FE discretization of the stator and rotor domains and is, therefore, the same as for the full FE case. The convergence factor is substantially lower because of the better resolution of the SE discretization.

V. EXAMPLE

The coupled method is applied to a magnetic brake (Fig. 2). This model is used to illustrate the convergence of the different discretizations for a velocity of 100 rad/s in Fig. 1. The magnetic flux lines are shown in Fig. 3. The linear calculation is technically irrelevant and serves only for comparison. The ferromagnetic saturation prohibits high magnetic fluxes at the surface of the cylinder. Hence, the flux is distributed more to the inside of the cylinder, causing a larger effective motional skin depth. This fact motivates the use of a SE scheme offering a high resolution.

VI. CONCLUSIONS

A SE model for a ferromagnetic rotor at high speed circumvents upwinding and alleviates the poor accuracy which is typical for a FE discretization of an Eulerian formulation. The SE model part is embedded in an overall FE model dealing with the remaining parts of a magnetic brake.

Abstract—The modified base functions of element-free Galerkin method generated by weight function control of Moving Least-Squares interpolants are investigated. Moreover, the modified base functions are applied to the numerical code for analyzing shielding current density in high temperature superconductor. The results of computations show that the proposed base functions leads essential phenomena.

I. INTRODUCTION

The critical current density of high temperature superconductor (HTS) is one of the most important parameters of HTSs, and it is necessary to take hold on the critical current density in order to understand the characteristics of the HTS. Therefore, methods for measuring the critical current density of HTS have been desired.

Ohshima *et al.* have proposed the permanent magnet (PM) method for measuring critical current densities [1]. Bringing a permanent magnet closer to an HTS thin film caused the electromagnetic repulsive force acting on the film and the maximum force was approximately proportional to the critical current density. They observed that the critical current density can be determined by measuring the electromagnetic interaction between the magnet and the HTS film. However, the position of point whose current density was measured is uncertain because the permanent magnets have a width. Moreover, critical current densities were measured at only center of HTSs by the system of permanent magnet method.

The shielding current density in axisymmetric HTS can be determined by solving a system of time-dependent integro-differential equation. The system is discretized by using element-free Galerkin (EFG) method [2] and completely implicit method in (r, θ, z) plane by taking the symmetry axis as z -direction and a nonlinear system is obtained. However, the values of the shielding current density on $r = 0$ are non zero though it should be zero essentially. The reason for the non zero values of the shielding current density will be attributable to the selected functional space of the base functions of EFG [2].

The purpose of the present study is to develop the numerical code for analyzing shielding current density in axisymmetric HTSs and to propose the modified base functions of EFG generated by weight function control of Moving Least-Squares

Fig. 1. The schematic view of the Permanent Magnet method for measuring the critical current density in HTS thin film.

(MLS) interpolants. By using the numerical code, the permanent magnet method is also simulated numerically.

II. AXISYMMETRIC SHIELDING CURRENT ANALYSIS

In this study, the target HTS to measure its critical current density is disk-shaped film; its radius is R and its thickness is $D = 2\varepsilon$, and the area of its circular cross-section is constant along the thickness direction. The schematic view of PM method is shown in Fig. 1. The cylindrical permanent magnet is located above the film whose radius is r_m and whose height is h_m . The film is exposed to the magnetic flux density \mathbf{B} generated by the magnet. The PM method is carried out as follows. The permanent magnet is brought closer to the film at a constant speed then it is raised at the same speed. That is to say, the distance L between the permanent magnet and the surface of the film changed from L_{\max} to L_{\min} and then L_{\min} to L_{\max} . Let τ_0 denote the moving time of the magnet from L_{\max} to L_{\min} .

The problem can be treated as axisymmetric. We assume that the shielding current density does not flow along c -axis because thickness is very thin compared with the radius of HTS (i.e., $R \gg \varepsilon$). Throughout this paper, let us use the cylindrical coordinate (r, θ, z) by taking the symmetry axis of HTS as z -direction.

Under these assumptions, there exists a scalar function $S(r, t)$ such that the shielding current density \mathbf{j} satisfies following equation.

$$\mathbf{j} = \frac{1}{\varepsilon} \nabla S \times \mathbf{e}_z. \quad (1)$$

Here \mathbf{e}_z denotes the unit vector in the z -direction. Using the scalar function $S(r, t)$, the behavior of the shielding current density in HTS can be expressed by the following time-dependent integro-differential equation.

$$\begin{aligned} \mu_0 \frac{\partial}{\partial t} \left(\int_0^R Q(r, r') S(r', t) r' dr' + \frac{S}{\varepsilon} \right) \\ = - \frac{\partial(\mathbf{B}_0 \cdot \mathbf{e}_z)}{\partial t} - (\nabla \times \mathbf{E}) \cdot \mathbf{e}_z, \end{aligned} \quad (2)$$

where μ_0 denotes the magnetic permeability of vacuum. The function $Q(r, r')$ uses the same function as the Ref. [3].

Let us scatter N nodes $0 = r_1 < r_2 < \dots < r_N = R$ on the analytic domain and the boundary for a discretization. As is well known that the base functions of meshless approaches are obtained on an each node by MLS interpolants. In addition, shapes of the base functions are different depending on the selecting weight function of MLS interpolants.

In the present study, we especially select the weight functions that contain r_1 and r_2 in the support R of the functions as following equation so that the delta function property might satisfies at $r = 0$.

$$\begin{aligned} w_1(r) &= \begin{cases} 1; & r \leq r_2, \\ 0; & r > r_2, \end{cases} \\ w_2(r) &= \begin{cases} 1; & r \leq r_2, \\ f(r, R); & r > r_2, \end{cases} \\ w_i(r) &= \begin{cases} f(r, |r_i - r_2|); & r \leq r_i, |r_i - r_2| \leq R, \\ f(r, R); & r > r_i, |r_i - r_2| \leq R. \end{cases} \end{aligned}$$

Here, function $f(r, \tilde{r})$ is denoted by following equation.

$$f(r, \tilde{r}) = \begin{cases} \frac{e^{-r^2} - e^{-\tilde{r}^2}}{1 - e^{-\tilde{r}^2}}; & r_i \leq \tilde{r}, \\ 0; & r_i > \tilde{r}. \end{cases} \quad (3)$$

In order to vanish the value of the derivative of the base functions at $r = 0$, the components of which constitute base functions of polynomial are defined as follows.

$$\mathbf{p} = \begin{cases} [1, r^2]^T; & r < r_2, \\ [1, r]^T; & \text{other wise.} \end{cases} \quad (4)$$

Following the standard manner of MLS interpolants, we can obtain modified base functions of EFG method. In Fig.2, we show the base functions of EFG. The inset indicate the weight functions for these base functions. This figure indicates that gradients of the base functions become zero at $r = 0$. That is to say, the derivative of the base functions at $r = 0$ satisfies $d\phi/dr = 0$.

Fig. 2. The base functions of EFG. The inset denotes the modified weight functions of MLS interpolants.

Fig. 3. The spatial distributions of the shielding current density of θ component in case of $j_c = 1.0$ MA/cm², $r_m = 2.5$ mm. Here j_c denotes the critical current density. A: $t/\tau_0 = 1/5$, B: $t/\tau_0 = 2/5$, C: $t/\tau_0 = 3/5$, D: $t/\tau_0 = 4/5$.

III. SHIELDING CURRENT ANALYSIS

The governing equation (2) and its associated conditions can be discretized by using EFG with modified base functions and the numerical code has been developed. The shielding current density in HTS thin film can be determined at any time step by the numerical code.

The spatial distributions of the shielding current density of θ component j_θ in the HTS are also obtained by the code and are shown in Fig. 3. We can see from this figure that the shielding current density rapidly flows to the vicinity of the center of HTS as the magnet approaches HTS. Note that the shielding current density at $r = 0$ becomes zero in both cases because of proposed base functions.

Interior Penalty Discontinuous Galerkin Method for the Time-Domain Maxwell's Equations

Stylianos Dosopoulos and Jin-Fa Lee
dosopoulos.1@osu.edu

Abstract— Discontinuous Galerkin(DG) methods support elements of various types, non-matching grid and varying polynomial order in each element. In DG methods continuity at element interfaces is weakly enforced with the addition of proper penalty terms on the variational formulation commonly referred to as numerical fluxes. An interior penalty DG method for solving the two first order Maxwell's equations in the time domain is presented. The proposed method is explicit and conditionally stable. In addition, a local time-stepping strategy is applied to increase efficiency and reduce the computational time.

I. INTRODUCTION

Discontinuous Galerkin(DG) finite element methods offer an alternative to FDTD for time-domain simulations and were recently applied for the solution of Maxwell's equations[1]. Moreover, they provide great flexibility since they allow for various shapes of elements, non-conformal meshes, non-uniform degrees of approximation. Furthermore, the resulting mass matrix is a block diagonal matrix with the block size equal to the degrees of freedom in the element. Therefore, the method can lead into a fully explicit and conditionally stable time-marching scheme. In addition, information exchange is required only between neighboring elements which is suitable for parallelization. In addition, a local time-stepping strategy [3] is necessary to reduce the computational time in multi-scale problems. Moreover, in this work we present a memory efficient implementation. Finally, validation of the method is presented through numerical examples.

II. FORMULATION

A. Original Boundary Value Problem(BVP)

We consider the time-dependent Maxwell's equations in three dimensions.

$$\begin{aligned}\nabla \times \mathbf{E} &= -\mu \frac{\partial \mathbf{H}}{\partial t} & \text{in } \Omega \\ \nabla \times \mathbf{H} &= \frac{\partial \mathbf{E}}{\partial t} & \text{in } \Omega\end{aligned}\quad (1)$$

On the boundary $\partial\Omega$ of the domain Ω we apply metallic or absorbing boundary conditions.

B. DGTD Formulation-Spatial Discretization

Let Ω be the computational domain of interest and T_h the discretization of Ω into tetrahedra K . Denote by F_h the set of all faces. Assuming that the material properties are constant within each element we can then proceed to define the following finite-dimensional discrete trial space

$V_h^k = \left\{ \mathbf{v}, \nabla \times \mathbf{v} \in [L^2(\Omega)]^3 : \mathbf{v}|_K \in [P^k(K)]^3 \right\}$. The interior

penalty discontinuous Galerkin method can be written as:

Find $(\mathbf{w}, \mathbf{v}) \in V_h^k \times V_h^k$ such that

$$\begin{aligned}\int_{\Omega} \mathbf{w} \cdot \left(\nabla \times \mathbf{v} + \frac{\mu \partial \mathbf{w}}{\partial t} \right) d\Omega - \int_{\Omega} \mathbf{v} \cdot \left(\nabla \times \mathbf{w} - \frac{\varepsilon \partial \mathbf{v}}{\partial t} \right) d\Omega \\ + \int_{F_h} \{ \{ \mathbf{v} \} \} \cdot [\mathbf{w}] dS - \int_{F_h} \{ \{ \mathbf{w} \} \} \cdot [\mathbf{v}] dS \\ - e \int_{F_h} [\mathbf{v}] \cdot [\mathbf{v}] dS - f \int_{F_h} [\mathbf{w}] \cdot [\mathbf{w}] dS = 0.\end{aligned}\quad (2)$$

where $\gamma_\tau(\mathbf{u}_i) = \mathbf{n}_i \times \mathbf{u}_i$, $\pi_\tau(\mathbf{u}_i) = \mathbf{n}_i \times \mathbf{u}_i \times \mathbf{n}_i$ and $\{ \{ \mathbf{u}_i \} \} = (\pi_\tau(\mathbf{u}_i) + \pi_\tau(\mathbf{u}_j)) / 2$, $[\mathbf{u}_i] = \gamma_\tau(\mathbf{u}_i) + \gamma_\tau(\mathbf{u}_j)$.

Finally, $e = \frac{1}{2Z_\Gamma}$ and $f = \frac{1}{2Z_\Gamma}$ with $Z_\Gamma = \frac{1}{2} \left(\sqrt{\frac{\mu_i}{\varepsilon_i}} + \sqrt{\frac{\mu_j}{\varepsilon_j}} \right)$ and

$$Y_\Gamma = \frac{1}{2} \left(\sqrt{\frac{\varepsilon_i}{\mu_i}} + \sqrt{\frac{\varepsilon_j}{\mu_j}} \right).$$

C. DGTD Formulation-Time Discretization

Within each element the electric and magnetic fields are expanded in terms of trial functions in V_h^k . Thus, the following semi-discrete system of coupled differential equations is obtained:

$$\begin{aligned}\mathbf{M}_\varepsilon \frac{\partial \mathbf{e}}{\partial t} &= \mathbf{S}_\varepsilon \mathbf{h} - \mathbf{F}_\varepsilon \mathbf{h} - e \mathbf{P}_\varepsilon \mathbf{e} \\ \mathbf{M}_\mu \frac{\partial \mathbf{h}}{\partial t} &= -\mathbf{S}_\mu \mathbf{e} + \mathbf{F}_\mu \mathbf{e} + f \mathbf{P}_\mu \mathbf{h}\end{aligned}\quad (3)$$

where \mathbf{e} and \mathbf{h} are the time dependent coefficient vectors for the electric and magnetic field respectively. The above system is discretized in time with a leap-frog scheme. The electric field unknowns are evaluated at $t_n = n\delta t$ and the magnetic field unknowns are evaluated at $t_{n+1/2} = (n+1/2)\delta t$. The first derivatives are approximated using central differences. The fully discretized update equation then becomes

$$\begin{aligned}\mathbf{e}^{n+1} &= \tilde{\mathbf{B}}\mathbf{e}^n + \tilde{\mathbf{C}}\mathbf{h}^{n+1/2} \\ \mathbf{h}^{n+3/2} &= \tilde{\mathbf{E}}\mathbf{h}^{n+1/2} + \tilde{\mathbf{F}}\mathbf{e}^{n+1}\end{aligned}\quad (4)$$

III. LOCAL TIME STEPPING

The resulting update scheme a mentioned above is explicit and conditionally stable. The stability condition is [2]:

$c_i \delta t \left[2\alpha_i + \beta_{ik} \max \left(\sqrt{\frac{\mu_i}{\mu_k}} + \sqrt{\frac{\varepsilon_i}{\varepsilon_k}} \right) \right] < \frac{4V_i}{P_i}$ where V_i is the volume of element K_i , $P_i = \sum_j S_j$, (S_i is surface of face i),

$c_i = 1/\sqrt{\varepsilon_i \mu_i}$ and α_i, β_{ik} are dimensionless constants that depend on the order of the basis functions. Note that for higher order basis or locally refined meshes the stability condition provides a very small δt and thus greater CPU time. To reduce the computational time a local time-stepping strategy is applied [3]. The set of elements is partitioned into N classes before the time-marching simulation. The partition is based on the stability condition. For the i^{th} class $\delta t_i = (2m+1)^i \delta t_{min}$. We choose $m=1$ so that each class has a time step three times larger than the previous class. To illustrate the method assume two classes (class 0 class 1) with $\delta t_0 = \delta t_{min}$ and $\delta t_1 = 3\delta t_{min}$. The update scheme is summarized below:

<i>E-Update</i>	<i>H-Update</i>
$\mathbf{e}^{n+1} = \tilde{\mathbf{B}}_1 \mathbf{e}^n + \tilde{\mathbf{C}}_1 \mathbf{h}^{n+1/2}$	$\mathbf{h}^{n+3/2} = \tilde{\mathbf{E}}_1 \mathbf{h}^{n+5/6} + \tilde{\mathbf{F}}_1 \mathbf{e}^{n+1}$
$\mathbf{e}^{n+4/6} = \tilde{\mathbf{B}}_0 \mathbf{e}^{n+2/6} + \tilde{\mathbf{C}}_0 \mathbf{h}^{n+3/6}$	$\mathbf{h}^{n+7/6} = \tilde{\mathbf{E}}_0 \mathbf{h}^{n+5/6} + \tilde{\mathbf{F}}_0 \mathbf{e}^{n+1}$
$\mathbf{h}^{n+5/6} = \tilde{\mathbf{E}}_0 \mathbf{h}^{n+3/6} + \tilde{\mathbf{F}}_0 \mathbf{e}^{n+4/6}$	$\mathbf{e}^{n+8/6} = \tilde{\mathbf{B}}_0 \mathbf{e}^{n+1} + \tilde{\mathbf{C}}_0 \mathbf{h}^{n+7/6}$
$\mathbf{e}^{n+1} = \tilde{\mathbf{B}}_0 \mathbf{e}^{n+4/6} + \tilde{\mathbf{C}}_0 \mathbf{h}^{n+5/6}$	$\mathbf{h}^{n+3/2} = \tilde{\mathbf{E}}_0 \mathbf{h}^{n+7/6} + \tilde{\mathbf{F}}_0 \mathbf{e}^{n+8/6}$

IV. NUMERICAL EXAMPLES

A. Coated Sphere

In this example we calculate the RCS of a coated sphere. The inner radius of the sphere is $a = 1$ m, the outer radius is $b = 1.2$ m and the coating has $\varepsilon_r = 4.0$. The absorbing boundary condition is set one λ at 300 MHz from the coating. The coated sphere is illuminated by a Gaussian pulse $\mathbf{E}^{inc} = \mathbf{E}_0 e^{-[t-t_0 - \mathbf{k} \cdot (\mathbf{r}-\mathbf{r}_0)/c]^2 / \tau^2}$ with $\mathbf{E}_0 = E_x$, $\mathbf{k} = k_z$, $t_0 = 5$ ns and $\tau = 0.6$ ns. From the Fourier transform of the time-dependent electric and magnetic currents on the sphere's surface we can evaluate the RCS at multiple frequencies. Fig.1 illustrates the computed RCS at the frequency of 300 MHz. A good agreement is observed between the numerical solution and the analytical solution.

Figure 1. E- and H-plane RCS(dB) at 300 MHz (blue-DGTD, pink-Mie series).

B. Scattering from a F-16 aircraft

In this example we calculate the RCS of a F-16 aircraft illuminated by a Gaussian pulse with $\mathbf{E}_0 = E_x$, $\mathbf{k} = k_z$, $t_0 = 5$ ns and $\tau = 0.6$ ns. The generated mesh in this case is an unstructured locally refined mesh with strong element-size disparities. In this case $\delta t_{min} = 4.35e-13$ and $\delta t_{max} = 7.98e-11$ which leads into 5 classes and the local time stepping provides a CPU gain of approximately 5 compared to the standard leap-frog scheme. Finally a matrix free implementation was applied to provide better memory efficiency. In this approach there is no assembly and storage of global matrices. The matrix-vector multiplications that are necessary for the update equation are performed in element level using the BLAS library for better performance.

Figure 2. Snapshot of the magnitude of the E field distribution of the Gaussian pulse propagating on the F-16 surface.

Abstract— A finite element method is proposed for an investigation of the bipolar bundled conductor ionized field. A computation program for the corona ionized field analysis was developed in which Deutsch's assumption was waived. The subconductors were considered as separate parts where the mutual impact was included. Each electric field line was initiated from the subconductor surface. The electric field was calculated by adopting the third order interpolating method. Furthermore, a method of estimating the initial space charge density of flux-tubes was introduced and then calculated by using the fourth order Runge-Kutta method. Finally, the computation program was verified and the corona current and related field properties of a $\pm 800\text{kV}$ HVDC transmission line were investigated.

I. INTRODUCTION

Many numerical attempts have been made to evaluate the ionized field associated with single and bundled conductors for monopolar transmission lines [1]-[3].

Some attempts have also been made to solve the bipolar ionized field equations. Sarma developed a method of calculating the electric field for bipolar lines based on Deutsch's assumption first [4]. Later, though Deutsch's assumption is waived, the bipolar ionized field equations were only solved in single conductor-to-plane configurations [5]-[6]. In [7] an integral form of the current continuity equation was used (instead of Poisson's equation) to compute the space potential with a bipolar bundled conductor line in a double circuit.

Al-Hamouz has done much more on the ionized field analysis. The main idea was solving Poisson's equation by using the FEM and calculating the charge density along the flux-tubes divided by field lines in the ionized field. His investigating range varied from monopolar to bipolar, from single conductor to bundled conductor, and to extending the limited boundary to infinity [1, 3, 6, 8]. However, the bipolar and bundled configuration aspects have not been taken into account simultaneously.

In this paper, an iterative FEM based numerical method is developed to solve Poisson's equation for the bipolar bundled conductor. Firstly, the computation process is explained in detail and then it is verified. Finally, the program is used to analyze the corona ionized field of a $\pm 800\text{kV}$ transmission line.

II. DESCRIPTION OF THE BIPOLAR IONIZED FIELD

The bipolar ionized field can be described by a group of equations:

$$\nabla \cdot \vec{E} = (\rho_+ - \rho_-) / \epsilon_0 \quad (1)$$

$$\vec{J}_{\pm} = k_{\pm} \rho_{\pm} \vec{E} \quad (2)$$

$$\nabla \cdot \vec{J}_{\pm} = \mp R_i \rho_{\pm} \rho_{\pm} / e \quad (3)$$

$$\vec{J} = \vec{J}_+ + \vec{J}_- \quad (4)$$

$$\nabla \cdot \vec{J} = 0 \quad (5)$$

where (1) is Poisson's equation; (2) is the equation of the positive and negative current density vectors \vec{J}_{\pm} ; (3) is the equation for \vec{J}_{\pm} continuity; (4) is the equation of the total current density vector \vec{J} ; and (5) is the equation for \vec{J} continuity. \vec{E} is the electric field, k_+ and k_- are the mobilities of positive and negative ions, ρ_+ and ρ_- are the modulus of the positive and negative space charge density values, R_i is the ion recombination coefficient in air, and e is the electron charge.

Using the FEM based numerical approach, with associated boundary and constraint conditions, the above partial differential equations can be solved.

III. PROPOSED ANALYSIS METHOD OF A BIPOLAR BUNDLED CONDUCTOR IONIZED FIELD

A general configuration of a bipolar HVDC transmission line is illustrated in Figure 1. A $\pm 800\text{kV}$ HVDC transmission line is used as an example. The triangular finite element grid is generated from quadrangles produced by the intersection of field lines with equipotential contours. In either the bipolar or monopolar component, the FEM is applied to obtain an evaluation of the nodal potential. The third order interpolating method is then adopted to calculate the electric field.

Fig. 1. Configuration of a $\pm 800\text{kV}$ HVDC transmission line

For the monopolar component, the initial estimation of the space charge density of each field line is:

$$\rho d_{j,k} = \rho_{ej} \cos((\pi - \alpha_k)/2), k = 1, 2, \dots, nd_{sub} \quad (6)$$

$$\rho_{ej} = \rho_e \cos((\pi - \theta_j)/2), j = 1, 2, \dots, n$$

where $\rho d_{j,k}$ is the space charge density in the monopolar component, nd_{sub} is the number of electric field lines in the monopolar component, ρ_{ej} is the value of $\rho d_{j,k}$ at $\alpha_k = \pm\pi$, n is the number of conductor bundles, ρ_e is the value of ρ_{ej} at $\theta_j = \pm\pi$ and can be calculated from an existing formula, and α_k and θ_j are shown in Figure 1.

In addition, the initial space charge density values in the bipolar component are assumed as [8]

$$\rho s_{j,k} = 0.02(\rho d_{j,k}), k = 1, 2, \dots, ns_{sub} \quad (7)$$

where $\rho s_{j,k}$ is the space charge density in the bipolar component, and ns_{sub} is the number of electric field lines in the bipolar component.

The fourth order Runge-Kutta method is then used to evaluate the space charge density of all nodes. The process is repeated until the errors of potential and space charge density calculated in two successive iterations are satisfied with the required accuracy. The errors of potential and space charge density are δ_1 and δ_2 respectively.

Figure 2 shows a block diagram of the solution procedure, where the corona current can be obtained.

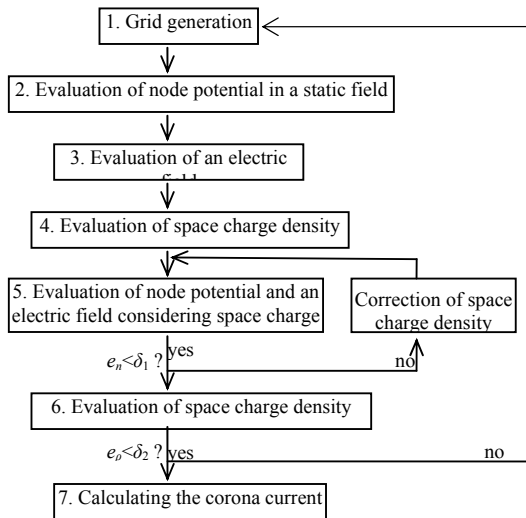

Fig. 2. The solution procedure

IV. VERIFICATION OF REAL ± 500 kV BIPOLAR LINES

In order to verify the proposed numerical program, a ± 500 kV transmission line model with experimental results was used to evaluate the corona ionized field as shown in Figure 3. The computation result (the solid line) was consistent with the experiment result (the star line). Thus, the computation program can be used to validate the ionized field of a bipolar bundled conductor.

Fig. 3. ± 500 kV line ground-plane electric field, the solid line is the calculated result and the star line is the experimental result.

V. RESULTS AND DISCUSSION ON ± 800 kV HVDC TRANSMISSION LINE IONIZED FIELDS

The proposed program is adopted to analyze the corona ionized field of a ± 800 kV HVDC transmission line. The configuration is shown in Figure 1. The algorithm converges in three mesh generations, each with 13 iterations for the HVDC models. The errors of δ_1 and δ_2 are less than 0.5%. The corona current, ground electric field and ground current density are calculated for a ± 800 kV HVDC transmission line.

VI. CONCLUSION

(1) The proposed FEM based numerical method is effective for calculating the ionized field of a bipolar bundled conductor.

(2) An increase in the number of bundles decreases corona current, while an increase in bundle spacing increases corona current. If the monopolar component is not included, the corona current will be overestimated. The ground electric field and ground current density of the present ± 800 kV HVDC transmission line is less than 30kV/m and 100nA/m² respectively.

(3) The computation program can be used as an effective numerical tool for evaluating the electromagnetic environment around the HVDC transmission line.

Abstract—Chip based multi-core processors (CMP) raise the possibility of significant improvement in the performance of electromagnetic simulation tools. They can impact the mesh generation, solution and result evaluation phases. This paper investigates the parallelization and scalability of Gauss-Seidel on CMP by using a new cache blocking technique to overcome the small cache problem while using a thread synchronization technique for better cache sharing and to maximize thread cycle utilization.

I. INTRODUCTION

The computer-based simulation of an electromagnetic field problem using a differential technique such as finite differences or elements consists of several phases which are computationally intensive and have complexities which can be beyond linear. These include mesh generation, equation solution and result evaluation. The introduction of chip-based multi-core processors (CMP), both within the main CPU and as part of high performance graphics systems, provides the possibility of significant speedups over the existing single core systems. Each phase of the simulation system presents its own challenges to parallelization. This paper is targeted at the equation solution phase.

In a differential method, the equation sets produced are both large and sparse and their solution has been the subject of considerable research over the last four decades and, for many problems, the algorithm of choice at present is the Incomplete Choleski-Congugate Gradient approach which has a complexity of approximately $O(N^{1.5})$. This is, however, a predominantly sequential algorithm optimized for a single processor machine. It is not obvious that this is an ideal algorithm for the new generation of processors and thus it is worth revisiting a range of solver algorithms and to re-examine their performance on the new architectures.

II. PROCESSOR ARCHITECTURE AND SOLVERS

One of the key issues in considering an algorithm for a multi-core system is the architecture of the processor. This must be considered as the given environment and the goal is to find an efficient algorithm for this architecture, not develop an effective architecture for a particular parallel algorithm. Most multi-core machines have been designed to handle several relatively small tasks in parallel – not to divide one large task amongst the processors which is the case for multiprocessor based computers. Although CMP has the advantage of low inter-thread communication and synchronization due to cache sharing, the cache memory is small relative to the

computational power of the cores and the amount of cache available for each core is limited. In addition, the memory bandwidth between the cores and the main system memory is relatively small. Consequently, the ideal algorithm for this architecture is one which can allow for the equation set to be broken up between the cores and to maximize the utilization of the equation set present in the cache.

In recent years, the high performance computing community has been revisiting both currently and long abandoned numerical methods to gain performance in solving large system of linear equations. In this paper, we investigate the speedup of a parallel Gauss-Seidel algorithm on a CMP. As a preliminary test of the algorithm, it is applied to the structured linear system of equations resulting from the finite difference solution of a parallel plate capacitor.

Iterative methods, such as Jacobi and Gauss-Seidel, have been investigated on parallel systems. The main concern was to reduce the synchronization points between processors leading to schemes known as chaotic or relaxation schemes [1] which are not suitable for implementation on a CMP.

The performance of parallel Gauss-Seidel as a multi-grid smoother on CMP has also been investigated in [2], where cache blocking [3], a technique to reuse data in cache, was used to decrease cache misses, hence increasing performance. It was used in conjunction with red-black and natural reordering techniques of the problem - techniques used on parallel systems where synchronization is expensive. However, a strong order of execution was imposed on threads, leading to lower thread execution time relative to thread waiting time.

It appears that, for larger problems, the gap between the slow data access due to a small cache relative to the high number of flops available is higher on CMP than other hardware architectures. For this reason, we used a more execution time hungry threading approach together with a cache blocking technique to solve the system of linear equations. Synchronized pipelined threading techniques, i.e. a producer-consumer model, [4], are used to provide better communication and synchronization between threads and to provide fair cache sharing and partitions between cores of the CMP.

III. METHODOLOGY

Gauss-Seidel is an iterative method used to solve a large sparse linear system of equations $AX = b$. The method is expressed in (1) for $A_{n \times n}$ matrix.

$$X_i^{(\Gamma+1)} = \frac{1}{a_{ii}} \left(b_i - \sum_{j<i} a_{ij} X_j^{(\Gamma+1)} - \sum_{j>i} a_{ij} X_j^{(\Gamma)} \right) \quad (1)$$

$i = 1, 2, 3, \dots, n$ and $j = 1, 2, 3, \dots, n$

Let S_{ss*n} be a sub block of matrix A_{n*n} , where ts is the total number of sub blocks and p is a sub-block index indicator

$$A_{n*n} = \bigcup_{p=1}^{ts=n/ss} S_{ss*n}^p \quad (2)$$

Let W_{w*n} be a block that is constructed from 1, 2, 3, ..., or N contiguous sub blocks S_{ss*n} and q is a block index indicator

$$W_{w*n}^q = \bigcup_{p=q}^{q+N} S_{ss*n}^p \quad (3)$$

Let T = the number of blocks to apply Gauss-Seidel on simultaneously or the number of threads

Let $\mathfrak{B}_r = \{W_{w*n}^q\}$ be a set of contiguous T blocks from A_{n*n} , where

$$\bigcap_{q=r}^{r+T} W_{w*n}^q = \emptyset \quad (4)$$

The matrix A_{n*n} is divided into ts blocks that are queued into Q as shown in Fig.1. At every new iteration Γ , a sub block S_{ss*n} is passed from Q to the first thread and subsequently each thread passes its last sub block S_{ss*n} to the next thread or back to Q . Threads communicate through buffers to avoid resource locking and contention. Each thread applies Gauss-Seidel on its correspondent element in \mathfrak{B}_r , updates its local solution x_w and has a read only access to the global solution X_n . Since threads have the same data size at each iteration, they will reach the synchronization point almost simultaneously before proceeding to the next iteration leading to a minimal thread waiting time.

Fig. 1. Synchronized Producer-Consumer model

IV. SIMULATIONS AND RESULTS

We ran our algorithm on a 10000x10000 sparse system of equations, using different combinations of block, W , and sub-block, S , sizes. We calculated thread cycle utilization as the ratio of thread execution time to thread waiting time. The results were compared to a single thread execution of the algorithm ($W=10000$ and $S=10000$). As can be seen in Fig.2, the speedup when using smaller W and S was super linear for 4 threads and less on a Quad-Core CMP machine with 2*2MB cache. Another observation is that there was a relatively high speedup, slightly sub linear, even when the number of threads exceeded the number of cores of the CMP. To further illustrate those results, Fig.3 shows the effect of increasing thread

numbers on speedup, thread utilization, and convergence rate when $W=500$, $S=100$. We notice that convergence rate is essential to speedup and thread utilization greatly impacts the speedup (between 6 and 8 threads) for this particular problem.

V. CONCLUSION AND EXTENDED WORK

We conclude that speedup can be achieved even when using more threads than the number of cores. Cache blocking affects convergence; however, maximizing thread utilization is important. In the full paper, the performance of the algorithm on an unstructured mesh produced by an FEM code will be examined. In addition, the use of a GPU(Graphics Processing Unit) to accelerate the calculation at each iteration on each block will be investigated.

Fig.2 Speedup for different block W and sub-block S sizes

Fig.3 Comparing the effect of increasing thread numbers from 2 on speedup, thread utilization and convergence rate when $W=500$, $S=100$

Abstract—In finite-element analysis, high-quality meshes are necessary to provide good conditioning of the system. It minimizes errors and avoid singularities that might arise. However, most triangle meshes can hardly be called satisfactory without any kind of post-processing to improve their intrinsic qualities. This work presents an effective and efficient algorithm to improve the quality of surface meshes representing models generated by the application of the Boolean and assembly operations to predefined primitives, like spheres and blocks; and also models obtained from surface reconstruction.

I. INTRODUCTION

Many researchers are investigating ways to automate the finite-element method (FEM), thus allowing improved productivity, more accurate solutions, and use by less trained personnel. Often the most time consuming and experience requiring task faced by an analyst is the discretization of the general geometric definition of a problem into a valid and well conditioned finite-element mesh. For complex geometries, the time spent on geometry description and mesh generation are the pacing items in the computational simulation cycle.

Automatic generation of consistent, reproducible, high quality meshes without user intervention makes the power of the finite element analysis accessible to those not experts in the mesh generation area. Therefore, tools for an automated and efficient mesh generation are important prerequisites for the complete integration of the FEM with design processes in CAD, CAE, and CAM systems.

Most of the research on development of fully automatic unstructured mesh generators has been concentrated on various triangulation schemes. The advantage of them lies in the fact that simplicial elements (triangles and tetrahedra) are most suitable to discretize domains of arbitrary complexity, particularly when locally graded meshes are needed. While the meshing schemes for the discretization of 2D problems matured into very robust and efficient algorithms, there are still many open issues in 3D, including not only theoretical guarantee of convergence, quality bounds but also implementation aspects as robustness and versatility.

The long-term goal for developers of meshing tools is the generation of high quality meshes directly from CAD models, without user intervention.

The main contribution of this paper is to speed up the generation process of high quality finite-element mesh from poor quality initial surface mesh, which can be obtained using a solid modeler [1]; or a surface reconstruction algorithm [2]. Here, the remeshing process driven by a smooth approximation of the mesh vertices is modified to take advantage of the multicore platforms.

II. MODEL GENERATION

Usually, automatic mesh generators can produce surface meshes with a specified quality degree for simple predefined primitives, like spheres, cylinders or prisms. However, to generate models with high complexity two options frequently can be chosen: the application of the Boolean (union, intersection or subtraction) and assembly operations over predefined primitives [1]; or the reconstruction of surfaces by an acquisition process, such as medical imagery, laser range scanners, contact probe digitizers, radar and seismic surveys [2]. Unfortunately, both methods produce surface meshes with a large number of badly shaped elements. For the Boolean and assembly operations, the elements in the intersection areas are usually split into degenerate ones, decreasing drastically the elements quality, as Figure 1 illustrates. The surface meshes with this level of quality cannot be used as input for finite element volumetric mesh generators.

Figure 1. Surface mesh generated by the application of Boolean operations over predefined primitives

Badly shaped triangles also raises in meshes generated by an acquisition process. During the reconstruction process, the algorithm guarantees good approximation for the geometry and topology, but it does not guarantee the triangle shape quality. In many cases, the generated mesh possess a large amount of triangles and many of them are badly shaped, which sometimes makes impracticable the volumetric mesh generation. Figure 2 shows an example of reconstructed mesh.

As consequence, the surface meshes of models generated by: the application of the Boolean and assembly

Figure 2. a) Reconstructed surface from a points cloud, b) Zoom In

applications over simple models; or from an acquisition process, should be improved, before being used as input to electromagnetic simulation by FEM.

III. STRATEGY TO IMPROVE THE SURFACE MESH QUALITY

Generally, tetrahedral mesh generators can add new vertices and edges to a surface mesh, when necessary, to try to generate a volumetric mesh with good quality. Nevertheless, vertices, edges, faces, slits and holes from the input geometric description are constraints that cannot be removed by them. Remeshing is very important to reduce the number of sharp angles, as well as improving the node distribution and their interconnections. Applying a series of local mesh modification operators that can enrich, simplify or locally improve the mesh is a good approach for improving the quality. This approach is known as a mesh adaptation process and works directly on the surface mesh. To avoid losing model geometric characteristics during the process, it is necessary to know the model surface geometry.

Unfortunately, after the surface is reconstructed, only the vertices and their interconnections are known. To overcome the lack of geometric information, an approximation of the model surface geometry is necessary. The surface approximation can control the movements of the vertices and ensure that they stay located on the original model surface during the application of the local mesh modifications. Since our set of points P was sampled from a smooth surface S , approximating them by a smooth surface is straightforward. B-Spline surfaces can give good approximations for a large variety of models, as has been proposed by Nunes et al. in [1]. Each mesh face is approximated by a B-Spline surface patch using the least squares formulation. To evaluate a patch, the vertices of the face we want to approximate and the vertices that surround it are used. The problem then consists of looking for an approximating B-Spline surface patch s , which minimizes:

$$F = \sum_{\tau=0}^{\mu} \|s(u_{\tau}, v_{\tau}) - p_{\tau}\|^2 = \sum_{\tau=0}^{\mu} \left[\sum_{\omega=0}^{\nu} \mathbf{M}_{\omega}(u_{\tau}, v_{\tau})c_{\omega} - p_{\tau} \right]^2 \quad (1)$$

where, c_{ω} are the control points, \mathbf{M}_{ω} are the blending functions and p_{τ} are the vertices around a given face. The model surface approximation is then a collection of overlapping B-Spline patches. Differently of Eck and Hoppe

work [3], this approach avoids the global parametrization. The overlapping set of patches gives a good approximation of the model and provides the necessary geometric information to the local mesh modification operators. The surface mesh is modified iteratively by the operators (edge-swapping, edge-collapsing, edge-splitting and vertex relocation) in order to improve the quality of the mesh elements.

The remeshing algorithm proposed in Nunes et al. in [1] is effective to produce high-quality finite-element meshes, but it is inefficient in time. Its computational cost is proportional to the number of mesh vertices.

We propose two main modifications on the Nunes et al. remeshing process. First, optimize the choice of the next element for the application of a local mesh modification operator, instead of scanning, in sequence, all edges of the model. This is done by having a priority queue, where the first element has the worst quality factor.

Second, applying parallel computational techniques to the remeshing algorithm. With the development of multi-core machines, parallelization of processes becomes very attractive to reduce the processing time of high computational cost tasks. The step of generating the B-Spline patches that represents the smooth approximation of the model geometry can easily be converted. The necessary information to produce each patch does not change during this step, then it is only necessary to coordinate the patches generation, sending to each core what they need to know. The adaptation process can also be parallelized. The mesh elements should be divided by sectors and each sector can be evaluated by different cores, but it is very important to evaluate carefully the intersection areas to guarantee consistency.

IV. CONCLUSION

An important goal of mesh generation is that the finite-element mesh should be formed by relatively well shaped elements. Elements with small angles may degrade the quality of the numerical solution, because they can make the system of algebraic equations ill-conditioned and this compromises the solution accuracy.

The modified remeshing algorithm obtain significant improvements in the surface mesh quality, without losing the models original features, in a fair amount of time. Optimization and parallel computational techniques are applied to speed up the generation of high-quality finite-element meshes.

Abstract— The dual-reciprocal boundary-node method has been reformulated without using integration cells. In the proposed method, boundary integrals are directly calculated by use of the vector equation of the boundary. The performance of the proposed method has been compared with the dual-reciprocal boundary-element method (DRM). The results of computations show that the accuracy of the proposed method is superior to that of the DRM. In addition, when the number of boundary nodes exceeds a certain limit, the speed of the proposed method becomes almost equal to that of the DRM.

I. INTRODUCTION

Since the boundary-node method (BNM) [1] is one of the meshless methods, the preparation of data is considerably simplified. However, a boundary must be divided into a set of cells to evaluate boundary integrals. In other words, a concept of elements partly remains in the BNM.

On the other hand, the method has been proposed for depicting a three-dimensional object by use of an implicit function [2], [3]. In the method, an implicit-function surface $g(\mathbf{x}) = 0$ is determined from nodes and unit normals on an object surface. Subsequently, the object surface is reconstructed by drawing the surface $g(\mathbf{x}) = 0$. If boundary integrals are evaluated by use of $g(\mathbf{x})$, the demerit of the BNM can be eliminated completely.

The purpose of the present study is to formulate the boundary-node method by using the implicit function $g(\mathbf{x})$ and to compare the performance of the resulting method with that of the dual-reciprocal boundary-element method (DRM).

II. DUAL-RECIPROCAL BOUNDARY-NODE METHOD

As a potential problem, we consider a two-dimensional Poisson problem:

$$-\Delta u = \rho \quad \text{in } \Omega, \quad (1)$$

$$u = \bar{u} \quad \text{on } \partial\Omega, \quad (2)$$

where Ω denotes a region bounded by a simple closed curve $\partial\Omega$. In addition, ρ and \bar{u} are known functions in Ω and on $\partial\Omega$, respectively.

Although (1) can be transformed to an equivalent boundary integral equation, the equation contains not only boundary integrals but also a domain integral. In order to approximate the domain integral as the sum of boundary integrals, we employ the idea of the DRM. In other words, we assume that $\rho(\mathbf{x})$ is written as

$$\rho(\mathbf{x}) = \sum_{l=1}^{N+K} \alpha_l f(|\mathbf{x} - \mathbf{z}_l|/R). \quad (3)$$

Here, $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_N$ are boundary nodes on $\partial\Omega$ whereas $\mathbf{z}_{N+1}, \mathbf{z}_{N+2}, \dots, \mathbf{z}_{N+K}$ are nodes in Ω . Moreover, R and α_l 's are all constants. For the function $f(r)$, we adopt a compactly supported radial basis function $f(r) = H(1-r)(1-r)^3(3r+1)$, where $H(x)$ denotes Heaviside's step function.

Substituting (3) into the boundary integral equation, we get

$$\begin{aligned} & \oint_{\partial\Omega} \frac{\partial w^*(\mathbf{x}(s), \mathbf{y})}{\partial n} [u(\mathbf{x}(s)) - u(\mathbf{y})] ds - \oint_{\partial\Omega} w^*(\mathbf{x}(s), \mathbf{y}) q(\mathbf{x}(s)) ds \\ &= \sum_{l=1}^{N+K} \alpha_l \left\{ \oint_{\partial\Omega} \frac{\partial w^*(\mathbf{x}(s), \mathbf{y})}{\partial n} [\hat{u}_l(\mathbf{x}(s)) - \hat{u}_l(\mathbf{y})] ds \right. \\ & \quad \left. - \oint_{\partial\Omega} w^*(\mathbf{x}(s), \mathbf{y}) \hat{q}_l(\mathbf{x}(s)) ds \right\}, \end{aligned} \quad (4)$$

where $w^*(\mathbf{x}, \mathbf{y}) = -\log|\mathbf{x} - \mathbf{y}|/2\pi$. In addition, \hat{u}_l is a particular solution of $-\Delta \hat{u}_l = f(|\mathbf{x} - \mathbf{z}_l|/R)$ and \hat{q}_l denotes its normal derivative. Furthermore, s indicates an arclength along $\partial\Omega$.

From the standard manner of the BNM, (4) and its associated boundary condition can be discretized to a linear system. By solving the system, we can determine the distributions of u and q on $\partial\Omega$.

III. EXTENDED BOUNDARY-NODE METHOD

A. Vector Equation of Boundary

In the conventional BNM, the boundary $\partial\Omega$ must be divided into a set of cells to evaluate boundary integrals. In this sense, a concept of elements has not been completely removed from the BNM. In the present study, the integrals are directly calculated by use of the vector equation of $\partial\Omega$. In III.A, let us briefly explain the method for determining the vector equation.

First, the implicit-function representation $g(\mathbf{x}) = 0$ is determined for the curve that passes through all boundary nodes, $\mathbf{z}_1, \mathbf{z}_2, \dots, \mathbf{z}_N$, on $\partial\Omega$. Subsequently, we numerically solve the following ordinary differential equation:

$$\frac{d\mathbf{x}}{ds} = \mathbf{R} \left(\frac{\pi}{2} \right) \cdot \frac{\nabla g}{|\nabla g|}, \quad (5)$$

where $\mathbf{R}(\theta)$ denotes a tensor representing a rotation through an angle θ . Apparently, the analytic solution of (5) gives the vector equation $\mathbf{x} = \mathbf{x}(s)$ of the curve $g(\mathbf{x}) = 0$. However, even if the higher-order Runge-Kutta method is applied to (5), the numerical solution $\mathbf{x}^{(n)}$ does not always satisfy $g(\mathbf{x}^{(n)}) = 0$. This

is mainly due to the discretization error. In order to diminish the error, we use the novel algorithm in which $\mathbf{x}^{(n+1)}$ is calculated from $\mathbf{x}^{(n)}$ by use of the following three steps.

- (i) An approximate solution of \mathbf{x}^* at the $(n+1)$ th step is determined by means of the forward Euler scheme:

$$\mathbf{x}^* = \mathbf{x}^{(n)} + \mathbf{R} \left(\frac{\pi}{2} \right) \cdot \left[\frac{\nabla g}{|\nabla g|} \right]_{\mathbf{x}^{(n)}} \delta s.$$

- (ii) For the purpose of determining an intersection of the straight line $\mathbf{x} = \mathbf{x}^* + \lambda (\nabla g)_{\mathbf{x}^*}$ and the curve $g(\mathbf{x}) = 0$, the nonlinear equation $g(\mathbf{x}^* + \lambda (\nabla g)_{\mathbf{x}^*}) = 0$ is solved for λ by using the Newton method.

- (iii) The numerical solution $\mathbf{x}^{(n+1)}$ is calculated as $\mathbf{x}^{(n+1)} = \mathbf{x}^* + \lambda (\nabla g)_{\mathbf{x}^*}$.

Finally, P data points, $\mathbf{x}^{(1)}, \mathbf{x}^{(2)}, \dots, \mathbf{x}^{(P)}$, are interpolated by using the cubic spline and, as a result, the vector equation $\mathbf{x} = \mathbf{x}(s)$ can be numerically determined. By means of the vector equation, boundary integrals can be easily evaluated without any integration cells.

B. Periodic shape functions

If the circumference of $\partial\Omega$ is denoted by L , $\mathbf{x}(s)$ is a periodic function with a period L . Thus, the integrands of boundary integrals become periodic only when the shape functions $\Phi_i(s)$'s have the same periodicity.

By means of the MLS approximation, the periodic shape functions $\Phi_i(s)$'s are easily determined as

$$\Phi_i(s) = \mathbf{p}(s)^T \mathbf{A}^{-1}(s) \mathbf{c}_i(s), \quad (6)$$

where $\mathbf{A}(s)$ and $\mathbf{c}_i(s)$ are given by

$$\mathbf{A}(s) = \sum_{i=1}^N w(d(s, s_i)) \mathbf{p}(s_i) \mathbf{p}(s_i)^T, \quad (7)$$

$$\mathbf{c}_i(s) = w(d(s, s_i)) \mathbf{p}(s_i). \quad (8)$$

Moreover, $d(s, s^*)$ is the distance between $\mathbf{x}(s)$ and $\mathbf{x}(s^*)$ along $\partial\Omega$, and $w(r)$ denotes a weight function. For the m -dimensional vector $\mathbf{p}(s)$, we assume the following type:

$$\mathbf{p}(s)^T = \begin{cases} 1 & ; m = 1, \\ (\cos(2\pi s/L), \sin(2\pi s/L)) & ; m = 2. \end{cases} \quad (9)$$

The above two techniques are incorporated into the method explained in II. Throughout the present study, the resulting method is called the eXtended Boundary-Node Method (X-BNM).

IV. PERFORMANCE OF X-BNM

In this section, we compare the performance of the X-BNM with that of the DRM. To this end, both two methods are applied to a simple Poisson problem. The boundary $\partial\Omega$ is assumed as

$$\partial\Omega = \left\{ \mathbf{x} \in \mathbf{R}^2 \mid g(\mathbf{x}) \equiv x^2 + (y/2)^2 - 1 = 0 \right\}. \quad (10)$$

In addition, ρ and \bar{u} are chosen so that the analytic solution of (1) and (2) may be given by

$$u = 3e^{-(x^2+y^2)} - \cosh x \sin y + \cos x \sinh y. \quad (11)$$

Fig. 1. Dependence of the relative error ε on the number N of the boundary nodes. Here, the symbols, \blacklozenge , \triangle and \blacktriangledown , indicate the values for the linear DRM, the X-BNM ($m = 1$) and the X-BNM ($m = 2$), respectively.

Fig. 2. Dependence of the ratio τ_X/τ_D on the number N of the boundary nodes.

Throughout the present study, the value of R is fixed as $R = 1$ and K is determined so as to satisfy $K \propto N^2$.

Let us first investigate the accuracy of the X-BNM and the DRM. The relative errors are calculated as a function of N and are depicted in Fig. 1. We see from this figure that, for both methods, the relative errors are almost proportional to $N^{-\beta}$ and that the power indices β 's satisfy $\beta \approx 1.1$, $\beta \approx 2.2$ and $\beta \approx 2.1$ for the linear DRM, the X-BNM ($m = 1$) and the X-BNM ($m = 2$), respectively. The above results indicate that the accuracy of the X-BNM is much higher than that of the DRM.

Next, we compare the speed of the X-BNM with that of the DRM. The ratio τ_X/τ_D of CPU times is calculated as a function of N and is depicted in Fig. 2. Here, τ_X and τ_D denote the CPU times for the X-BNM ($m = 1$) and that for the DRM, respectively. This figure indicates that τ_X/τ_D decreases monotonously with an increase in N until $\tau_X/\tau_D \approx 1$ is satisfied for $N \gtrsim 10^2$. This tendency shows that, for $N \gtrsim 10^2$, the speed of the X-BNM is almost equal to that of the DRM.

From the above results, we might conclude that the X-BNM can be a powerful method for solving a potential problem.

Abstract-- It is known, that the eddy current losses of conductors of circular or rectangular cross section can be reduced by cutting them into sectors. This paper presents an analytical-numerical mixed solution of this problem as reference for numerical methods like FEM.

I. INTRODUCTION

Due to the necessary energy saving multiple efforts are made to reduce losses in electric circuits, networks etc. Recently shape and distance of bar conductors for high current systems have been optimised and hereby demonstrating reduction of power losses [1]. Another thesis [2] minimised the losses by optimising the conductors' shape, applying the Evolution Strategy and Finite Element Method (FEM). In [3] it was shown how the eddy current losses in circular and rectangular conductors can be reduced by dividing them into semi- and quarter-circular or -rectangular ones (Fig.1). Although in principle known and applied for high frequency twisted conductors since long time this effect should be exploited also in electrical energy saving.

This paper deals particularly with the semi- and quarter-circular conductors, approaching each other (Fig.2) perfectly. For these cases an analytical-numerical method will be derived.

Fig.1. Cross-sections of different conductors with cuts

II. ANALYTICAL-NUMERICAL MODELING

The time harmonic field problem to be solved for the cut conductors, see fig.2, is governed by the complex inhomogeneous Helmholtz equation inside ($r \leq a$) and the Laplace equation outside ($r \geq a$) the conductors:

$$\Delta A - j\omega\kappa\mu A = -\kappa\mu C \quad r \leq a \quad (1)$$

$$\Delta A = 0 \quad r \geq a \quad (2)$$

A is the complex vector potential, ω, κ, μ angular frequency,

conductivity, permeability, a the conductor radius and C a so far undetermined constant, also known as impressed electric force.

Fig.2. Semicircular (left) and quartercircular (right) conductor with related constants C . I : given current.

$C(\varphi)$ as shown in fig.2 is expanded in a Fourier series, and the homogeneous solution $A_h(r, \varphi)$ and particular solution $A_p(r, \varphi)$ of (1), composing the total solution

$$A^i(r, \varphi) = A_h(r, \varphi) + A_p(r, \varphi) \quad (3)$$

have to be found.

A. The semicircular conductor

A_h is found by separation of variables and its radial dependence is typically given by Bessel functions J_{2k+1} . Instead of these for the particular solution a sum of power series is chosen, which after applying several recurrence relations leads to the following total solution:

$$A^i(r, \varphi) = \sum_{k=0}^{\infty} \cos(2k+1)\varphi [a_k J_{2k+1}(pr) - c_k M_{2k+1}(pr)] \quad (4)$$

containing the particular solution

$$M_{2k+1}(pr) = \sum_{n=1}^{\infty} \frac{(pr)^{2n}}{\prod_{\mu=1}^n [(2k+1)^2 - 4\mu^2]} \quad (5)$$

the graph of which will be shown in the full paper. So far unknown coefficients are a_k , and c_k are the coefficients of the Fourier series expansion of the piecewise constant C , and $p^2 = -j\omega\kappa\mu$. Interestingly the derived functions $M_{2k+1}(z)$ are, apart from the sign, identical with a subclass of

Lommel functions $s_{\mu,\nu}(z)$ for $\mu=1$ and $\nu=2k+1$, as we found in the literature [4].

B. The quartercircular conductor

Unfortunately in this case and also in higher divided conductors (e.g. circle divided by 6,8,...) the setup of a sum of power series as particular solution was leading to contradictions in the recurrence relations. Finally the following way was successful: the angle of 90 degrees of the conductors was replaced by $90/1+\epsilon$ with $\epsilon \ll 1$, power series applied and then taking the limit $\epsilon \rightarrow 0$ let us discover a new term

$$\ln(pr) \cdot J_{2(2k+1)}(pr) \tag{6}$$

the behaviour of which was so far missing in the particular solution. The whole solution will be shown in the full paper, and it cannot be expressed by known closed form functions like those of Lommel or Struve.

III. CURRENT DENSITY, LOSSES AND INDUCTIVITY

Finally the boundary conditions at $r=a$ enable to define the coefficients a_k . The current density is related to the vector potential by

$$G(r, \varphi) = -j\omega\kappa A(r, \varphi) + C \tag{7}$$

and the integration of the current density over the conductors' cross section, equalling the given total current I, delivers the constant C. Losses and inductivity are related to this constant by a simple formula [5].

IV. NUMERICAL RESULTS

Fig.3 shows, that the current density distribution in the case of the quartercircular conductor is more uniform than with the semicircular one, indicating already higher eddy current losses in the latter one. This is quantitatively proven and shown together with the inductivity in fig.4.

Fig.3. Lines of constant current density (amount) for the normalized frequency $\lambda = \sqrt{F\omega\kappa\mu} = 5$, F : cross section area of go and return conductor.
Left: semicircular conductor. Right: quartercircular conductor

The results, documented in fig.3 and fig.4, were calculated by the analytical-numerical method. The curves fit the results calculated by FEM.

Fig.4. Power losses P and inductivity L in dependence on normalized frequency λ . P_o, L_o are reference values for DC ($\lambda = 0$) and semicircular conductor

V. CONCLUSIONS

The contribution shows quantitatively, how conductors, cut into sectors, can reduce power losses in the example of semi- and quarter-circular conductors. The latter example turned out to be much more difficult to find an analytical-numerical solution of the inhomogeneous Helmholtz equation than the first one, where the solution is related to Lommel functions. The two solutions found by this contribution can now serve as reference for numerical methods like FEM.

Fields and Current BEM Formulation for Radiofrequency Antennas

Nabil El Alami, Bernard Bandelier and Françoise Rioux-Damidau

 Bat 220, 91405 Orsay, France
 bernard.bandelier@u-psud.fr

Abstract—A new boundary formulation for the computation of the current and electromagnetic fields on a printed circuit antenna is presented. The state variables are the surface current density j on the metal, the tangential electrical field on the dielectric boundary and the tangential magnetic field on the whole boundary. We obtain good results. We give comparisons between numerical results and experimental measurements.

I. INTRODUCTION

We are interested by modelling printed circuit antennas made of thin metallic layers on a dielectric substrate. It is then necessary to use an integral fields representation but, as the metal is not a perfect conductor, we have to satisfy Ohm law. This one imposes that the current and the electric field are expanded with the same basis functions. This implies a real problem as e and h being naturally expanded with edges elements, the surface current density j has to be expanded with edge elements rotated by $\frac{\pi}{2}$. A few years ago, in [1], we proposed a formulation where the unknowns were the surface currents on the metallic layer and the electrical and magnetic fields on the whole boundary of the system. But the Ohm law was only weakly satisfied. This formulation permitted to treat the case of a substrate widely covered by a thin metallic layer but the simulation of a printed-circuit antenna was not efficient enough for all frequencies and geometries. We here propose a different method where the unknown quantities are j on the metal, $n \times e$ on the dielectric boundary and $n \times h$ on the total boundary. The current j and the field e never appear together at the same place and the Ohm law is strongly verified.

II. PHYSICAL PROBLEM

Let Ω be a dielectric substrate of permittivity ϵ_d ; its boundary is Γ . A part of Γ is covered by a metallic layer (with slit) of small thickness d and conductivity σ ; it is called Γ_m and the other part of Γ is called Γ_d ; the boundary line between Γ_m and Γ_d is called γ_0 . \vec{n} is the outward normal to Ω on Γ and \vec{N} is the outward normal to γ_0 tangent to Γ . A source field (h^s, e^s) is applied at angular pulsation ω ; skin-depth δ in the metal is such that $\delta \gg d$. On Γ_m , Ohm law gives:

$$j = \sigma de$$

where j is a surface current density.

Across Γ_m :

- $n \times e$ is constant upon d as $\delta \gg d$,

Fig. 1. The system

- $n \times (h_a - h_d) = j$, h_a being the magnetic field on the external face of Γ in the air and h_d on the internal face in the dielectric.

Across Γ_d :

- $n \times e$ and $n \times h$ are continuous.

III. INTEGRAL REPRESENTATIONS OF THE FIELDS

By using Stratton-Chu formulae [2], we obtain an integral representation of the tangential electric field on the external face of Γ :

$$\begin{aligned} \frac{n \times e}{2}(x) &= n(x) \times e^s(x) \\ &+ i\omega\mu_0 n(x) \times \int_{\Gamma} G_a(x, y)(n \times h_a)_y \\ &- \frac{1}{i\omega\epsilon_0} n(x) \times \text{grad} \int_{\Gamma} G_a(x, y) \text{div}_{\Gamma}(n \times h_a)_y \\ &+ n(x) \times \int_{\Gamma} \text{grad}_x G_a(x, y) \times (n \times e)_y. \end{aligned} \quad (1)$$

where G_a and G_d are the Green functions in the air and in the dielectric for the Helmholtz equation.

By noting that Stratton-Chu formulae inside Ω do not contain the source field, we have on the inside face of Γ :

$$\begin{aligned} -\frac{n \times e}{2}(x) &= i\omega\mu_0 n(x) \times \int_{\Gamma} G_d(x, y)(n \times h_d)_y \\ &- \frac{1}{i\omega\epsilon_d} n(x) \times \text{grad} \int_{\Gamma} G_d(x, y) \text{div}_{\Gamma}(n \times h_d)_y \\ &+ n(x) \times \int_{\Gamma} \text{grad}_x G_d(x, y) \times (n \times e)_y. \end{aligned} \quad (2)$$

Fig. 2. The antenna (metallic layers only)

Fig. 4. Second antenna

We shall take as variable for the magnetic field:

$$h = h_d, \text{ and we have : } n \times h_a = n \times h + j \quad (3)$$

As j is the jump of the tangential magnetic field across Γ , it has to be defined in the same functional space than $n \times h$ and $n \times e$. But as $j = \sigma de$, j must be defined in the same functional space than e and would be discretized with the same basis functions. Clearly, there is an incompatibility, because it would necessitate to have the same discretization for j and $n \times j$. The only way to avoid this problem is to never have both the unknowns j and e in the same place. So, we adopt j as state variable on Γ_m and e on Γ_d .

By making the difference between equations (1) and (2), replacing e by $j/\sigma d$, multiplying by a test current j' and integrating on Γ_m we obtain a first variational equation. By multiplying by a test field e' and integrating on Γ_d , we obtain a second one. Finally, by taking the sum between equations (1) and (2), multiplying by h' and integrating on Γ we obtain the third variational equation.

IV. RESULTS

We take a dielectric disc with radius equal to 8 cm and height equal to 1.6 mm; it is covered with two metallic layers, one on the upper face and the second one on the lower face. We see the layers and their meshing on fig. 2.

We computed the numerical resonance frequency ($f_0= 44$ Mhz) and numerical quality factor Q ($Q_0= 44$) from numerical (NF) curve of resonance (fig. 3). The error percentage is 8 % in comparison with experimental measurement ($f_{exp} = 48, Q_{exp} = 48$).

Fig. 3. The resonance curve

We next take a dielectric disc with radius equal to 10 cm and height equal to 0.788 mm; it is covered with two metallic layers, one on the upper face and the second one on the lower face, 2 slits in each layers like in fig. 4.

Fig. 5. The resonance curve

We computed the numerical resonance frequency $f_0= 62.3$ Mhz and numerical quality factor $Q_0= 432$ from numerical (NF) curve of resonance of the second antenna (fig. 5). The error percentage is 8 % in comparison with experimental measurement ($f_{exp} = 67.9, Q_{exp} = 400$).

V. CONCLUSION

This method uses an integral representation formula of the tangential fields on the boundary, such that the Ohm law is strongly verified. The comparison with experimental measurements was interesting and we can use this method for several types of antennas.

A New Method to Solve 3D Magnetodynamic Problems without Assembling an $Ax = b$ system

J.P.A. Bastos and N. Sadowski
GRUCAD/EEL/CTC, Universidade Federal de Santa Catarina
CP. 476, Florianópolis, SC, 88040-900, Brazil
jpab@grucad.ufsc.br and nelson@grucad.ufsc.br

Abstract — In this paper we present a technique to solve magnetodynamic FEM cases where the assembling, storing and solving the matrix system $Ax = b$ is performed in a different way compared with the classical techniques. The application of this technique for static cases was already presented. Using the T- Ω formulation, we consider here eddy currents in the conductive parts of the domain using time stepping discretization. As main result, the implementation is much simpler than traditional techniques widely used in virtually all the FEM codes. The final results match the ones obtained by the classical methods with very good accuracy.

I. INTRODUCTION

In a previous work we presented this method for static cases [1]. Here, we consider the time stepping dynamic cases, where eddy currents exist in the conductive parts of the domain. The T- Ω formulation is here employed. It means that the unknown variables are the scalar potential Ω on the nodes and the circulation T of vector electrical potential \mathbf{T} on the edges of the conductive elements [2][3].

The FEM requires the calculation of the elemental contribution matrices, whose evaluation is normally performed element by element and assembled in the global matrix system commonly designated $Ax = b$. Boundary conditions are inserted and the system is solved by a direct method (as Gauss Elimination) or by an iterative one (as ICCG). With the proposed technique, we operate mainly by nodes (it was called *N Scheme* in the previous paper). Now we must consider also the \mathbf{T} potentials on the edges of the 3D, first order tetrahedron elements and time discretization.

The resulting implementation is much simpler compared to the regular way of classical FEM codes because it is not necessary to assemble, store and solve an $Ax = b$ system as normally done. These steps are performed in only a single procedure. The only drawback is the computation time which is somewhat higher than traditional implementations. In spite of this drawback, the new scheme is effective and provides reliable results.

II. THE PROPOSED TECHNIQUE – *N SCHEME*

For didactical purposes, we replicate here the description of the method, already presented in [1]. For the same reason, a very simple 2D mesh is here considered, even though the T- Ω formulation is applied in 3D cases. The *N scheme* requires working node by node using element “cells” around the nodes.

In Fig. 1, the nodes are indicated by numbers while the elements by letters. Suppose that the nodes 3, 5, 7 and 11 are

unknowns and the others (1, 2, 4, 6, 8, 9, 10, 12, 13 and 14) have imposed boundary condition values.

Fig. 1 – 2D mesh

Firstly, let us consider the node 3. The corresponding elements are: a, b, c, g, h, t and u and this cell is indicated in thick lines (the cell of the node 7 is indicated with dashed lines). When calculating the elemental matrix for this element (a typical rigidity matrix for a linear 2D triangular element), we obtain an $a(3,3)$ matrix; for the source we have a $s(3)$ vector. Suppose that the potential unknown is called v and that the element a is the only one acting for the node 3. If the nodes numbering created by the mesher has the sequence 14, 3 and 1, the elemental matrix system given by this sole element is:

$$\begin{bmatrix} a_{1,1} & a_{1,2} & a_{1,3} \\ a_{2,1} & a_{2,2} & a_{2,3} \\ a_{3,1} & a_{3,2} & a_{3,3} \end{bmatrix} \begin{bmatrix} v_{14} \\ v_3 \\ v_1 \end{bmatrix} = \begin{bmatrix} s_1 \\ s_2 \\ s_3 \end{bmatrix} \quad (1)$$

Supposing that the values of v_1 and v_{14} are known (as Dirichlet boundary conditions, for instance) we can write, for the potential v_3 :

$$a_{2,2}v_3 = s_2 - a_{2,1}v_{14} - a_{2,3}v_1 \quad (2)$$

The above expression must interact with other elements surrounding the node 3. Similar equations are calculated for all the elements of this cell. Using the notations of [1], we proceed with the sum of all the diagonal terms related to the node $n=3$ as:

$$diag_sum = a_{nn}^a + a_{nn}^b + a_{nn}^c + a_{nn}^g + a_{nn}^h + a_{nn}^t + a_{nn}^u$$

The sum of the right hand side of (2) is also calculated for all the elements as

$$right_sum = r_{jl}^a + r_{jl}^b + r_{jl}^c + r_{jl}^g + r_{jl}^h + r_{jl}^t + r_{jl}^u$$

The node 3 has interaction with the unknown nodes 5, 7 and 11 through the common elements c, g, h and u . Since the procedure is iterative, the potential of these nodes will be placed on the right hand side with their current values (exactly

as the boundary condition nodes). Once $diag_sum$ and $right_sum$ are calculated, the value of v_3 is given by:

$$v_3 = (right_sum)/(diag_sum) \quad (3)$$

Similar operations are performed for the v_5, v_7, v_{11} unknowns. Once it is done, we have a first approximation for these unknowns. Then the second iteration starts, with unknown values somewhat closer to the solution. As the iterative procedure progresses, the convergence is reached. This procedure is strictly equivalent to the application of the Gauss-Seidel iterative method with a relaxation technique [4][5].

In this work we must take into account the potential circulation T on the edges of the conductive elements. For doing so, we apply a similar procedure: for each edge having an unknown T , it is necessary to consider the elements "surrounding" the edge and the same technique is applied. However, there is a coupling between the potentials Ω and T , but it does not imply in any particular difficulty. In fact, the resulting matrix system can be written, as:

$$\begin{bmatrix} P & Q \\ Q^T & A \end{bmatrix} \begin{bmatrix} T^i \\ \Omega^i \end{bmatrix} = \begin{bmatrix} R & Q \\ 0 & 0 \end{bmatrix} \begin{bmatrix} T^{i-1} \\ \Omega^{i-1} \end{bmatrix} + \begin{bmatrix} 0 \\ U \end{bmatrix} \quad (4)$$

whose values are indicated in [2][3]. T^{i-1} and Ω^{i-1} are known from the previous time step. Therefore, applying the same principle as for the static case above, for generic T^i and Ω^i unknown we have their values given by:

$$T^i = (-P^*T^i - Q\Omega^i + RT^{i-1} + Q\Omega^{i-1})/sum_diagT^i \quad (5)$$

$$\Omega^i = (-Q^T T^i - A^* \Omega^i + U)/sum_diag\Omega^i \quad (6)$$

In the matrices P^* and A^* the diagonal terms are not considered. They are present on the diagonal sums.

III. IMPLEMENTATION

As similar to [1], it is necessary to set an array furnishing the elements "around" the unknown nodes and here another one with the elements "around" the edges T . Then the N scheme for this formulation is:

Loop of iterations:

Loop for the N unknowns Ω_n^i

- Calculate the diagonal sum;
- Calculate the right hand side sum;
- Calculate the new value of Ω_n^i by (6);

End of the Nodes loop;

Loop for the M unknowns T_m^i

- Calculate the diagonal sum;
- Calculate the right hand side sum;
- Calculate the new value of T_m^i by (5);

End of the T edges loop;

End of the iterations loop (until convergence).

IV. EXAMPLE

As example, we have the magnetic circuit of the Fig. 2a. The conductive part is at the right of the U-type magnetic piece which is surrounding a coil. A pulse of current is imposed on the coil, generating the eddy currents on the massive part. In Fig. 2a the magnetic induction is indicated by the arrows. The larger ones in the figure are located in the conductive part since its cross section is relatively thin. In Fig. 2b the induced current density distribution is shown.

Fig. 2a – Flux distribution

Fig. 2b – Eddy currents

The number of elements is 16410. There are 3400 (unknown) nodes and 4000 T unknown edges (only in the conductive piece). The computation time with the traditional technique is 33 seconds and, with the proposed method, 61 seconds. As in [1], the calculation is longer with this method. The relative errors are 1.1%, 0.2% and 1.4% on the maximal B values, magnetic energy and eddy current losses, respectively. It is an accurate result for two different methods.

V. FINAL CONSIDERATIONS

The main focus of this work is to show that the N scheme proposed in [1] could be used on time stepping, eddy currents cases as well. We can also inform that, in a parallel work, it has been successfully employed on vector potential edge elements cases [6]. Our goal from now is to concentrate efforts on the convergence procedure in order to diminish the computational time. If this investigation yields good results, it will be possible to propose a technique as fast as the traditional one providing implementation advantages.

Abstract—A common structure of several physical laws emerges naturally from the Tonti diagrams of different physical theories so that topological operators can be built only once and used to assemble resolving matrices of the various problems. This process is known in algebraic topology as coboundary process and is briefly presented as the theoretical background for solving multiphysics problems.

I. INTRODUCTION

One of the most important ideas in the work of Tonti and his algebraic formulation of physical theories [1], is the rigorous classification of physical variables and their link to geometrical entities. This classification is not specifically related to one particular physical phenomenon but, as a fundamental issue, highlights the common space-time structure underlying many physical theories. For this reason Tonti's work is a natural environment for developing a multiphysics analysis based on a numerical technique, which will be hereinafter called Cell Method (CM). Many aspects of the CM are common with the Finite Integration Theory [2] and similar ideas have been explored extensively by many researchers, e.g. [3].

II. PRIMAL AND DUAL CELL COMPLEX

In the algebraic formulation of physical theories, variables are associated with oriented space-time geometrical entities. Two discretizations are defined over the problem domain: the usual discretization adopted by many numerical methods forms a complex of space elements called *primal complex* but another cell complex is also defined, which is intertwined with the primal one by duality relations. Thus dual volumes are one-to-one associated to primal nodes, dual faces are dual geometrical entities of primal lines, dual lines of primal faces and dual points of primal volumes. Depending on their nature, global variables are associated to the primal or dual complex [1]. Equations that link a quantity defined on the primal complex and another on the dual complex are called constitutive equations and can be represented by square matrices due to the duality of the complexes. When global variables are used, physical equations can be written in a discrete form. The discrete operators that are representative of gradient, curl and divergence operators are the incidence matrices \mathbf{G} (edge-to-node), \mathbf{C} (face-to-edge), \mathbf{D} (volume-to-face). Since the same spatial entities are present in the dual complex, similar incidence matrices can be defined for the dual complex. They are represented by a tilde sign: $\tilde{\mathbf{G}}$, $\tilde{\mathbf{C}}$, $\tilde{\mathbf{D}}$. At least for topologically trivial complexes of cells, duality

relations impose that:

$$\tilde{\mathbf{D}} = -\mathbf{G}^T; \quad \tilde{\mathbf{C}} = \mathbf{C}^T; \quad \tilde{\mathbf{G}} = \mathbf{D}^T. \quad (1)$$

Topological laws link variables defined on the same cell complex by making use of these discrete operators. Topological equations are of three possible kinds:

- 1) *balance equations*, in particular conservation laws: in a differential setting they are expressed by the *div* operator; in algebraic methods they make use of $\tilde{\mathbf{D}}$;
- 2) *circulation equations*: in a differential setting they are expressed by the *curl* operator, while in a discrete setting by a $\tilde{\mathbf{C}}$ matrix
- 3) *difference equations*: in a differential setting they are expressed by the *grad* operator or by \mathbf{G} in discrete formulation.

Different phenomena sharing the same topological equation on the same space discretization (for instance thermal flow and electric flow balance) keep the same matrix equation structure and differ only by their constitutive matrices.

III. COBOUNDARY PROCESS

In order to define the *coboundary process* it is necessary to introduce some algebraic topology concepts. The reader can refer to [4] for a thorough introduction to this subject. Given a global physical quantity associated with a generic p -cell of a cell complex (where p is the spatial dimension), the knowledge of the amount of a physical variable associated with a set of p -cells is called *p -cochain*. As an example, in heat conduction problems, the assignment of the temperature to every node (0-cell) gives rise to a 0-cochain. In current flow problems, the assignment of voltage to every edge (1-cell) gives rise to a 1-cochain. The $(p+1)$ -cells that share a generic common p -cell are called *cofaces*.

The *coboundary process* is a procedure that starting from a p -cochain gives rise to a $(p+1)$ -cochain by a two-step process:

- 1) for every p -cell the value of the physical variable associated with it is transferred to all cofaces of the p -cell, with the correct incidence number;
- 2) for every $(p+1)$ -cell all these values are added together. In this way we obtain a new physical variable, with the same physical dimensions, associated with every $(p+1)$ -cell. In this way a new $(p+1)$ -cochain is obtained.

The coboundary process is the theoretical background of all topological laws based on discrete gradient, curl and divergence. Since these operators are built as a coboundary process,

Fig. 1. Tonti diagrams.

it is easy to understand that they are incidence matrices. The most important consequence is that the coboundary process is a purely topological operation, it is not related to a specific physical theory but it is common to different problems. When studying a multiphysics problem, if the different fields share the same discretization, discrete operators that are representative of gradient, curl and divergence still remain the same for all problems.

IV. ELECTRO-THERMO-MECHANICAL PROBLEM

In this section the aforementioned coboundary process is applied to the multiphysics study of a microresistor beam involving electrical, thermal and mechanical effects. The example is taken from a library of test cases provided by the COMSOL Multiphysics finite element program [5] which is used as reference. In this particular application electric current generates heat, and the temperature increase leads to displacement through thermal expansion.

A. Stationary current field

The global variables used in stationary current problems are electric scalar potential φ , voltage u and electric current i . Their placement in Tonti diagram is reported in Fig. 1(a). Ohm's discrete constitutive matrix \mathbf{M}_σ for tetrahedra can be built by making use of Whitney edge-elements [6]. By following the primal cycle, i.e. starting from the electric scalar potential on the primal complex in order to obtain given sources on the dual complex, it is easy to obtain the equation:

$$\mathbf{G}^T \mathbf{M}_\sigma \mathbf{G} \varphi = 0. \quad (2)$$

B. Transient thermal conduction field

In Fig. 1(b) the Tonti diagram for transient thermal conduction is shown: by assembling the topological and constitutive equations presented, following equation is obtained

$$\left(\mathbf{M}c + \frac{\tau}{2} \mathbf{G}^T \mathbf{M}_\lambda \mathbf{G} \right) \theta_k = \left(\mathbf{M}c - \frac{\tau}{2} \mathbf{G}^T \mathbf{M}_\lambda \mathbf{G} \right) \theta_{k-1} + \frac{1}{2} (\mathbf{W}_k + \mathbf{W}_{k-1}) \quad (3)$$

where: \mathbf{M} is the mass matrix of dual volumes, c is the thermal capacity, τ the amplitude of primal time interval, \mathbf{M}_λ the discrete matrix of thermal conductivity. Since \mathbf{M}_λ links temperature difference and heat flux, which are defined on primal edges and dual faces, respectively, this constitutive matrix is built in the same way as the discrete electrical conductivity matrix. The coupling terms with the stationary current field are the thermal dependence of electrical conductivity and joule losses as thermal sources. Equation (3) proposes the Crank-Nicholson time integration scheme, but it is possible to derive other integration schemes by a suitable definition of duality in time discretization [7].

Fig. 2. Results of coupled electro-thermo-mechanical analysis (steady state).

TABLE I
COMPARISON BETWEEN COMSOL AND DUALLAB

	Total current, A	max T, K	max Δz , m
COMSOL	0.773	1017.4	8.18E-8
DualLab	0.775	1017.1	8.28E-8

C. Elastostatics

Tonti diagram for elastostatics is depicted in Fig. 1(c). By following the same rationale of other physical theories, with the only difference in the constitutive equation \mathbf{M}_E and neglecting details for the sake of conciseness, the equation of elastostatics is:

$$\mathbf{G}_3^T \mathbf{M}_E \mathbf{G}_3 \mathbf{u} = \mathbf{F}_v \quad (4)$$

\mathbf{G}_3 is a tri-block diagonal matrix, where each block is made by the \mathbf{G} matrix that appears in (2) and (3).

D. Results

The aforementioned formulation, implemented in the DualLab code, has been applied to the described benchmark problem, and maps of electric scalar potential, temperature and Von Mises stresses are shown in Fig. 2. A comparison with results obtained with COMSOL is shown in Table I (note that high temperature values are due to a voltage of 1 V applied between the electrodes).

V. CONCLUSIONS

The described approach, based on Tonti diagrams, has been shown to deliver an elegant approach for the efficient implementation of multiphysics problem formulations. More complicated multiphysics applications will be presented in the full paper together with CPU time and memory usage comparisons with leading finite element codes.

Abstract—The aim of the paper is to present a three-dimensional geometric time-domain eddy-current A formulation for hexahedral grids. The resulting singular differential algebraic linear system of equations (DAE) is solved by means of a *Singly-Diagonally Implicit Runge-Kutta* (SDIRK) variable step-size solver. The formulation is validated by comparing the results from a benchmark problem with respect to a Finite Elements commercial software.

Index Terms—Cell Method (CM), Finite Integration Technique (FIT), Discrete Geometric Approach (DGA), eddy-currents, time-domain.

I. INTRODUCTION

The so-called “Discrete Geometric Approach” (DGA) [1], similarly to the Finite Integration Technique (FIT) [2] or the Cell Method [3], allows to solve directly Maxwell’s equations in an alternative way with respect to the classical Galerkin method in Finite Elements.

In this paper, a three-dimensional geometric time-domain eddy-current formulation suitable for hexahedral grids based on the circulation A of a magnetic vector potential \mathbf{A} is described.

The domain of interest D of the eddy-current problem has been partitioned into a passive conductive region D_c , a source region D_s and a non-conductive region D_a . The domain D is covered by a finite element mesh of hexahedra; The corresponding cell complex [3] is denoted as \mathcal{K} . From \mathcal{K} , the barycentric dual complex \mathcal{B} is also introduced [3]. The incidence matrix between edges e and nodes n is denoted by \mathbf{G} , the incidence matrix between faces f and edges e is denoted by \mathbf{C} and the incidence matrix between hexahedra v and faces f is denoted by \mathbf{D} . The matrices $\tilde{\mathbf{G}} = \mathbf{D}^T$, $\tilde{\mathbf{C}} = \mathbf{C}^T$ and $\tilde{\mathbf{D}} = -\mathbf{G}^T$ describe the mutual interconnections of the dual barycentric complex [3].

Next, we consider the integrals of the field quantities with respect to the oriented geometric elements of the mesh, yielding the Degrees of Freedom (DoF) arrays:

- Φ is the array of magnetic fluxes associated with faces $f \in D$; \mathbf{F} is the array of m.m.f.s associated with dual edges $\tilde{e} \in D$; \mathbf{I} is the array of currents associated with dual faces $\tilde{f} \in D_c$. In D_s we introduce the array \mathbf{I}_s of impressed currents; \mathbf{U} is the array of e.m.f.s on primal edges $e \in D_c$.

- \mathbf{A} is the array of circulations of the magnetic vector potential A along the primal edges $e \in D$.

Maxwell’s laws can be written *exactly* as topological balance equations between DoFs arrays, as

$$\begin{aligned} (\mathbf{C}^T \mathbf{F})_e &= 0, & e \in D_a \\ (\mathbf{C}^T \mathbf{F})_e &= (\mathbf{I}_s)_e, & e \in D_s \\ (\mathbf{C}^T \mathbf{F})_e - (\mathbf{I})_e &= 0, & e \in D_c \end{aligned} \quad (1)$$

$$(\Phi)_f = (\mathbf{C}\mathbf{A})_f, \quad f \in D \quad (2)$$

where (1) is the Ampère’s Law, (2) involves the array \mathbf{A} in such a way that Gauss’ Law $\mathbf{D}\Phi = 0$ is satisfied identically (since $\mathbf{D}\mathbf{C} = 0$). The discrete counterpart of the constitutive laws can be written as

$$\mathbf{F} = \boldsymbol{\nu} \Phi, \text{ in } D \quad (\text{a}) \quad \mathbf{I} = \boldsymbol{\sigma} \mathbf{U}, \text{ in } D_c \quad (\text{b}) \quad (3)$$

where the matrices $\boldsymbol{\nu}$ and $\boldsymbol{\sigma}$ are square symmetric positive-definite and consistent matrices which can be efficiently constructed in a pure geometric way for an hexahedral primal grid, as described in [4].

Combining the discrete Faraday’s law $(\mathbf{C}\mathbf{U})_f = -\frac{d}{dt}(\Phi)_f$, $f \in D_c$, with (2) yields

$$(\mathbf{U})_e = \left(-\frac{d\mathbf{A}}{dt} \right)_e, \quad e \in D_c. \quad (4)$$

II. TIME-DOMAIN EDDY-CURRENT A FORMULATION

The symmetric algebraic system of equations, having $\mathbf{A}(t)$ as unknown, can be obtained by combining (3a), (3b), (2) and (4) into (1)

$$\begin{aligned} (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A}(t))_e &= 0, & e \in D_a \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A}(t))_e &= (\mathbf{I}_s(t))_e, & e \in D_s \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A}(t))_e + (\boldsymbol{\sigma} \frac{d}{dt} \mathbf{A}_c(t))_e &= 0, & e \in D_c \end{aligned} \quad (5)$$

where \mathbf{A}_c contains the entries of \mathbf{A} relative to the edges of D_c . The source currents vector $\mathbf{I}_s(t)$ can be expressed as $\mathbf{I}_s \cdot s(t)$, where \mathbf{I}_s can be computed as described in [5] for a unit current and $s(t)$ is a function of time that describes the time evolution of the source current.

III. INTEGRAL SOURCES

When modeling stranded coils, it is useful to introduce integral sources, which do not require the coils to be meshed. With this aim, we express the array \mathbf{A} as $\mathbf{A} = \mathbf{A}_s + \mathbf{A}_r$, where \mathbf{A}_s contains the contribution produced by the source currents in D_s and \mathbf{A}_r due to the eddy-currents in D_c . Equation (5) can be rewritten as

$$\begin{aligned} (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A}_r(t))_e &= 0, & e \in D_a \\ (\mathbf{C}^T \boldsymbol{\nu} \mathbf{C} \mathbf{A}_r(t))_e + (\boldsymbol{\sigma} \frac{d\mathbf{s}(t)}{dt} \mathbf{A}_r(t))_e &= -(\mathbf{v}(t))_e, & e \in D_c \end{aligned} \quad (6)$$

where $(\mathbf{v}(t))_e = \left(\boldsymbol{\sigma} \mathbf{A}_s \frac{ds(t)}{dt} \right)_e$. Each entry $(\mathbf{A}_s)_e$ of the array \mathbf{A}_s can be pre-computed as $(\mathbf{A}_s)_e = \int_e \mathbf{A}_s \cdot d\mathbf{l}$, where e is a primal edge in D_c and \mathbf{A}_s is the magnetic vector potential due to a unit source current in D_s .

IV. NUMERICAL RESULTS

The time-domain A geometric eddy-current formulation, with both meshed and integral sources, is implemented in the GAME code [6].

It should be noted that the matrices in (5) and (6) are singular and to solve (5) or (6) we rely on a in-house developed Singly-Diagonally Implicit Runge-Kutta (SDIRK) DAE solver with a variable step-size [7].

A fully three-dimensional geometry consisting of a circular coil placed above a conducting plate ($\sigma_c = 4 \cdot 10^7$ S/m) is considered as a benchmark problem, see Fig. 1. The source is

Fig. 1. The geometry of the benchmark problem is shown.

enforced by a stranded circular coil D_s with $s(t) = 400 \cdot (1 - e^{-t/\tau})$, where $\tau = 1$ ms.

To compare the results obtained with the A geometric formulation, the ANSYS commercial Finite Elements software is used. Since the problem is axisymmetric, a first solution is computed with ANSYS using a two-dimensional quadrilateral mesh consisting of about 50,000 elements of second order (time step of 0.01 ms). Then, the full three-dimensional simulations, using the same mesh consisting of 19,136 hexahedra (59,330 DoFs), are run with ANSYS and the GAME code (fixed time-step of 0.05 ms for both ANSYS and GAME).

The amplitude of the current density along a number of points evenly distributed along a sampling line shown in Fig. 1 for $t = 1$ ms is represented in Fig. 2. In Fig. 3, the time behavior of the module of the current density in the point P (situated on the sampling line, at a distance of 7.5 mm from the axis) is shown. The results obtained by the DGF are in very good agreement with ANSYS. The CPU time will be described in detail in the full paper.

Fig. 2. Amplitude of the current densities along a sampling line.

Fig. 3. Time behavior of the module of the current density in the point P .

V. CONCLUSIONS

A three-dimensional geometric time-domain eddy-current A formulation suitable with hexahedral meshes has been presented. The formulation has been successfully validated using a Finite Elements commercial software.

jon.webb@mcgill.ca

Abstract—In bioelectromagnetics and other domains, the structures in which the electromagnetic field is to be computed are sometimes defined by a fine Cartesian grid of voxels (3D cells), in each of which the material properties are specified. A novel finite element method is proposed for such cases. A simple, regular mesh of cube elements is constructed, each containing the same, integer number of voxels. There may be several different materials present within an element, but this is accommodated by computing element basis functions that approximately respect the interface conditions between different materials. Results are presented for a test model consisting of nested conducting cubes, driven by a current dipole, which is a crude version of the electroencephalography forward problem. The static potential computed with the new method agrees well with that of a conventional finite element code.

I. INTRODUCTION

Tomographic techniques such as magnetic resonance imaging (MRI) provide information on the size, shape and material properties of a slice through a complex 3D structure, and an assembly of such slices allows us to construct the geometry of the entire structure as a Cartesian grid of voxels. This can be used as the starting point for a finite element (FE) analysis of the electromagnetic fields. The conventional approach is to construct a solid model from the voxel data and to subdivide that into finite elements [1]. The process is time-consuming and prone to error. An alternative strategy was proposed in 2D in [2] and is here extended to 3D. A simple, regular mesh of cube elements is superimposed directly on the voxel grid. In general, each cube will contain several different materials, possibly with large differences in their electromagnetic properties. This is not possible with conventional finite elements, but the usual basis functions of the cube element are replaced by computed basis functions that take into account the different materials.

II. THE METHOD OF COMPUTED BASIS FUNCTIONS IN 3D

The computational domain Ω consists of $n \times n \times n$ voxels. Each voxel has a known electromagnetic material property, e.g. conductivity σ . There may be material discontinuities in this model, represented by neighboring voxels of different materials. This type of voxelization is used to approximate smooth geometric objects with abrupt boundaries in tomographic techniques.

Consider the following partial differential equation in Ω :

$$Lu = g \quad (1)$$

where u is an unknown scalar function, L is a partial differential operator depending on the material property, and g is a known excitation applied in Ω . We subdivide domain Ω into a set of cube elements, and each element consists of $p \times p \times p$ voxels. Each element may contain several different materials. One such element is shown in Fig. 1. Color shading indicates different materials.

Fig 1. A $p \times p \times p$ cube finite element containing two different materials. Here $p = 4$.

The conventional FE method does not allow different materials within one element. The element basis function therefore does not depend on materials but only on the geometry. In our method, we use computed basis functions to allow for this material difference within one element. The computed basis function satisfies the following equation

$$Lu = 0 \quad (2)$$

approximately within each element. In this way, the computed basis function tends to respect the internal discontinuities and therefore serves as a reasonable local approximation even with non-uniform filling material.

The computed basis function also needs to satisfy the continuity condition between adjacent elements. This continuity is obtained by imposing the same computed functions for all the edges and faces shared by neighboring elements. First we compute the functions for edges. Take the edge from $(0, ph)$ to (ph, ph) in Fig. 2 as an example. This edge is shared by four neighboring cube elements. The edge function $e(x)$ for node (ph, ph) is the solution to:

$$\begin{aligned} Le(x) &= 0 \\ \text{s.t. } e(0) &= 0 \quad e(ph) = 1 \end{aligned} \quad (3)$$

The equation is solved by the finite difference method. The material property for each point on this edge is obtained by taking the average material property of the four voxels sharing the point.

These edge functions are next used as boundary conditions in solving for the face functions, $f(x, y)$. Suppose we are solving for the face function for node (ph, ph) in Fig. 2. The boundary conditions are as follows:

$$\begin{aligned} f(x, ph) &= e(x) & f(ph, y) &= e(y) \\ f(x, 0) &= 0 & f(0, y) &= 0 \end{aligned} \quad (4)$$

where $e(x)$ and $e(y)$ are edge functions for node (ph, ph) .

Fig 2. An element face, which is shared by two elements. $p=4$.

After we obtain all the face functions, we use them to compute the element basis function. This is done by solving the differential equation (2) throughout the volume of the cube element. The boundary condition on each face of the cube is defined by a face function.

When all the element basis functions are obtained, they are used in a conventional FE variational formulation to find the scalar u throughout Ω .

III. TEST CASE

In electroencephalography (EEG), the forward problem can be defined as: given the position and moment of current dipoles in the brain, find the electric potential distribution over the scalp. The head model obtained by MRI consists of voxels representing anatomical tissue of the head and this can be used in the forward problem computation.

A case similar to the EEG forward problem is analyzed by the new method and the results compared with those from a conventional FE method. A rectilinear geometry is chosen, so that the voxelized version matches exactly the geometric model treated by the conventional FE method; this would not be the case if, for example, a spherical geometry were used, because of the staircase approximation to the spherical surfaces that is unavoidable in voxelized data such as that obtained by tomography. In this way, the intrinsic accuracy of the new method can be established, without the added geometric uncertainty caused by the voxelization. We apply our method to a four layer cube model consisting of

128x128x128 voxels. The sides of the concentric “scalp”, “skull” and “brain” cubes have lengths 104, 96 and 88 voxels respectively. The conductivities are 1 Sm^{-1} , 0.0125 Sm^{-1} , and 1 Sm^{-1} for brain, skull and scalp, respectively. A current dipole is placed symmetrically. Fig. 3 is the middle slice of the model on a coronal plane.

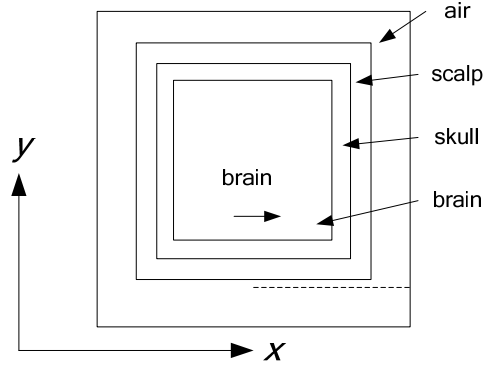

Fig 3. A cube model consisting of 128x128x128 voxels

An element size of 4x4x4 voxels is used and the potential is sampled along a line one voxel away from the scalp. The sample line is shown as dashed in Fig. 3. The result is compared with those obtained by ElecNet [3] which uses a fine mesh of conventional, 3rd-order, tetrahedral elements. Then we perturb the problem by increasing the size of each nested cube (except the outermost one) by 2 voxels. Comparisons for both cases are plotted in Fig.4. Both results show good agreement, which indicates the competence of the new method in dealing with elements containing strong material discontinuities.

Fig 4. Comparison of the new method with conventional FE method

Abstract— The giant magnetostrictive material Terfenol-D show superior properties that combine both a broad bandwidth, high force and small or moderate displacements. As a kind of active material, it can be used in ultrasonic power transducer. Hysteresis losses are the main source for heating the Terfenol-D ultrasonic power transducer. A new method of calculation for hysteresis losses, which based on Jiles-Atherton hysteresis model and electro-magnetic field finite element analysis, is proposed in this paper. The hysteresis losses obtained by this method can be used as thermal sources in electro-thermal finite element analysis.

I. INTRODUCTION

The giant magnetostrictive material Terfenol-D show superior properties that combine both a broad bandwidth, high force and small or moderate displacements. Furthermore, the advent of magnetostrictive equipment including new magnetic materials and design concepts have made it possible to manufacture high-frequency, high-power transducers for ultrasonic applications³. Transducers capable of delivering up to 6 kW mechanical power have recently been commercially available and a 25 kW is under development³. This transducer will continuously operate at its rated maximum power, which should be about one order of magnitude higher than competing technologies such as PZT transducers. One of the big disadvantages with PZT in ultrasonic transducers is the very low heat conductivity. This limits the power rating to about 4.5 kW. A high frequency, high-power transducer would significantly increase the commercial use of ultrasonic transducers in sono-chemistry, e.g. applied to petroleum production and processing, accelerated chemical reaction studies and in the dairy industry.

The eddy current losses and hysteresis losses are the main source for heating the magnetostrictive material in Terfenol-D ultrasonic magnetostrictive transducer. The eddy current losses can be reduced significantly by laminating the magnetostrictive material. However, the hysteresis losses are the main source for heating the ultrasonic magnetostrictive power transducer. The hysteresis losses can be used as thermal sources in electro-thermal finite element analysis. The calculation of hysteresis losses is very important for designation of Terfenol-D ultrasonic magnetostrictive transducer.

In this paper, a method combined of Jiles-Atherton hysteresis model [1][2] and time-step electromagnetic field finite element analysis for hysteresis losses' calculation of magnetostrictive ultrasonic power transducer is used. By this

method, the hysteresis losses of Terfenol-D transducer are calculated accurately.

II. INVERSE JILES-ATHERTON HYSTERESIS MODEL

A. Original Jiles-Atherton Hysteresis Model

In original Jiles-Atherton hysteresis model, the magnetization M can be defined as addition of the reversible component M_{rev} and irreversible component M_{irr} .

$$M = M_{irr} + M_{rev} \quad (1)$$

Considered the magnetization process of the material, the relationship of the M_{rev} , M_{irr} and M_{an} is given by follow equation.

$$M_{rev} = c(M_{an} - M_{irr}) \quad (2)$$

The remained equations of the Jiles-Atherton hysteresis model is given as equation (3-6).

$$\frac{dM_{irr}}{dH_e} = \frac{M_{an} - M_{irr}}{k\delta} \quad (3)$$

$$M_{an} = Ms \left[\coth\left(\frac{He}{a}\right) - \frac{a}{He} \right] \quad (4)$$

$$He = H + \alpha M \quad (5)$$

$$B = \mu_0(H + M) \quad (6)$$

In above equations, Ms is the saturate magnetization of the material which can be obtained from manufacture. c , k , α and a are the parameters can be extracted from experimental data [3]. δ is a directional parameter and takes the value 1 for $dH/dt > 0$ and -1 for $dH/dt < 0$. M_{an} is the anhysteretic magnetization.

B. Inverse Jiles-Atherton Hysteresis Model

With the proposed inverse Jiles-Atherton model [4], H will be calculated from the magnetic induction B , integrating a differential equation in terms of dM/dB .

$$\frac{dM}{dB} = \frac{(1-c) \frac{dM_{irr}}{dB_e} + \frac{c}{\mu_0} \frac{dM_{an}}{dH_e}}{1 + \mu_0(1-c)(1-\alpha) \frac{dM_{irr}}{dB_e} + c(1-\alpha) \frac{dM_{an}}{dH_e}} \quad (6)$$

$$\frac{dM_{irr}}{dB_e} = \frac{M - cM_{an}}{1 - c} \quad (7)$$

$$\frac{dM_{an}}{dH_e} = \frac{M_s}{a} \left[1 - \coth^2 \frac{H_e}{a} + \left(\frac{a}{H_e} \right)^2 \right] \quad (8)$$

III. FILED EQUATION OF TIME-STEP FINITE ELEMENT ANALYSIS

This way to include hysteresis in field calculation is to introduce a differential reluctivity ν_d defined as

$$\nu_d = \frac{dH}{dB} \equiv \frac{\Delta H}{\Delta B} = \frac{H(t+\Delta t) - H(t)}{B(t+\Delta t) - H(t)} \quad (9)$$

From (4), the magnetic field $H(t + \Delta t)$ at time $(t + \Delta t)$ is

$$H(t + \Delta t) = \nu_d \Delta B + H(t) \quad (10)$$

Applying (5) in Ampère's law and using the magnetic vector A potential gives the final equation for this formulation

$$\text{rot } \nu_d \text{rot } A(t + \Delta t) = J(t + \Delta t) + \text{rot } \nu_d \text{rot } A(t) - \text{rot } H(t) \quad (11)$$

In equation (6), ν_d is calculated in each time step $t + \Delta t$. $A(t)$ and $H(t)$ is known in previous time step.

The hysteresis is included in magnetic field analysis by (11). The hysteresis losses are obtained by integral B with H [5].

$$P_t = \frac{1}{\rho T} \int_0^T \left(H_x \frac{dB_x}{dt} + H_y \frac{dB_y}{dt} \right) dt \quad [\text{W / kg}] \quad (12)$$

IV. RESULT

In this paper, A magnetostrictive ultrasonic power transducer with a moderate driving current of 10A and the frequency of 21kHz is used to analysis the hysteresis loss. Its magnetic field distribution in the time of 1/4 current period is shown as Fig.1. In the Fig.1, the area with green color is the air, the grey area is the silicon sheet, the pink area is the Terfenol-D and the yellow area is the copper and the dark red area is the steel.

Fig. 1. Magnetic field in the time of 1/4 current period

V. CONCLUSION

Hysteresis losses are the main source for heating the Terfenol-D ultrasonic power transducer. A new method combined of Jiles-Atherton hysteresis model and time-step electromagnetic field finite element analysis for hysteresis losses calculation is proposed in this paper. By this method, the hysteresis losses of Terfenol-D transducer are calculated accurately. In the near future, the calculation of eddy current and anomalous losses will be undertaken.

Abstract— This paper presents an efficient method to implement an advanced eddy-current model with bidirectional flux feeding and investigates the techniques required for its incorporation in the 2D FE analysis of electrical machines. The results show that the implementation and the incorporation of the advanced model in FE analysis are feasible. Furthermore the proposed implementation produces results close to the ones observed in measurements.

I. INTRODUCTION

Accurate power loss computation is needed for the design of electrical machines. In addition to the losses in the windings, the losses in the iron core are of great interest. The core losses are usually separated into hysteresis, eddy currents, and excess losses, the accurate computation of which requires advanced vector-hysteresis models [1]. When the iron core is modeled with a single-valued non-linear BH-curve, the only part of the core losses that can be accurately modeled is the eddy currents part. In this work, the so-called 1D eddy-current model [2] is used for this purpose.

This paper presents an efficient method to implement the advanced model and investigates the techniques required for its incorporation in the 2D FE analysis of electrical machines. The latter task is carried out using a 2D-like procedure. Results of application in FE simulation are presented in [3].

II. THE ADVANCED MODEL AND ITS IMPLEMENTATION

The adequate modeling of eddy currents is intrinsically a 3D problem. However if the behavior of the eddy currents at their loop edges is ignored, the problem reduces to two coupled 1D equations [2]. This assumption is reasonable since the dimensions of the lamination in the x - y direction are larger than its thickness. If σ is the material conductivity, \mathbf{h} the magnetic field strength, \mathbf{b} the magnetic flux density and z the coordinate in the depth of the lamination, the equations are

$$\begin{aligned} \frac{\partial^2 h_x(z,t)}{\partial z^2} &= \sigma \frac{\partial b_x(z,t)}{\partial t} \\ \frac{\partial^2 h_y(z,t)}{\partial z^2} &= \sigma \frac{\partial b_y(z,t)}{\partial t} \end{aligned} \quad (1)$$

Eq. (1) can be solved in terms of \mathbf{h} and \mathbf{b} but it requires boundary values of \mathbf{h} , which are not known a priori. We propose the use of a two-component vector potential to reformulate (1) as in (2) and solve it with FEM.

With $\mathbf{a} = a_x(z,t)\mathbf{e}_x + a_y(z,t)\mathbf{e}_y$ and $\mathbf{j} = j_x(z,t)\mathbf{e}_x + j_y(z,t)\mathbf{e}_y$,

$$\begin{aligned} \frac{\partial}{\partial z} \left(\nu \frac{\partial a_x}{\partial z} \right) + \sigma \frac{\partial a_x}{\partial t} &= 0 \\ \frac{\partial}{\partial z} \left(\nu \frac{\partial a_y}{\partial z} \right) + \sigma \frac{\partial a_y}{\partial t} &= 0 \end{aligned} \quad (2)$$

where ν is the reluctivity, which is given as a spline function of \mathbf{b}^2 . After discretization in the lamination depth, one obtains

$$\begin{bmatrix} \mathbf{S} & \mathbf{0} \\ \mathbf{0} & \mathbf{S} \end{bmatrix} \begin{bmatrix} \mathbf{a}_x \\ \mathbf{a}_y \end{bmatrix} + \frac{2}{\Delta t} \begin{bmatrix} \mathbf{T} & \mathbf{0} \\ \mathbf{0} & \mathbf{T} \end{bmatrix} \begin{bmatrix} \mathbf{a}_x \\ \mathbf{a}_y \end{bmatrix} = \begin{bmatrix} \mathbf{0} \\ \mathbf{0} \end{bmatrix}$$

$$\text{where } S_{ij} = \int_{\Omega} \nu(a_x, a_y) \nabla N_i \cdot \nabla N_j d\Omega \quad (3)$$

$$T_{ij} = \int_{\Omega} \sigma N_i N_j d\Omega$$

$$\text{and the boundary values } \begin{aligned} a_x(d,t) &= d \cdot b_y(t); & a_x(0,t) &= 0 \\ a_y(d,t) &= -d \cdot b_x(t); & a_y(0,t) &= 0 \end{aligned} \quad (4)$$

with d half of the depth and the origin of the z -axis is at the middle of the lamination. The solution of (3) presents difficulties originating from the non-linearity of the reluctivity and its dependency on both components of the magnetic vector potential or magnetic flux density. This step requires some attention, as we only know how ν depends on \mathbf{b}^2 . We suggest the use of the same value of ν in both directions to keep the material isotropic i.e. $\nu(a_x, a_y) = \nu(\mathbf{b}^2(a_x, a_y))$.

Applying the Newton-Raphson method, one obtains

$$\begin{bmatrix} \mathbf{P}_x & \mathbf{P}_{xy} \\ \mathbf{P}_{xy} & \mathbf{P}_y \end{bmatrix} \begin{bmatrix} \Delta \mathbf{a}_x \\ \Delta \mathbf{a}_y \end{bmatrix} = \begin{bmatrix} \mathbf{R}_x \\ \mathbf{R}_y \end{bmatrix} \quad (5)$$

$$\begin{aligned} P_{xij} &= S_{ij} + \frac{2}{\Delta t} T_{ij} + \\ & 2 \sum_{m=1}^n \sum_{l=1}^n \int_{\Omega} \frac{\partial \nu}{\partial \mathbf{b}^2} a_{xl} a_{xm} (\nabla N_i \cdot \nabla N_l) (\nabla N_j \cdot \nabla N_m) d\Omega \\ P_{yij} &= S_{ij} + \frac{2}{\Delta t} T_{ij} \\ & 2 \sum_{m=1}^n \sum_{l=1}^n \int_{\Omega} \frac{\partial \nu}{\partial \mathbf{b}^2} a_{yl} a_{ym} (\nabla N_i \cdot \nabla N_l) (\nabla N_j \cdot \nabla N_m) d\Omega \\ P_{xyij} &= 2 \sum_{m=1}^n \sum_{l=1}^n \int_{\Omega} \frac{\partial \nu}{\partial \mathbf{b}^2} a_{xl} a_{ym} (\nabla N_i \cdot \nabla N_l) (\nabla N_j \cdot \nabla N_m) d\Omega \end{aligned} \quad (6)$$

The residuals ($\mathbf{R}_x, \mathbf{R}_y$) are computed in a conventional FE manner. The inclusion of P_{xy} in the jacobian matrix allows for a fastest convergence (quadratic convergence is achieved).

Fig. 1 shows the computed flux density distribution in the z -axis at a given time for the case of alternating flux in a direction $\theta = 45^\circ$. Fig 2. shows the same result for the case of rotating flux (circular). Both results are at 500 Hz and 1.5 T.

III. INCORPORATION OF THE ADVANCED MODEL IN 2D FE

The implemented advanced eddy-current model can be coupled with the FE simulation of the electrical machines. An intrinsic coupling quantity is the reluctivity. This approach has been used in the time-harmonic simulation of electrical machines [4].

Fig. 1. Computed flux density distribution in the depth of the sheet when the model is fed by alternating flux at 500 Hz, 1.5 T at 45°. The dark line at $x=0$, $y=0$ represents the 1D model and the other straight lines the magnetic flux density vector at the center of each 1D element (only half the depth is shown).

Fig. 2. Computed flux density distribution in the depth of the sheet when the model is fed by circular flux at 500 Hz, 1.5 T.

However, the same approach is not possible in time stepping; the reluctivity is negative at certain times. We propose the use of the magnetic field strength to incorporate the advanced model in the 2D FE simulation. The magnetic field strength H_{1D} seen by the 2D model is calculated as the product of the magnetic flux density at the surface of sheet and the reluctivity at that point. The BH-curves obtained with this approach are shown in Fig. 3 for the case of an elliptic flux and Fig. 4 for the case of alternating flux (non coupled case).

H_{1D} is assumed to be the sum of the magnetic field strength in the 2D simulation H_{2D} and a component H_{ec} due to the eddy currents. The governing equation of the 2D problem $\nabla \times \mathbf{H}_{1D} = \mathbf{J}$ is reformulated as $\nabla \times \mathbf{H}_{2D} = \mathbf{J} - \nabla \times \mathbf{H}_{ec}$. The 2D FE equations are then derived in a conventional manner except that $-\nabla \times \mathbf{H}_{ec}$ is added to the right-hand side.

To test the coupling methodology, we use a 2D-like model, which is fed by a predefined magnetic field strength \mathbf{H} . The iterations are carried out in a sequential manner with an over-relaxation for the 2D-like model until convergence.

The results of the 2D-like model are affected when it is coupled with the advanced model. This is seen from Fig. 4, where the BH-loops from coupled computations and non coupled are shown for an alternating magnetic field strength at 200 Hz, 1000 A/m increased by the 5th harmonic at 200 A/m.

IV. DISCUSSION AND ANALYSIS

The advanced model implemented in this work has been previously used in conjunction with hysteresis models [2], [5]. The merits of this paper reside in the extension of the model to be used in conjunction with the single-valued bidirectional problems. The statement that the same reluctivity is to be used in both directions guarantees isotropy and the use of the derived coupling terms in the jacobian matrix of the advanced model achieves fast convergence.

Fig. 3. Computed dynamic BH-loop when the model is fed by elliptic flux at 500 Hz with $b_x=1.8$ T and $b_y=1.5$ T. The single-valued BH-curve is also shown.

Fig. 4. Computed BH-loops when the advanced model is incorporated in the simple H-fed model (coupled) and without (non coupled). The simple model is fed from an alternating magnetic field strength with a fundamental at 200 Hz, 1000 A/m with the 5th harmonic at 1000 Hz, 200 A/m.

The purpose of the test runs is two-folds. The feasibility of the incorporation is demonstrated and some phenomena caused by the eddy currents in the lamination are raised. The eddy currents damp the flux, resulting in narrow BH-loop and lower computed losses (loop areas in Fig. 4). The eddy currents also distorted the components of the BH-loops in the case of elliptic field as can be seen from Fig. 3.

V. CONCLUSIONS

The investigations carried out in this work show that the advanced eddy-current model can be efficiently implemented when it is fed from a bidirectional flux too. It is also shown that the incorporation of the advanced model in a 2D FE program is possible and that this incorporation results in better computation of the eddy-current losses in the lamination. A better accuracy is expected in the computation of other quantities such as line currents and torque since they depend directly on the field solution.

Abstract—Thanks to the unique magnetic properties, soft magnetic composite (SMC) materials and their application in electromagnetic devices have achieved significant development. The typical example of SMC application is the electrical machine with complex structure, in which the magnetic flux is basically rotating. To design and analyze such devices, vector magnetic properties of the core material should be properly determined, modeled and applied. This paper presents the modeling of vector magnetic hysteresis of SMC based on a Stoner-Wohlfarth (S-W) elemental operator. A phenomenological mean-field approximation is used to consider the interaction between particles. With the presented model, the magnetization processes of SMC under both alternating and rotating fluxes are numerically simulated. The simulations have been verified by experimental measurements.

I. INTRODUCTION

Thanks to their many unique properties such as 3-D magnetic isotropy, very low eddy current loss, design flexibility and low production process for electromagnetic devices, SMC (soft magnetic composite) materials and SMC electrical machines have undergone significant development in the past decade [1]. Typical applications include claw pole and transverse flux machines in which the flux flows substantially in 3-D space [2]. The conventional laminated electrical steel is not suitable for constructing the core of such machines because the flux component perpendicular to the steel plane may cause excessive eddy current loss. The SMC material seems to be an ideal substitute.

The relationship between the magnetic flux density (\mathbf{B}) and the magnetic field strength (\mathbf{H}) is among the basic properties of magnetic materials. When \mathbf{B} and \mathbf{H} are restrained in the same direction, their relation is reduced to the well-known scalar B-H loop. However, in the 3-D flux machines, \mathbf{B} and \mathbf{H} are not aligned. Furthermore, both \mathbf{B} and \mathbf{H} are rotating and \mathbf{B} lags \mathbf{H} by an angle. In other word, both the magnitudes and directions of the \mathbf{B} and \mathbf{H} may vary, as well as the directional angle difference between the two vectors [2]. Therefore, the vector magnetic properties, such as the vector \mathbf{B} - \mathbf{H} relation and core loss, under different vector magnetizations, should also be investigated. Owing to the very complex mechanism of the magnetic hysteresis, particularly the vector hysteresis, which is not yet fully understood so far, the development of mathematical models of magnetization process has not been successful, in particular for the engineering practice.

A huge amount of work has been conducted by various researchers for modeling the vector magnetic hysteresis.

Among the noticeable work are: (a) the Stoner and Wohlfarth (S-W) model that was postulated based on the rotation of magnetic moments of single domain particles with respect to their easy axes [3]; (b) the vector Preisach model constructed by the superposition of scalar Preisach models [4]; and (c) the combined model that incorporates the vector elemental operator of the S-W model into the Preisach diagram such that the new model has the vector nature of the S-W model while retaining the efficiency of the Preisach model [5]. However, the phenomenological modeling of vector hysteresis has long been centered on the classical S-W model [6]-[7] because of the vector nature of the model.

This paper presents the modeling of vector magnetic hysteresis of SMC based on a Stoner-Wohlfarth (S-W) elemental operator [6]. A phenomenological mean-field approximation is used to consider the interaction between particles [7]. With the presented model, the magnetization processes of SMC under both alternating and rotating fluxes are numerically simulated. The simulations have been verified by experimental measurements.

II. MODELING OF VECTOR HYSTERESIS

Under a magnetic field \mathbf{H} , the magnetic moment \mathbf{m}_s of an S-W particle rotates to the orientation which results in a minimum energy. The position of \mathbf{m}_s changes with respect to \mathbf{H} , and the domain rotation can be reversible or irreversible. The equilibrium orientation of \mathbf{m}_s can be evaluated by the asteroidal rule in the plane containing \mathbf{H} and the easy axis as shown in Fig. 1, where \mathbf{H}_e and \mathbf{H}_p are the \mathbf{H} components along the easy axis and the perpendicular direction respectively, $H_k=2K/(\mu_0 m_s)$, and K is the domain crystal anisotropy constant.

Fig. 1. Asteroid vector elemental hysteresis operator

A mean field term is added to account for the macroscopic effect of interaction between S-W particles [7], $\mathbf{H}_{\text{eff}} = \mathbf{H} + k\mathbf{M}$, where k is a constant feedback coefficient and can be theoretically determined from experimental data [8]. The contribution of an S-W particle can be expressed by $\mathbf{M} = \mathbf{S}(\mathbf{H}_{\text{eff}})$, where $\mathbf{S}()$ stands for the S-W model. The bulk material can be considered as a collection of many S-W single domain particles and the total magnetization is the vector sum of contributions of all these constitute domains. In numerical implementation, the magnetization is computed by the vector sum of \mathbf{m}_i of a group of magnetic particles.

III. NUMERICAL IMPLEMENTATION

The magnetization processes of SMC with isotropic magnetic properties under both alternating and rotating magnetic fields have been simulated numerically. The results (Fig. 2 and Fig. 3) show that in an isotropic magnetic material \mathbf{M} and \mathbf{H} vector are collinear for an alternating magnetic field excitation, while for a rotating magnetic field excitation of constant magnitude M vector lags the \mathbf{H} vector for a certain angle.

Fig. 3. Loci of (a) rotating magnetic field \mathbf{H} , and (b) magnetization \mathbf{M}

IV. EXPERIMENTAL RESULTS

The B-H relationships of SMC samples under various alternating and 2-D and 3-D rotating magnetic excitations have been measured by the authors [9], validating the numerical simulations by using the presented model.

The detailed implementation process and more simulation results will be presented in the full paper. The simulation and experimental results will be compared and analyzed in detail.

Abstract — A method using multi-direction Si-Fe sheet sample magnetic properties measured by the Epstein frame for finite element analysis is presented in this paper to consider the 2D magnetic anisotropy of the sheet. The validity of the method is verified by the comparison between the computational results and measured ones of a model of three phase transformer.

I. INTRODUCTION

Although the method of measuring magnetic characteristics of Si-Fe sheet by 1D single sheet tester has been included in the IEC standard for years, and an advanced 2D measuring method to consider the vector magnetic properties was proposed [1], the method of Epstein frame are still used by many electrical sheet manufacturers and industrial users according to the international standard [2]. The deficiencies of the measurement with the Epstein frame were indicated by authors of [3]-[4], etc. However, in view of its widely use, if we can do something with the Epstein test, and try to improve its traditional measuring method, this work is also of significance. A method using multi-direction Si-Fe sheet sample magnetic properties measured by the Epstein frame for finite element analysis is presented in this paper to involve the 2D magnetic anisotropy of the sheet.

II. METHOD DESCRIPTION

There are many researches have been done with the measuring and modeling of 2D magnetic properties of the silicon steel sheet. K. Fujiwara et al proposed an anisotropic reluctivity tensor, given as [5]

$$\nu = \begin{bmatrix} \nu_x & 0 \\ 0 & \nu_y \end{bmatrix} = \begin{bmatrix} \frac{H \cos \theta_H}{B \cos \theta_B} & 0 \\ 0 & \frac{H \sin \theta_H}{B \sin \theta_B} \end{bmatrix} \quad (1)$$

where θ_H and θ_B denote for the angle to x -axis of \mathbf{H} and \mathbf{B} respectively. With a 2D Single Sheet Tester (SST) [1], a rotational magnetic field is excited and \mathbf{H} and \mathbf{B} with different direction in a Si-Fe sheet can be measured while the sheet sample is fixed in space. Taking the hint of 2D SST, we can set the magnetic field fixed in space and let the sheet samples which consist of the Epstein frame have different angles to the rolling direction, as if the sheets “rotate”. However, the difference between the Epstein frame and 2D SST is that the measurement with the former is one dimensional. Therefore, the following method is used to deal with the problem.

A. B - H curves of multi-direction Si-Fe sheet samples measured by Epstein frame

Fig.1. B - H curves of multi-directions (30ZH120 Si-Fe sheet)

Fig. 2 Angle from the rolling direction to the measurement direction: θ and $90^\circ - \theta$

In multi-direction sampling, the angle from the rolling direction to the measurement direction is set in advance, such as 0° , 10° , 20° , 30° , 40° , 50° , 55° , 60° , 70° , 80° and 90° . For this kind of multi-direction samples, according to the report of [6] we know that when using narrow sample (25mm×300mm) \mathbf{B} and \mathbf{H} remained in a direction parallel to the length of the sample for both low and high level of magnetization. This is the case close to the Epstein test. After the Epstein testing at different measurement directions, the every corresponding B - H curve is yielded as shown in Fig.1. One can find the relationships of those curves measured at different specified measurement directions. For example, the curves at 20° and 70° represent the magnetic properties from two orthogonal measurement directions, see Fig.2. This is easy to understand as long as we notice that here $20^\circ + 90^\circ = 110^\circ$, and along this direction the magnetic property is the same as 70° according to the symmetry of the sample. By using these curves, the 2-D magnetic properties can be obtained.

B. Formulation in finite element analysis of magnetic fields

The governing equation under a global coordinates including 2D magnetic properties is given by

$$\frac{\partial}{\partial x} \left(v_{yx} \frac{\partial A}{\partial y} - v_{yy} \frac{\partial A}{\partial x} \right) - \frac{\partial}{\partial y} \left(v_{xx} \frac{\partial A}{\partial y} - v_{xy} \frac{\partial A}{\partial x} \right) = J \quad (2)$$

Eq. (2) is solved with FE analysis and the Newton-Raphson iteration.

To use the multi-direction B - H curves, a local coordinate system x' - y' is set in each element, and another iterative process of local reluctivities is needed. The corresponding reluctivity of an element is given by

$$v^k = \begin{bmatrix} v_{x'}^k & 0 \\ 0 & v_{y'}^k \end{bmatrix} \quad (3)$$

where the superscripts denote the iteration number, and

$$v_{x'}^k = f_1(B_x^{k-1}, \theta^{k-1}), \quad v_{y'}^k = f_2(B_y^{k-1}, 90^\circ - \theta^{k-1}) \quad (4)$$

in (4) θ^{k-1} is the angle from the direction of B^{k-1} to the rolling direction. Based on a coordinate transformation, the relation of the global and local reluctivities can be deduced, which is given as

$$\begin{cases} v_{xx} = v_{x'} \cos^2 \alpha + v_{y'} \sin^2 \alpha \\ v_{xy} = v_{x'} \cos \alpha \sin \alpha - v_{y'} \sin \alpha \cos \alpha \\ v_{xy} = v_{yx} \\ v_{yy} = v_{x'} \sin^2 \alpha + v_{y'} \cos^2 \alpha \end{cases} \quad (5)$$

where α is the angle between the local and global coordinates.

C. Numerical Model

Fig. 3 A model of transformer without secondary coils

A model of three-phase transformer without the secondary coils is taken as a numerical example. Three windings of 106 turns are placed on each limb of the iron core which is made of laminated grain-oriented silicon steel sheets of 30ZH120, shown in Fig. 3. The computation steps are as follows.

Step 1: Set the iteration number $k = 0$, input the initial reluctivities $v_{x'}^0$ and $v_{y'}^0$ for each element.

Step 2: Solve (2) with FEM, then calculate B_x^0 , B_y^0 , and

$$\theta^0 = \begin{cases} \arctan(|B_y^0|/|B_x^0|) & \text{in the area of the limbs} \\ \arctan(|B_x^0|/|B_y^0|) & \text{in the area of the yoke} \end{cases} \quad \text{for each element.}$$

Step 3: $k = k+1$, determine the B - H curves of element according to (4) with an interpolation, calculate $v_{x'}^k$ and $v_{y'}^k$, then solve (2) with Newton-Raphson iteration, and calculate B_x^k, B_y^k .

Step 4: $\Delta B_x^k = |B_x^k - B_x^{k-1}|$, $\Delta B_y^k = |B_y^k - B_y^{k-1}|$. If the total iterative error $\sum \sqrt{\Delta B_x^2 + \Delta B_y^2} \leq \varepsilon_1$, then stop; or else continue, where ε_1 is a tolerance specified in advance.

Step 5: modify θ^k according to a relaxation rule, then go to Step 3.

III. RESULTS

Fig. 4 Comparison of measured and calculated $|B|$

Fig. 5 Comparison of measured and calculated angle of B to x -axis

Fig. 4 and Fig. 5 show the comparisons of measured and calculated flux density B at the position of test coil C3 and C4 for the maximum electric current of 2.6A. More results and discussions will be proposed in the extended paper.

Abstract — In this paper, the nature of iron losses in electrical steel during alternating field excitation is investigated more closely. A more exact definition of the ac iron losses is proposed by accurately measuring the losses for conditions of both sinusoidal H and sinusoidal B . In addition, inverse hysteresis model considering eddy current loss is developed to analyze the iron loss when the input is voltage source. With this model, inrush current in inductor or transformer as well as the iron loss can be calculated. The results of this new approach to iron loss calculations in electrical steel are compared to experimentally-measured losses.

I. INTRODUCTION

For a precise design and analysis of electric machine, iron loss analysis becomes very important and essential part [1]. For measuring hysteresis loss, the input can be sinusoidal magnetic field intensity or the sinusoidal flux density. The iron losses in these two cases are not same, but this fact has received almost no attention to date. If harmonics are present in the excitation, the iron loss calculation becomes even more complex. One approach [2] for including harmonics in the iron loss analysis uses Discrete Fourier Transform to decompose the flux density into its harmonic components. The iron losses at each element are then calculated using iron loss data sheet and the total loss is obtained by summation of the iron losses at all of the elements. However, the results of this approach can be too large in comparison to the actual iron losses. The purpose of this research is to investigate more closely the nature of iron losses in electrical steel during alternating field excitation. In this work, a more exact definition of the ac iron losses is proposed by accurately measuring the losses for conditions of both sinusoidal H and sinusoidal B . In addition, inverse magnetization-dependent hysteresis model considering eddy current loss is developed to analyze the iron loss when the input is voltage source. With this model, inrush current in inductor or transformer as well as the iron loss can be calculated. The results of this new approach to iron loss calculations in electrical steel are compared to experimentally-measured losses.

II. IRON LOSS FOR ALTERNATING MAGNETIC FIELD

A) Hysteresis loss

Hysteresis loss is the B-H loop area not including the eddy current loss by applying the lowest frequency. Fig. 1 shows the two kinds of B-H loops of the bulk ring, whose areas represent iron losses for the input of 0.2[Hz]. The dotted line shows the loop whose input is magnetic field intensity and the output becomes magnetic flux density.

Let's call this as sinH condition loop and it means the input H is sinusoidal. The solid line is sinB loop and the sinusoidal flux density B becomes input. To accomplish these experiments, a apparatus shown in Fig. 2 is developed and the shapes of H or B can be controlled. As can be seen in Fig. 1, the loop areas under sinH and sinB are different. Under sinH condition, the flux density waveform is no more sinusoidal and it becomes to have harmonics which cause harmonic eddy current losses. As a result, the hysteresis loss needs to be measured under the sinusoidal flux density condition.

Fig. 1. Measured B-H loops for sinB and sinH conditions

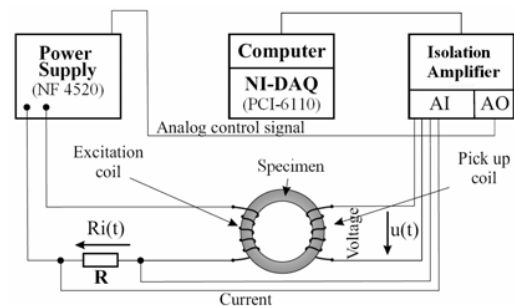

Fig. 2. Measurement system.

B) Iron Losses including harmonics

The current of exciting coil and flux density can be measured with the measurement system in Fig. 2. Fig. 3 shows the measured B-H loop (solid line) under sinH condition and separated loops according to their frequencies by FFT. As can be seen, the fundamental frequency loop (dotted line, 1st B) is larger than the original loop (all B). This means the iron loss cannot be calculated by the summation of the each frequency component and it must be calculated by measuring the loop area. If the B-H data are known or measured, the loss can be calculated by integrating the magnetic field intensity for the flux density [3]. Table 1 shows the measured and FFT results for Fig. 3.

Fig. 3. Original and harmonic loops

Table 1. Measured and FFT loops results for Fig. 4.

	Freq.	Phase (degree)	Bm[T]	Loss/ Iperoid	Total Loss
Original B	1Hz		0.993149	0.186105	0.186105
FFT 1st	1Hz	0	1.196438	0.232240	0.494115
3rd	3Hz	11.60586	0.289885	0.049908	
5th	5Hz	8.67891	0.114318	0.014979	
7th	7Hz	-3.53840	0.049945	0.004099	
9th	9Hz	5.09336	0.020309	0.000801	
11th	11Hz	-18.28070	0.006875	0.000123	

Fig. 4 shows the waveforms measured by the developed system in Fig. 2. In the figure, the magnetic field intensity, magnetic flux density, minor loops and initial magnetization curves are shown. These experiments are under sinB condition. As can be seen in the figures, the measured results are different according to the input conditions. When the input is sinH, the flux density becomes like square waves, so they include lots of harmonics and increase iron loss because the eddy current loss increases.

Fig. 4. Experiment results under sinB.

III. INVERSE HYSTERESIS ALGORITHM

In many cases, the input becomes not current but voltage, and then the input element for iron loss calculation needs to be also not magnetic field intensity but magnetic flux density. Therefore the inverse algorithm $H = f^{-1}(B)$ is required. If the flux density $B(H)$ changes, by changing the magnetic field intensity with ΔH , $B(H)$ can be determined using Preisach algorithm. To reduce the calculation efforts and error,

interpolation method is used. For example, if $B(t_p) > B(t_{p-1})$ and exact value $B(t_p)$ is between the two calculated flux densities where p is a time step, $H(t_p)$ can be calculated by (1) and any iteration process is not needed.

$$H(t_p) = H_2 \frac{B(t_p) - B_1}{B_2 - B_1} + H_1 \frac{B(t_p) - B_2}{B_1 - B_2} \quad (1)$$

When the load is R-L circuits, the voltage equation can be transformed to discrete equation as (2). By solving this equation for flux ϕ , flux density, iron loss, inrush current etc. can be calculated.

$$\phi(k+1) = \phi(k) + \frac{\Delta t}{n} [E_m \sin(\omega \cdot t_k + \theta) - r \cdot i] \quad (2)$$

Where k is time step, n is number of turn or ring core and θ is the phase angle of voltage. The eddy current loss can be considered with (3) where δ is the thickness of the steel, w is the width, and ρ is the electrical resistivity. Eddy current i_e can be calculated because P_e can be calculated with (3) and the applied voltage is known. The total current is calculated by adding i_e to i in (2).

$$P_e = \frac{1}{\delta w} \int_V \rho J^2 dV = \frac{1}{\delta w} \int_{-\frac{\delta}{2}}^{\frac{\delta}{2}} \rho \left(\frac{x}{\rho} \frac{dB}{dt} \right)^2 w dx \quad (3)$$

$$= \frac{\delta^2}{12\rho} \left(\frac{dB}{dt} \right)^2$$

IV. CONCLUSION

In this paper, exact definition of hysteresis loss is proposed. That is, it needs to be measured under the sinusoidal flux density condition. In addition, the iron loss including harmonics is defined by the experimental results. The iron loss cannot be calculated by the summation of the each frequency component and it must be calculated by the real loop area through integrating the magnetic field intensity for the flux density. To simulate this phenomenon, inverse algorithm is proposed and inrush current in an inductor is experimented and simulated. They are compared and it shows good agreement.

Abstract — This paper presents an improved magnetic reluctivity model for vector magnetic properties of anisotropic electrical steel sheet under distorted magnetic flux density condition. In the modeling, the non-sinusoidal magnetic flux density (B) waveform is expanded into fundamental and higher harmonic components using Fourier series expansion. For the fundamental component, the relationship between B and H (magnetic field intensity) is expressed by an improved reluctivity model with higher accuracy. For the higher harmonic components, their eddy current effects are estimated into the vector relationship based on a lot of experimental tests. The accuracy of the proposed model is verified by comparing its results with experimentally measured B - and H -waveforms with 30PG110 silicon steel sheet.

I. INTRODUCTION

An effective expression of two-dimensional (2-D) magnetic properties of electrical steel sheet is necessary to analyze field performance and loss characteristics of electromagnetic devices accurately. There have been foregoing researches, therefore, to develop some permeability (or reluctivity) models to express the 2-D magnetic properties under sinusoidal magnetic flux density (B) condition, that is under pure alternating or rotating magnetic flux conditions [1]–[3]. In the researches, the magnetic reluctivity parameters are obtained by using Fourier series expansion of the waveforms of magnetic field intensity (H) using direct description of the relationship between B and H . However, the accuracy of the permeability model is greatly affected by the order of harmonic components considered in the Fourier series expansion. For example, the reluctivity model considering only the first and third harmonic components is proven not accurate enough to describe the vector magnetic properties as soon as the material is saturated [4].

On the other hand, the B -waveform in electric machines and transformers is often distorted from sinusoidal one. For a precise field analysis, hence, a magnetic permeability model under distorted B -waveform is also necessary. However, experimental measurements under distorted B -waveform condition are very difficult because of the nonlinearity of the material properties and lack of the criterion for measurement. Very recently, Enokizono proposed a reluctivity model by estimating the H -waveforms generated by the eddy currents induced by the higher harmonic components of the magnetic flux density [5]. But, the modeling of 2-D properties of silicon steels under distorted B -waveform is still in its infancy, and requires more experimental verifications.

In this paper, an improved 2-D magnetic reluctivity model under distorted B -waveform is developed taking account of both the modeling accuracy and computational cost when combined with finite element analysis (FEA). The magnetic field intensity affected by the eddy currents induced by the higher harmonic components of B -waveform is numerically modeled based on measured data.

II. MAGNETIC RELUCTIVITY MODEL FOR SINUSOIDAL MAGNETIC FLUX DENSITY

The distorted B -waveform can be expressed using the Fourier series expansion as follows:

$$B_x(\tau) = B_{1mx} \sin(\tau + \varphi_{1B_x}) + \sum_{n=2}^N \{B_{nm_x} \sin[(2n-1)\tau + \varphi_{nB_x}]\} \\ = B_{1x}(\tau) + \sum_{n=2}^N B_{nx}(\tau) \quad (1)$$

where only x -directional equations are shown and the y -directional ones can be obtained by substituting ‘ y ’ instead of ‘ x ’. The first term in (1) is the fundamental component of which frequency is 50Hz or 60Hz, and others are higher harmonic terms, as shown in Fig.1.

Under a purely rotational magnetic flux condition, a magnetic reluctivity model for 2-D magnetic property of grain-oriented silicon steel is proposed in [1], and can be defined as follows:

$$H_{1x} = v^{xr} B_{1x} + v^{xi} \frac{\partial B_{1x}}{\partial \tau} \quad (2)$$

where H_{1x} is the magnetic field intensity obtained when the specimen is excited by 50Hz sinusoidal B -waveform. The magnetic reluctivity coefficients v^{xr} and v^{xi} can be expressed as in (3) considering only the first and third harmonic components of the measured H -waveforms using the 2-D single sheet tester under sinusoidal B -waveform condition.

$$v^{xr} = \kappa^{-xr} + \kappa^{-xi} \cdot B_{1x}^2 + \kappa^{-xi} \cdot B_{1x} \cdot \frac{\partial B_{1x}}{\partial \tau} + \kappa^{-xi} \cdot \left(\frac{\partial B_{1x}}{\partial \tau}\right)^2 \quad (3)$$

In this paper, it is revealed that the hysteresis model in (3) considering only the first and third harmonic components of H -waveform is not accurate enough to describe the vector magnetic property especially when the material is magnetically saturated, as shown in Fig.2. Thus, improved reluctivity models for v^{xr} and v^{xi} considering both the higher harmonic components up to 7 and computational cost are proposed in this paper as follows:

Fig. 1 Distorted magnetic flux density. (a) B -waveform; (b) fundamental component; (c) higher harmonic components.

Fig. 2 Harmonic components of H_x and H_y .

$$\nu^{xr,xi} = \kappa_0^{xr,xi} + \kappa_1^{xr,xi} \cos^2 \tau + \kappa_2^{xr,xi} \sin^2 \tau + \kappa_3^{xr,xi} \cos^4 \tau + \kappa_4^{xr,xi} \sin^4 \tau + \kappa_5^{xr,xi} \cos^6 \tau + \kappa_6^{xr,xi} \sin^6 \tau \quad (4-a)$$

$$\begin{aligned} \kappa_0^{xr} &= (R_{1H_{1x}} - 3R_{3H_{1x}} + 5R_{5H_{1x}} - 7R_{7H_{1x}}) P_x \\ &\quad + (I_{1H_{1x}} + 3I_{3H_{1x}} + 5I_{5H_{1x}} + 7I_{7H_{1x}}) Q_x \\ \kappa_2^{xr} &= (-4I_{3H_{1x}} - 20I_{5H_{1x}} - 56I_{7H_{1x}}) Q_x \\ \kappa_4^{xr} &= (16I_{5H_{1x}} + 112I_{7H_{1x}}) Q_x; \quad \kappa_6^{xr} = -64I_{7H_{1x}} Q_x \end{aligned} \quad (4-b)$$

Fig. 3 shows a comparison of H -waveforms computed from (4) and (3) and experimentally measured for 30PG110 Grain-oriented silicon steel. It can be seen that the improved reluctivity models in (4) give better agreement with the measured ones. In the version of full paper, detailed derivations and more discussions will be given.

III. IMPROVED RELUCTIVITY MODEL CONSIDERING HIGHER HARMONIC COMPONENTS OF B -WAVEFORM

For the higher harmonic components of B , it is hard to give an effective vector relationship between B and H directly because measurements under distorted B -waveform are difficult due to nonlinearity of the material properties and lack of criterion for the measurement. In order to consider the effects of eddy current induced from the higher harmonic components of B , the reluctivity model proposed in [4] was based on the skin depth of the eddy current and effective thickness d_{eff} was employed instead of the thickness d of the steel sheet. With the assumption that eddy current decreases linearly instead of exponentially toward the center from the surface, the following relation can be obtained

$$J_{ey} = \sigma \frac{d}{2d_{eff}} \frac{\partial B_x}{\partial t} z \quad (5)$$

where z denotes the position in thickness-direction. The eddy current loss W_e generated by J_{ey} is given by

$$W_e = \frac{f}{\rho} \int_T \left(\frac{\sigma d_{eff} d}{6} \frac{\partial B_x}{\partial t} \right) \frac{\partial B_x}{\partial t} dt \quad (6)$$

where ρ is the material density. On the other hand, the power loss due to the eddy current is defined by the following equation

Fig. 3 Comparison of the measured and calculated H -waveforms.

Fig. 4 2-D single sheet tester.

$$W_e = \frac{f}{\rho} \int_T H_{ex} \frac{\partial B_x}{\partial t} dt \quad (7)$$

The magnetic field intensity due to higher harmonic components of B -waveform, thus, can be written as follows

$$H_e = \frac{\sigma d_{eff} d}{6} \frac{\partial B}{\partial t} \quad (8)$$

By considering the (1), (2) and (8), the magnetic field intensity corresponding to a distorted B -waveform can be written as follows

$$H_x = \nu^{xr} B_{1x} + \nu^{xi} \frac{\partial B_{1x}}{\partial \tau} + \frac{\sigma d_{eff} d}{6} \frac{\partial}{\partial t} \sum_{n=2}^N B_{nx}(t) \quad (9)$$

In this paper, to make clear the behavior of distorted flux density and the magnetic field intensity, we have verified the estimation modeling method expressed in (9) based on sufficient measurement data under distorted flux conditions using a 2-D single sheet tester shown in Fig. 4.

The experimental verification and more discussions including FEA application will be given in the version of full paper.

Abstract — The presented work investigates the modeling of inrush currents in a three phase transformer under sinusoidal operating conditions. The transformer core is modeled taking into account the magnetic hysteresis. A Jiles-Atherton vectorized model is used for the nonlinear core modeling. The key advantage of this vector model is its reluctivity tensor which is appropriated for the Finite Element Analysis implementation. A time-domain simulation was carried out and the results are compared with experimental data for the procedure validation.

I. INTRODUCTION

Inrush currents are high magnitude currents generated during energization of a transformer. In fact, these are the consequence of a residual magnetic flux that is added to the magnetizing flux when the device is turned on. This phenomenon leads to a highly saturated transitory state of the magnetic core of the transformer. The magnitude of inrush current can reach initially several times the rated load current but slowly decreases by the effect of oscillation damping due to winding and magnetizing resistances of the transformer as well as the impedance of the system where it is connected. Finally it reaches the rated current value. This process typically can take several electrical periods [1].

These currents have undesirable effects as potential damage, reduction of the life of the transformer, protective relay miss operation and reduced power quality on the system. Furthermore, nowadays, power transformers usually operate at higher magnetic flux density values as high performance grain oriented steels are used more and more. It results that modern transformers will have higher inrush currents. This affects the transformer design and size.

In the present work, the Jiles-Atherton (J-A) inverse vector model was chosen to model the iron core behaviour. This model is able to represent a possible anisotropic steel behaviour as well as the rotational flux in the transformer T-joints. If the flux does not change its space direction, the model reduces itself to the scalar model.

The J-A vector hysteresis model is incorporated in a 2D Finite Element (FE) code, with vector potential formulation, using the magnetic differential reluctivity tensor. The mathematical model is used for the calculation of the inrush currents in a three-phase transformer. The magnitude of the inrush current being also strongly dependent on the voltages switching instant, we focus in this work on the switching instant of the three phase voltage source. The presented model must be able to perform an analysis of inrush amplitudes by simulating arbitrary voltages switching instants.

Comparison between the calculated and measured curves is also performed.

II. NONLINEAR CORE MODEL

The non linear behaviour of a transformer core can be modelled by different methods. The use of a vector model allows us to take into account the fields in the principal lamination directions avoiding the approximation of an average permeability in each finite element, performing a more realistic calculation. To this purpose, a vector model is the more appropriate choice to take into account magnetic hysteresis.

Bergqvist proposed a vector generalisation of the Jiles-Atherton scalar hysteresis model [2][3]. In its inverse version, i.e., giving the magnetization with the induction as input variable, the main equation is [4]:

$$d\mathbf{M} = \frac{1}{\mu_0} [\mathbf{1} + f_\chi(\mathbf{1} - \bar{\alpha}) + \bar{c}\bar{\xi}(\mathbf{1} - \bar{\alpha})]^{-1} \cdot [f_\chi + \bar{c}\bar{\xi}] d\mathbf{B} \quad (1)$$

with $f_\chi = \bar{\chi}_f |\bar{\chi}_f|^{-1} \bar{\chi}_f$ and where the auxiliary vector variable $\bar{\chi}_f$ is given by $\bar{\chi}_f = \bar{k}^{-1}(\mathbf{M}_{an} - \mathbf{M})$. \mathbf{M}_{an} and \mathbf{M} are, respectively, the anhysteretic magnetization and the total magnetization. \bar{k} , $\bar{\alpha}$ and \bar{c} are second rank tensors which terms must be obtained experimentally. $\mathbf{1}$ is the diagonal unity matrix and $\bar{\xi}$ is the diagonal matrix of the anhysteretic functions derivatives with respect to the effective field components.

Using $d\mathbf{M}$ obtained from equation (1), one can write $d\mathbf{H} = \|\partial v\| d\mathbf{B}$, where $\|\partial v\|$ is the differential reluctivity tensor.

III. VOLTAGE FED AND MAGNETIC VECTOR POTENTIAL FORMULATION

The formulation, with a magnetic vector potential \mathbf{A} and an electric scalar potential φ , is obtained from the weak form of the Ampere's law [5][6]:

$$\begin{aligned} & (\|\partial v\| \operatorname{curl} \mathbf{A}(t + \Delta t), \operatorname{curl} \mathbf{A}')_{\Omega} - (\|\partial v\| \operatorname{curl} \mathbf{A}(t), \operatorname{curl} \mathbf{A}')_{\Omega} + \\ & + (\mathbf{H}(t), \operatorname{curl} \mathbf{A}')_{\Omega} + (\sigma \partial_t \mathbf{A}, \mathbf{A}')_{\Omega_c} + (\sigma \operatorname{grad} \varphi, \mathbf{A}')_{\Omega_c} + \\ & - (\mathbf{J}_s, \mathbf{A}')_{\Omega_s} = 0, \quad \forall \mathbf{A}' \in F_a(\Omega), \end{aligned} \quad (2)$$

where $F_a(\Omega)$ denotes the space function defined on Ω which contains the basis and test functions for both vector potentials $\mathbf{A}(t+\Delta t)$, $\mathbf{A}(t)$ and \mathbf{A}' . The function $\|\partial v\|$ represents the magnetic behavior law, which comes from the 2D vector hysteresis model. The block $(\cdot, \cdot)_{\Omega}$ denotes a volume integral in Ω of scalar or vector fields products. The electric field \mathbf{E} and the magnetic flux density \mathbf{B} , as well as the magnetic field \mathbf{H} and the current density \mathbf{J} , are expressed in terms of the potentials \mathbf{A} and φ by

$$\mathbf{E} = \sigma^{-1} \mathbf{J} = -\partial_t \mathbf{A} - \text{grad} \varphi \quad \text{in } \Omega_c, \quad (3)$$

$$\mathbf{B} = \|\mu\| \mathbf{H} = \text{curl} \mathbf{A} \quad \text{in } \Omega. \quad (4)$$

The circuit relation associated with a stranded inductor $j \in \Omega_s$, relating its current I_j to its voltage φ_j , has been established for the \mathbf{A} -formulation as follows

$$\partial_t (\mathbf{A}, \mathbf{w})_{\Omega_s} + R I_j = -\varphi_j, \quad (5)$$

where R is the resistance of the inductor and \mathbf{w} is called the wire density vector [7].

IV. RESULTS

The numerical simulation of the inrush currents was performed at no load and the three-phase voltage source was at 230V-50Hz. The switching instant of the transformer corresponds to the first phase passing through zero. To have the same initial magnetic conditions in the numerical simulation and in the experimental measurements, the transformer was initially demagnetized before switching on for the inrush currents measurement. The identification of the hysteresis model parameters was achieved using experimental measurement on a sample of the same FeSi steel used in the construction of the transformer.

The measured and calculated transitory inrush currents behavior for the transformer no-load operation are shown, respectively, in Figs. 1 and 2.

Figures 1 and 2 show that the FE model results are in a very good agreement with the measured inrush current. This indicates that the developed FE model is able to represent with accuracy the nonlinear magnetization of the studied transformer.

From a numerical aspect, a better convergence of the nonlinear system has been observed when using the vector model. One can note that an average of five numerical iterations was sufficient for each time-step calculation. This robustness can be explained by the natural match between the reluctivity tensor and the field equations.

Abstract — In this paper we compare different approaches for the lamination stack homogenization with a short-circuit due to an electrical fault between several sheets. The presented techniques are based on the determination of a complex equivalent magnetic permeability for the homogenized domain. The eddy current losses are calculated in the homogenized lamination stack and in the fault. These losses are compared with those obtained from a reference system where the lamination is modeled with its real geometry.

I. INTRODUCTION

Stator laminations of large generators are coated with insulating varnishes to avoid electrical contact that leads to additional Joule losses. In some situations due, for example to manufacturing faults or local overheating, the insulation can be damaged and electrical contacts appears between the laminations. It may generate electrical currents, which can be significant during electrical faults. Such a situation may be very dangerous for the machine integrity [1].

To investigate the effect of eddy currents on the global behaviour of the system, it is necessary to use a technique that takes into account the magneto-dynamic effects in the lamination stack without modelling the real geometry of the laminations. Homogenization techniques can be very useful in such a case. Nevertheless, adding a fault between several sheets in the laminations modifies the assumptions made for the homogenizing model.

The purpose of this work is to evaluate the accuracy of a homogenized lamination stack considering an electrical fault. The Joule losses are calculated in both parts of the system, i.e. the homogenized and the fault parts. Several approaches [2, 3], based on the low and high frequency assumptions, are investigated for the lamination stack homogenization, and their behaviour when a fault is inserted in the homogenized region. A comparison is made with a reference system which models the real sheet geometry of the lamination.

II. MATHEMATICAL MODEL

We consider a domain Ω whose boundary is denoted Γ . Two sub-domains are introduced in Ω : an electrically conducting domain Ω_c with boundary Γ_c and a homogenized domain Ω_h that simulates the equivalent magnetic behaviour of a lamination stack (Fig. 1).

In time harmonic magnetodynamics, the Maxwell's equations can be written as,

$$\text{curl } \underline{\mathbf{E}} = -j\omega \underline{\mathbf{B}} \quad \text{and} \quad \text{div } \underline{\mathbf{B}} = 0 \quad (1)$$

$$\text{curl } \underline{\mathbf{H}} = \underline{\mathbf{J}}_s + \underline{\mathbf{J}}_{\text{ind}} \quad \text{and} \quad \text{div } (\underline{\mathbf{J}}_s + \underline{\mathbf{J}}_{\text{ind}}) = 0 \quad (2)$$

with $\underline{\mathbf{H}}$ the magnetic field, $\underline{\mathbf{B}}$ the magnetic flux density, $\underline{\mathbf{E}}$ the electric field, $\underline{\mathbf{J}}_s$ the current density supposed to be known in stranded inductors, $\underline{\mathbf{J}}_{\text{ind}}$ the eddy current density and ω the pulsation. To ensure the uniqueness of the solution, homogeneous boundary conditions are applied on the fields ($\Gamma = \Gamma_B \cup \Gamma_H$ and $\Gamma_c = \Gamma_E \cup \Gamma_{\text{Jind}}$). The electric and magnetic behaviour laws are given by,

$$\underline{\mathbf{H}} = \nu \underline{\mathbf{B}} \quad \text{in } \Omega - \Omega_h, \quad \underline{\mathbf{J}}_{\text{ind}} = \sigma \underline{\mathbf{E}} \quad \text{in } \Omega_c \quad (3)$$

$$\underline{\mathbf{H}} = \|\tilde{\nu}\| \underline{\mathbf{B}} \quad \text{in } \Omega_h \quad (4)$$

with ν the magnetic reluctivity, σ the electric conductivity and $\|\tilde{\nu}\|$ a complex reluctivity tensor. Each component of $\|\tilde{\nu}\|$ can be expressed such as $\tilde{\nu}_{ij} = \tilde{\nu}'_{ij} + j\omega \tilde{\nu}''_{ij}$. To solve this problem, the electric formulation can be used. From (1.a) and (1.b), two potentials are introduced: the magnetic vector potential $\underline{\mathbf{A}}$ in the whole domain Ω and the electric scalar potential ϕ in Ω_c . Then, the magnetic flux density and the electric field can be rewritten such that,

$$\underline{\mathbf{B}} = \text{curl } \underline{\mathbf{A}} \quad \text{and} \quad \underline{\mathbf{E}} = -j\omega \underline{\mathbf{A}} - \text{grad } \phi \quad (5)$$

By using (2), (3) and (4), the weak formulation to solve can be obtained such that,

$$\begin{aligned} & (\nu \text{curl } \underline{\mathbf{A}}, \text{curl } \underline{\mathbf{A}}')_{\Omega - \Omega_h} + (\|\tilde{\nu}\| \text{curl } \underline{\mathbf{A}}, \text{curl } \underline{\mathbf{A}}')_{\Omega_h} \\ & + (\sigma j\omega \underline{\mathbf{A}}, \underline{\mathbf{A}}')_{\Omega_c} + (\sigma \text{grad } \phi, \underline{\mathbf{A}}')_{\Omega_c} - (\underline{\mathbf{J}}_s, \underline{\mathbf{A}}')_{\Omega_s} = 0 \end{aligned} \quad (6)$$

with $\underline{\mathbf{A}}'$ a test function defined in the same space as $\underline{\mathbf{A}}$. To discretize the fields and the potentials, Whitney's elements are used.

Fig. 1. Studied domain

For the homogenization of the lamination stack magnetic behaviour, different approaches have been considered. The

7. Material Modelling

first one [2], based on a static approach (S-Model), represents the anisotropy of the stack by using the components \tilde{v}'_{ij} (\tilde{v}''_{ij} are fixed to zero). If the steel sheets are on the xy plane, \tilde{v}'_{11} and \tilde{v}'_{22} are the tangential components and \tilde{v}'_{33} is the normal component. A wide-frequency-band model (W-F Model) is proposed [3], considering $\delta = (\pi f \sigma \mu)^{-1/2}$ the skin depth and d the lamination thickness. Thus, we have,

$$\tilde{v}_{ij} = \tilde{v}'_{ij} + j\omega \tilde{v}''_{ij} = \frac{\sigma_{ij} d \delta_{ij} \omega (1+j)}{8} \frac{\sinh((1+j)d/\delta_{ij})}{\sinh^2((1+j)d/(2\delta_{ij}))}. \quad (7)$$

Here both components \tilde{v}' and \tilde{v}'' are complex. For lower frequencies, a simplified model (L-F model) can be obtained from equation (7),

$$\tilde{v}_{ij} = \tilde{v}'_{ij} + j\omega \tilde{v}''_{ij} = 1/\mu_{ij} + j\omega(\sigma_{ij} d^2/12). \quad (8)$$

With these techniques eddy currents can be considered. Moreover, combining the static approach for the lamination stack anisotropy and eddy currents effects (model [2] + [3]), it is possible to introduce the permeability tensor in (7). The skin depth δ is calculated according to this tensor.

III. APPLICATION

A simple geometry representing a lamination stack was chosen, considering only the linear case. For the reference system, the lamination stack dimensions are 30 mm x 30 mm with 6 sheets whose thickness is 500 μm . Two successive sheets are separated by a 10 μm insulating layer.

The mesh has about 60000 prismatic elements. The magnetic flux is imposed on the way that the average magnetic induction is 1.5 Tesla. To have good accuracy for the eddy currents in the reference system, each lamination is meshed with four elements in its thickness dimension. In case of homogenization, the same mesh is used but without the lamination and insulation separation.

To test the robustness of the homogenization techniques in case of a fault between several sheets, a short circuit represented by a cylindrical volume is placed in the middle of the lamination stack. This volume remains with the same physical properties in the reference and homogenized models.

The iron parts have been considered with an isotropic conductivity $\sigma=2 \times 10^6$ S/m and a magnetic permeability $\mu=1000\mu_0$, where $\mu_0=4\pi \times 10^{-7}$ H/m. The insulation has $\sigma=0$ and $\mu=\mu_0$. The electrical cylinder fault, when considered, has the same characteristics as the iron. The eddy current losses (P_{EC}) are calculated as follows,

$$P_{EC} = \int_V \underline{E} \underline{J}^*_{ind} dv. \quad (9)$$

The magnetic energy of the system is calculated as,

$$W_{mag} = \int_V \frac{1}{2} \underline{B} \underline{H}^* dv \quad (10)$$

Solving the system with the $\mathbf{A}\text{-}\phi$ formulation considering the electrical fault, the magnetic energy of the entire system is given in Tab.1 and the eddy current losses in the electrical fault are given in Tab. 2.

Frequency	Magnetic energy in the entire system (J)	
	50 Hz	1000 Hz

S-Model + W-F	9.61	28.38	57.41

Tab.2 Eddy current losses in the electrical fault, $\mathbf{A}\text{-}\phi$ formulation

From results in Tab.1, we can see that the global magnetic energy obtained with the different homogenization approaches remains close with the one of the reference system, even for the frequency 1 kHz. Nevertheless, if we focus on the eddy current losses in the electrical fault given in Tab.2, the homogenization approaches give satisfactory results up to 50 Hz in the case of the studied system. At the frequency 100 Hz, the error becomes much larger. Such results are predictable as the electrical fault introduces a non-homogeneity in the supposed homogenized lamination stack.

IV. CONCLUSION

Different homogenization methods for lamination stacks were presented and compared. The results show that all the models are valid including the case when an electrical fault is inserted in the homogenized volume, especially for lower frequencies.

In the extended version we intend to explore more in detail the obtained results, showing also the results using the $\mathbf{T}\text{-}\Omega$ formulation. We will also present a study in which the number of short-circuited sheets varies, and we will evaluate its influence on the results. All these calculations will be performed in the industrial frequency range.

Abstract — This paper presents a 2D finite element model to analyze the iron losses in a three-phase transformer. In this model, the effects of non-linear core behavior is taken into account by means of a vector hysteresis model incorporated in the finite element formulation by using a magnetic differential reluctivity tensor. The reluctivity tensor emerges naturally from the vectorized Jiles-Atherton model. The complete model includes eddy current losses and the anomalous losses. The magnetization currents are calculated and compared with the measured ones. Calculations of hysteresis loops at spotted points of the transformer are also performed. The comparisons between the iron losses measured and calculated with vectorial hysteresis are performed.

I. INTRODUCTION

The core of magnetic devices can experiment two different types of magnetic fluxes. The alternating flux occurs when the flux changes its magnitude but not its spatial direction. The rotational flux is present when the magnetic flux rotates in the plane of the lamination. The losses due to the rotational flux are higher than the one due to the alternating flux.

In a three-phase transformer, rotational flux is observed in the corner joints (T-joints). In T-joints the magnetic behaviour is very complex, differently from the central limb. That is the reason why, under rotational flux conditions, the vector relationship between magnetic field and induction must be considered. The rotational losses, which can be more important than alternating ones, contribute to a significant part of the global losses [1].

In this paper, a vector hysteresis model is incorporated in a 2D finite element (FE) code, with magnetic vector potential formulation, using the magnetic differential reluctivity tensor. This model emerges naturally from the vectorized Jiles-Atherton model. The complete model includes eddy current losses and the anomalous losses.

The FE model is used for the analysis of a non loaded three-phase transformer. The magnetization currents are calculated and compared with the measured ones. Calculations of hysteresis loops at spotted points of the transformer are also performed. The comparisons between the iron losses measured and calculated with vectorial hysteresis will be performed and the results will be presented on the extended paper.

II. MAGNETODYNAMIC FORMULATION

A bounded domain Ω of the two or three-dimensional Euclidean space is considered. Its boundary is denoted Γ . The equations characterising the magnetodynamic problem in Ω are [2]:

$$\text{curl } \mathbf{H} = \mathbf{J}, \quad \text{curl } \mathbf{E} = -\partial_t \mathbf{B}, \quad \text{div } \mathbf{B} = 0, \quad (1a-b-c)$$

$$\mathbf{B} = \mu \mathbf{H}, \quad \mathbf{J} = \sigma \mathbf{E}, \quad (2a-b)$$

where \mathbf{H} is the magnetic field, \mathbf{B} is the magnetic flux density, \mathbf{E} is the electric field, \mathbf{J} is the electric current density, including source currents \mathbf{J}_s in Ω_s and eddy currents in Ω_c (both Ω_s and Ω_c are included in Ω), μ is the magnetic permeability and σ is the electric conductivity.

The boundary conditions are defined on complementary parts Γ_h and Γ_e , which can be non-connected, of Γ ,

$$\mathbf{n} \times \mathbf{H}|_{\Gamma_h} = 0, \quad \mathbf{n} \cdot \mathbf{B}|_{\Gamma_e} = 0, \quad \mathbf{n} \times \mathbf{E}|_{\Gamma_e} = 0, \quad (3a-b-c)$$

where \mathbf{n} is the unit normal vector exterior to Ω . Furthermore, global conditions on voltages or currents in inductors can be considered [2].

A. Inclusion of the differential reluctivity tensor

The relationship between $d\mathbf{H}$ and $d\mathbf{B}$ is given by [1]

$$d\mathbf{H} = \|\mathbf{v}_d\| d\mathbf{B}, \quad (4)$$

where $\|\mathbf{v}_d\|$ is called as magnetic reluctivity tensor.

Using Euler's scheme to represent the derivatives, (4) becomes

$$\Delta\mathbf{H} = \|\mathbf{v}_d\| \Delta\mathbf{B}, \quad (5)$$

where $\Delta\mathbf{H} = \mathbf{H}(t+\Delta t) - \mathbf{H}(t)$, $\Delta\mathbf{B} = \mathbf{B}(t+\Delta t) - \mathbf{B}(t)$, and (5) can be written as

$$\mathbf{H}(t+\Delta t) = \|\mathbf{v}_d\| \Delta\mathbf{B} + \mathbf{H}(t), \quad (6)$$

with (6) one can write Ampere's law (1a) for time $(t+\Delta t)$, as

$$\text{curl} [\|\mathbf{v}_d\| \Delta\mathbf{B} + \mathbf{H}(t)] = \mathbf{J}(t+\Delta t), \quad (7)$$

using $\mathbf{B}(t+\Delta t) = \text{curl } \mathbf{A}(t+\Delta t)$ and $\mathbf{B}(t) = \text{curl } \mathbf{A}$, where \mathbf{A} is the magnetic vector potential, (7) becomes [1]

$$\text{curl} [\|\mathbf{v}_d\| \text{curl } \mathbf{A}(t+\Delta t)] = \mathbf{J}(t+\Delta t) + \text{curl} [\|\mathbf{v}_d\| \text{curl } \mathbf{A}(t)] - \text{curl } \mathbf{H}(t). \quad (8)$$

B. Voltage fed and magnetic vector potential A-formulation

The \mathbf{A} -formulation, with a magnetic vector potential \mathbf{A} and an electric scalar potential V , is obtained from the weak form of the Ampère equation (1a) and (2a-b) [2], i.e.

$$\begin{aligned} & \langle \|\mathbf{v}_d\| \text{curl } \mathbf{A}(t+\Delta t), \text{curl } \mathbf{A}' \rangle_{\Omega} - \langle \|\mathbf{v}_d\| \text{curl } \mathbf{A}(t), \text{curl } \mathbf{A}' \rangle_{\Omega} + \\ & \langle \mathbf{H}(t), \text{curl } \mathbf{A}' \rangle_{\Omega} + (\sigma \partial_t \mathbf{A}, \mathbf{A}')_{\Omega_c} + (\sigma \text{grad } V, \mathbf{A}')_{\Omega_c} + \\ & - (\mathbf{J}_s, \mathbf{A}')_{\Omega_s} = 0, \quad \forall \mathbf{A}' \in F_d(\Omega), \end{aligned} \quad (9)$$

where $F_d(\Omega)$ denotes the function space defined on Ω which contains the basis and test functions for both vector potentials $\mathbf{A}(t+\Delta t)$, $\mathbf{A}(t)$ and \mathbf{A}' . The block $(\cdot, \cdot)_{\Omega}$ denotes a volume integral in Ω of scalar or vector fields products.

The circuit relation associated with a stranded inductor $j \in \Omega_s$, relating its current I_j to its voltage V_j , has been established for the \mathbf{A} -formulation as follows [2].

$$\partial_t(\mathbf{A}, \mathbf{w})_{\Omega_s} + R I_j = -V_j, \quad (10)$$

where R is the resistance of the inductor and \mathbf{w} is called the wire density vector.

C. Inclusion of the eddy current losses and the anomalous losses in the finite element modelling

The \mathbf{A} -formulation considering the inclusion of the eddy current losses and the anomalous losses in the FE modelling is given by [3]

$$\begin{aligned} (\kappa \operatorname{curl} \mathbf{A}(t+\Delta t), \operatorname{curl} \mathbf{A}')_{\Omega} - (\kappa \operatorname{curl} \mathbf{A}(t), \operatorname{curl} \mathbf{A}')_{\Omega} + \\ (\mathbf{H}(t), \operatorname{curl} \mathbf{A}')_{\Omega} + (\sigma \partial_t \mathbf{A}, \mathbf{A}')_{\Omega_c} + (\sigma \operatorname{grad} V, \mathbf{A}')_{\Omega_c} + \\ - (\mathbf{J}_s, \mathbf{A}')_{\Omega_s} = 0, \quad \forall \mathbf{A}' \in F_d(\Omega). \end{aligned} \quad (11)$$

The term κ is given by [3]

$$\kappa = \left(\|\mathbf{v}_d\| + \frac{\sigma d^2}{12 \Delta t} + \sqrt{\sigma G V_o S} \frac{1}{\Delta t^{0.5} |\Delta \mathbf{B}|^{0.5}} \right), \quad (12)$$

where d is the magnetic sheet thickness, S is the cross section of the magnetic sheet, G is the magnetic object (MO) friction coefficient, V_o is the relation between the number of MO taking place in the magnetization process and the excess magnetic field [3].

III. APPLICATION

The experimental device used for the validation of the proposed approach is a three phase transformer of 2 kVA. The magnetic core is made of FeSi electrical steel laminations which thickness is 0.5 mm. Fig. 1 shows the studied domain (left) and the 2D mesh (the air regions are not shown) of the calculation domain (right).

Fig. 1. The studied domain (left) and the 2D mesh (the air regions are not shown) of the calculation domain (right).

The magnetic flux distribution and the magnetic flux density in the calculation domain are shown in Fig. 2 (left) and Fig. 2 (right), respectively.

The BH loops in the points P1 and P2 (see Fig. 1(left)) are shown in Fig. 3.

Fig. 2. The magnetic flux distribution (left) and the magnetic flux density (right) in the calculation domain.

Fig. 3a. The BH loop in the point P2 (central limb).

Fig. 3b. The BH loops in the point P1. The rotational flux in the T-joint increases the magnetic losses.

From the figures above, one can observe that the vector hysteresis model naturally reduces itself to a scalar model if in presence of an alternating flux (central limb) and it is able to represent the vector relationship in the transformer T-joint.

The results on the iron losses measured and calculated with vectorial hysteresis will be compared and presented on the extended paper.

Abstract — Two calculation methods for iron-loss estimation of rotating machines are investigated. One is based on the conventional three-term expression. In this case, the losses are calculated from the time variation in the flux density obtained by the finite element analysis, which approximates the stator and the rotor cores as the solid magnetic material without the conductivity. The other is based on the 3-D eddy current analysis in the electrical steel sheet. In this case, the excess loss is calculated with a simple approximation. It is clarified that both methods can estimate the no-load iron loss in the similar accuracy and that the method based on the eddy current analysis is suitable for the estimation of high-order harmonic iron losses.

I. INTRODUCTION

Owing to environmental problems, the estimation of iron loss in rotating machines became more important subject in recent years. Many papers reported the iron-loss estimation using the 2-D or 3-D finite element methods.

The iron loss can be classified into three components, which are the hysteresis loss, eddy-current loss and excess loss [1]. In this case, appropriate coefficients of each loss are determined by experiments of the electrical steel sheets. The losses are usually calculated from the time variation in the flux density obtained by the finite element analysis, which approximates the stator and the rotor cores as the solid magnetic material without the conductivity. This method is widely applied and developed by many researchers [2]-[4].

On the other hand, when the frequency of the magnetic field is high, the flux and eddy currents must concentrate at the surface of the electrical steel sheets due to the skin effect [5] because the sizes of the domains in non-oriented steels employed for the rotating machines are usually much smaller than the thickness of the sheets [6]. This phenomenon cannot be taken into account by the conventional modeling. Therefore, we proposed an iron-loss model based on the 3-D eddy current analysis in the electrical steel sheet [7]. In this case, the excess loss is estimated with a simple approximation.

It can be stated that the above-mentioned methods are based on the different approximations. As a consequence, they must have the strong and weak points, respectively. In this paper, both methods are applied to several kinds of rotating machines and the results are compared. The experimental validations are also carried out. It is clarified that both methods can estimate the no-load iron loss of machines in the similar accuracy and that the proposed method is suitable for the estimation of the high-order harmonic iron losses.

II. IRON LOSS MODELING

The conventional three-term iron-loss model [1]-[4] is:

$$\begin{aligned} W_i &= W_e + W_h + W_{ex} \\ &= \frac{\sigma h^2}{12} \frac{1}{T} \int_0^T \int_{iron} \left(\frac{dB}{dt} \right)^2 dv dt \\ &\quad + \frac{K_h D}{T} \int_{iron} B_m^\alpha \left(1 + \sum_{i=1}^n \frac{\beta}{B_m} (\Delta B_i) \right) dv \\ &\quad + \frac{K_{ex} D}{T} \int_0^T \int_{iron} \left| \frac{dB}{dt} \right|^{1.5} dv dt \end{aligned} \quad (1)$$

where W_e , W_h , W_{ex} are the eddy-current loss, hysteresis loss, and excess loss in the core, σ is the conductivity, h is the thickness of the electrical steel sheets, D is the density, T is the time period, K_h , α , and β is the hysteresis coefficients, f is the fundamental frequency, B_m is the maximum flux density during the time period, ΔB_i is the local amplitude of the flux density that cause minor hysteresis loss, K_{ex} is the excess loss coefficient. The flux density B is estimated by the finite-element method that neglects the eddy currents in the steel sheets.

On the other hand, in the proposed model, the iron loss is expressed by two terms as follows:

$$\begin{aligned} W_i &= W_e' + W_h' = \frac{1}{T} \int_0^T \int_{iron} \kappa \sigma |E|^2 dv dt \\ &\quad + \frac{K_h D}{T} \int_{iron} B_m^\alpha \left(1 + \sum_{i=1}^n \left(\frac{\beta}{B_m} \Delta B_i \right) \right) dv \end{aligned} \quad (2)$$

where W_e' is the eddy-current loss including excess loss, W_h' is the hysteresis loss, κ is the modified coefficient of the excess loss, and E is the electric field. The electric and magnetic fields are calculated by the 3-D nonlinear time-stepping eddy-current analysis in the electrical steel sheet. By using this model, both the eddy-current loss and the hysteresis loss are calculated by taking into account the concentration of the electric and magnetic fields near the surface of the steel sheets.

By applying several assumptions, the coefficients in (1) and (2) can be determined from the iron-loss characteristics of the electrical steel sheets obtained by the Epstein-frame test.

III. APPLICATIONS

First, the methods are applied to the calculation of no-load iron loss in a permanent magnet motor. Fig. 1 shows the 3-D finite element mesh in half the thickness of the electrical steel sheet. The applied steel sheet is 20RMHF1200, whose thickness is 0.2 mm. the skin effect can be considered as small. On the other hand, the excess loss is relatively large [8]. Fig. 2 shows the calculated eddy current distribution.

Fig. 3 shows the experimental and calculated no-load iron losses. The difference in the total losses obtained by the conventional and proposed method is slight.

Next, the methods are applied to the calculation of harmonic iron losses in an induction motor driven by a PWM inverter. Fig. 4 shows the 3-D finite element mesh. The applied steel sheet is 50A1300, whose thickness is 0.5mm. The excess loss is negligible [8]. On the other hand, the skin effect is large. Fig. 4 shows the flux density waveform at a tooth. It can be observed that the harmonic ripples concentrate at the surface of the sheet.

To confirm the accuracy in the high-order harmonic iron losses, the loss caused by the inverter-carrier harmonics $W_{carrier}$ is separated not only by the calculation but also by the experiment as follows:

$$W_{carrier} = W_{inv} - W_{sin} \quad (3)$$

where W_{inv} and W_{sin} are the total losses when the motor is driven by the inverter and a sinusoidal power supply,

Fig. 1. 3-D finite element mesh for PM (1,186,127 tetrahedron elements).

Fig.2. Eddy current distribution near top of stator tooth.

Fig. 3. Experimental and calculated no-load iron loss (1000min⁻¹).

respectively. $W_{carrier}$ mainly consists of the losses in the cores.

Fig. 6 shows the experimental and calculated $W_{carrier}$. The accuracy is much improved by the proposed method. It is clarified that the proposed method is especially suitable for the estimation of the high-order harmonic iron losses.

Abstract — In order to improve the induction heating system for an object of magnetic material, it is necessary to clarify the heating property due to eddy current loss by using a magneto-thermal coupled analysis taking account of the temperature dependence of magnetic properties of magnetic material to be heated. In this paper, the effect of temperature dependence of magnetic properties on heating characteristics of a billet heater is analyzed considering the heat emission, heat conduction and temperature dependence of magnetic characteristics of the billet. It is shown that the consideration of temperature dependence of magnetic properties is indispensable for the accurate analysis of the phenomena. The heat emission should also be taken into account for the precise analysis. The skin depth is increased because the resistivity of the billet is increased and the permeability is decreased at high temperature. As a result, the flux in the billet is reduced, and then the power (eddy current loss) in the billet is decreased.

I. INTRODUCTION

In order to control the billet heater accurately so that the input and output of heat is well controlled, and to avoid billets which were not heated at a desired temperature, it is necessary to clarify the heating properties of billets by the magneto-thermal coupled analysis [1]. Although the heating characteristics of the billet made of magnetic material is affected by the temperature dependence of magnetic properties, the report of precise discussion is few.

In this paper, the detailed behavior of the eddy current loss and the temperature distribution in billets are analyzed by the magneto-thermal coupled method considering the heat emission, the heat conduction and the temperature dependence of magnetic characteristics of the billet. The effect of the temperature dependence of magnetic properties on heating characteristics is discussed in detail.

II. MODEL AND METHOD OF ANALYSIS

Fig. 1 shows the examined billet heater. The material of the billet is S45C (carbon steel). The insulating material is rolled out of the fire-resistant material. The Curie temperature of the billet is 760°C. We assumed that the model is isotropic.

3-D FEM using edge elements is used for the magnetic field analysis, and 3-D FEM using nodal elements is used for the thermal field analysis. Although coils are divided into parts in an actual billet heater, it is assumed that they are not divided

into parts in the analysis in order to make the analysis simple. Fig. 1 shows the cross section of the examined model. We considered the division of coils by feeding the current at the instant when the analyzed region corresponds to the cross section with the coil or by feeding no current at the instant when it corresponds to that without the coil. The boundaries of analyzed region in Fig. 1 are assumed as the adiabatic boundaries.

The B-H curves are changed with the temperature. Fig.3 shows B-H curves as a reference.

III. EFFECT OF TEMPERATURE DEPENDENCE OF MAGNETIC PROPERTIES

Fig.1. Analyzed model (1/4 model).

Fig.2. Temperature dependence of B-H curve of billet (reference).

Fig.3. Effect of temperature dependence of B-H curve and conductivity σ .

Fig.4 Comparison of calculated and measured temperature at the center and on the surface of billet.

Fig.3 shows an example of the calculated result of the change of temperature. The figure denotes that the behavior of temperature is completely different, if the temperature dependence of conductivity and B-H curve is neglected. Fig. 4 shows the comparison of calculated temperature with the measured one. The temperature is measured using thermocouples. As the measured B-H curves are used in the analysis, the calculated results are considerably in good agreement with the measured ones.

Fig. 5 shows the temperature distribution at $t=105$ sec. The figure denotes that the heat emission should be taken into account, because the temperature distribution is considerably affected by the heat emission at high temperature.

Fig.5. Effect of heat emission.

Fig.6. Distribution of eddy current loss.

Fig. 6 shows the distribution of power (eddy current loss) and temperature in the billet. The power invades inside the billet with the increase of temperature, and its value is reduced. The reason is as follows: The skin depth is increased due to the decreased of the conductivity and permeability, and the flux is also decreased due to the decrease of the permeability at such high temperature. As a result, the generated eddy current loss (power) is decreased.

IV. CONCLUSION

The effect of the temperature dependence of magnetic properties on heating characteristics is discussed in detail. The effect of the temperature dependence of magnetic properties on the distortion of the voltage waveform of the coil, etc. will be discussed in the full paper.

Abstract — The inspection of volume fraction of retained austenite in the high chromium cast iron is important in keeping the quality of hot-rolling etc. The permeability and the conductivity of the cast iron are decreased when the volume fraction of retained austenite is increased. Therefore, the inspection of volume fraction of retained austenite is possible by detecting the difference of the electromagnetic characteristic. However, the inspection is not easy, because the permeability of the cast iron is usually non-uniform. As a result, the signal of the electromagnetic inspection has a magnetic noise.

In this paper, the inspection technique for reducing the effect of the non-uniformity of the permeability on the large magnetic noise, and that for measuring the retained austenite is examined using 3-D edge-based hexahedral nonlinear FEM. In addition, the experimental verification is also carried out.

I. INTRODUCTION

High chromium cast iron is used as abrasion proof components of such as, a steel of hot-rolling, a ball and a liner of mill for mineral pulverization. The hardness is reduced by the appearance of the retained austenite in the cast iron [1,2]. Therefore, the evaluation of volume fraction of retained austenite (γ) in the cast iron is important in keeping the quality of steel of hot-rolling etc. The permeability of the cast iron decreases when γ is increased, because the austenite is a nonmagnetic material. Therefore, the evaluation of the amount of γ in the cast iron is possible by detecting the change of the magnetic characteristic using the electromagnetic inspection. However, the inspection is not easy, because the permeability of the cast iron is usually non-uniform. As a result, the signal of the electromagnetic inspection has a magnetic noise [3].

In this paper, the inspection technique for reducing the effect of the non-uniformity of the permeability on the large magnetic noise, and that for measuring γ is examined using 3-D edge-based hexahedral FEM, and the experimental verification is also shown.

II. MEASUREMENT OF INITIAL MAGNETIZATION CURVE, NON-UNIFORMITY OF PERMEABILITY AND CONDUCTIVITY

Fig.1 shows the initial magnetization curves for various γ in

the cast iron. In addition, Fig. 2 shows the conductivities for various γ . These figures denote that the permeability and conductivity of the cast iron are decreased with the increase of the retained austenite. Fig.3 shows the maximum dispersion rate ε_u of non-uniformity of permeability with different amount of γ in the high chromium cast iron. The figure denotes that the non-uniformity (ε_u) of permeability is increased when γ is increased. When the magnetic field is increased in the high chromium cast iron, ε_u is decreased, because the direction of each magnetic moment becomes nearly the same.

III. ELECTROMAGNETIC INSPECTION OF RETAINED AUSTENITE IN HIGH CHROMIUM CAST IRON

A. Effect of Non-uniformity of Permeability in High Chromium Cast Iron

Fig.4 shows the 1/2 domain of the proposed inspection model for evaluation of γ in the high chromium cast iron. The

Fig.1. Initial magnetization curves of the high chromium cast iron with different γ (Cr=17%).

Fig.2. Conductivity of high chromium cast iron with different γ (Cr=17%).

7. Material Modeling

Fig.3. Dispersion rate ε_{μ} of permeability of high chromium cast iron ($Cr=17\%$).

non-uniformity of flux density in a search coil is estimated by calculation. Many kinds of B-H curves with the dispersion within ε_{μ} are generated for various average flux density B_{ave} in the specified region in the cast iron, and they are distributed in random in each element in the cast iron. The movement of magnetic yoke is simulated by shifting the permeability and conductivity inside the high chromium cast iron region in the x-direction by 1mm step. The B-H curves of the high chromium cast iron ($\gamma=45\%$) with the largest non-uniformity of initial permeability are used for investigation. The exciting frequency is 500Hz. Fig.5 shows the calculated results of flux density in a search coil when the magnetic yoke is moved. The figure denotes that ε_B is reduced when the flux density B_E inside the exciting coil is increased. In this magnetic yoke, the heat generation of the exciting coil is large when the exciting flux density B_E is more than 0.08T. But, ε_B is remained about $\bullet 0.07\%$, even if B_E is larger than 0.08T. Therefore, the exciting flux density B_E in this model was set as 0.08T.

Fig.4. Electromagnetic inspection model for high chromium cast iron with different γ (1/2 domain).

Fig.5. Effect of non-uniformity of permeability in high chromium cast iron (calculated, 500Hz, $\gamma = 45\%$, $Cr=17\%$).

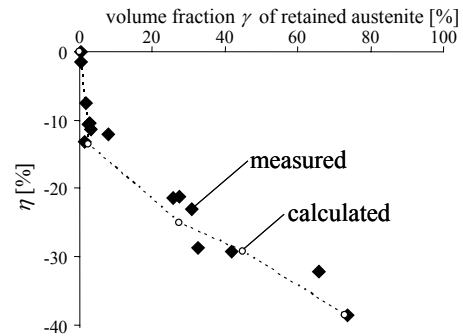

Fig.6. Effect of γ in high chromium cast iron on change of flux density in a search coil (500Hz, $B_E = 0.08T$, $Cr=17\%$).

B. Inspection of Retained Austenite

Fig.6 shows the effect of γ on the change η of flux density $|B|$ of a search coil. 14 pieces of the high chromium cast irons with various volume fractions γ of retained austenite were measured. The frequency and exciting flux density B_E are 500Hz and 0.08T, respectively. The measured values are in agreement with the calculated ones. In the full paper, the optimal magnetization condition for the inspection is examined using the 3-D edge-based hexahedral FEM. In addition, the experimental verification is also carried out.

IV. CONCLUSIONS

The results obtained are summarized as follows:

- (1) When the volume fraction of retained austenite in high chromium cast iron is increased, the permeability and conductivity are decreased and the non-uniformity of permeability is increased. However, when the magnetic field is increased, the non-uniformity of permeability is decreased, because the direction of each magnetic moment becomes nearly the same.
- (2) The flux density in a search coil of the proposed electromagnetic inspection method is decreased when the volume fraction of retained austenite in high chromium cast iron is increased, because the permeability and the conductivity are decreased. Therefore, if the exciting flux density that reduces the non-uniformity of the permeability in high chromium cast iron is applied, the non-destructive inspection of the volume fraction in the cast iron of retained austenite is possible by the proposed inspection method.

Abstract — In order to investigate the noise reduction of a reactor under inverter power supply, coupled magnetic and mechanical analyses should be carried out taking account of magnetostriction or electromagnetic force in the iron core. In this paper, a method of modeling the magnetostriction 3-dimensionally with equivalent nodal forces is proposed to enable the mechanical analysis taking account of the magnetostriction. Then, the spatial distributions of displacements in the core of a single phase of reactor due to magnetostriction and electromagnetic force are calculated to determine the dominant cause of noise. It is shown that both causes should be taken into account for a reactor.

I. INTRODUCTION

Recently, inverter power supplies have been widely used for electrical machines. However, because of the harmonics, noises from electrical machines are loud. Generally, the major cause of noise for non-rotating machines such as transformers is considered to be magnetostriction [1]. And for rotating machines it is considered to be electromagnetic force in the gaps between the rotor and stator [2]. Moreover, for reactors, both mechanisms are considered to be responsible for the noise because it is non-rotating machines with large gaps in the core. To investigate the noise reduction for such various machines, 3-dimensional (3D) coupled magnetic and mechanical analyses should be carried out. In the mechanical analysis, the local force distribution in the iron core is required. The 3D local forces due to electromagnetism can be calculated by the nodal force method [3]. However, for magnetostriction, only 2D modelling has been reported [1],[2].

In this paper, the method of modeling the magnetostriction 3-dimensionally with equivalent nodal forces is proposed to enable the 3D mechanical analysis taking account of the magnetostriction. In this modeling, the nodal forces in the core due to magnetostriction are calculated by using the flux distribution obtained from the magnetic field analysis. In order to show the effectiveness of the proposed method, the spatial 3D distributions of displacements in the iron cores of a single phase of reactor due to magnetostriction and electromagnetic force are calculated by the static structure analysis using the nodal forces obtained from the proposed method and the nodal force method, respectively, and are compared with each other.

II. 3D MODELLING OF MAGNETOSTRICTION

The magnetostriction in the iron core is modeled with equivalent nodal forces. The material of the core is assumed to be isotropic in this paper. The nodal forces $f_{ms}^{(ip)}$ due to

magnetostriction at each node ip of each element ie when subject to flux density $B^{(ie)}$ are obtained by using the following method. First, when the magnetic material is subject to flux density B , the magnetostriction ε_p and ε_v in the directions parallel and vertical to B respectively are assumed to be

$$\varepsilon_p = \alpha B^2 \quad (1)$$

$$\varepsilon_v = -\nu \varepsilon_p, \quad (2)$$

where α and ν are constants obtained from experiment. ν corresponds to the Poisson's ratio. The shape change of a cylinder with length L and radius R due to magnetostriction subject to flux density in the parallel direction to the axis of the cylinder is illustrated in Fig. 1. In the element ie with center of gravity O on the cylinder axis as shown in Fig. 1, the displacement $u^{(ip)}$ on node ip can be represented by

$$u^{(ip)} = \varepsilon_p l i_p + \varepsilon_v r i_v, \quad (3)$$

where l and r are the lengths of the axial and radial components of the line $O-ip$ respectively, as shown in Fig. 2. i_p and i_v are unit vectors in the axial and radial directions respectively. The equivalent nodal force f_{ms} on each node of element ie are obtained by using the displacement u at each node and the stiffness matrix K [4] defined by the finite element method as following

$$f_{ms} = K u. \quad (4)$$

Fig. 1. Change in the shape of a cylinder due to magnetostriction.

Fig. 2. Displacement on node ip (cross section of Fig.1).

7. Material Modelling

In order to investigate the validity of the proposed method, the nodal forces f_{ms} for a cubic element with edges of 2 m, Young's modulus E of 200 GPa, ν of 0.3, and α of 7.8×10^{-6} subject to flux densities (0, 0, 1 T) and (0.577 T, 0.577 T, 0.577 T) are calculated. The distributions of the flux densities B , displacements u , and nodal forces f_{ms} are shown in Fig. 3. This figure shows the validity of the proposed method because the element extends in the direction parallel to the flux density and contracts in the direction vertical to the flux density.

The nodal forces in the core can be obtained by adding up the nodal forces f_{ms} in each element.

Fig. 3. Distributions of (a) Flux densities B , (b) displacements u , and (c) nodal forces f_{ms} when subject to flux densities (i) $B=(0, 0, 1T)$, (ii) $B=(0.577T, 0.577T, 0.577T)$.

III. APPLICATION

To investigate the effectiveness of the proposed method, the spatial distributions of displacements in the iron core of a single phase of reactor, described in Ref. [5], due to magnetostriction and electromagnetic force are calculated and compared with each other.

For calculating the magnetic field distribution, 3D nonlinear eddy current finite element analysis using the $A-\phi$ method (where A and ϕ are the magnetic vector and electric scalar potentials, respectively) is carried out. The laminated core of reactor is modeled as an anisotropic solid core considering the gaps between the steel plates and eddy currents in the steel plates [5].

The flux distribution and the nodal force distributions for magnetostriction and electromagnetism in the middle plane of the core and at the instant when the flux is the maximum are shown in Fig. 4. The nodal forces due to magnetostriction are larger near the gaps and holes where the flux densities change suddenly. The nodal forces due to magnetostriction are about six times as those due to electromagnetism. The nodal forces due to electromagnetism are attractive forces generated between cores. The nodal forces due to electromagnetism are obtained by using the nodal force method and the Maxwell stress tensor of the Chu model [3].

The spatial distributions of displacements obtained from the static structure analysis using the nodal forces due to the magnetostriction and electromagnetism in the same plane at the same instant are shown in Fig. 5. The displacements due to magnetostriction in the yoke are larger than those in the leg. This is because the yoke is longer than the leg. The displacements due to electromagnetism in the yoke are large whereas those in the leg are very small. This is because the yoke is only acted upon by forces pulling from the leg, whereas the leg is acted upon by nodal forces in opposite directions which can cancel with each other. Both displacements are of the same order. Therefore, both causes should be taken into account in the noise reduction.

Tolerance Analysis of NMR Magnets

Alessandro Formisano and Raffaele Martone

Dipartimento di Ingegneria dell'Informazione, Seconda Università di Napoli

Via Roma 29, Aversa (CE), I-81031, Italy

Alessandro.Formisano@unina2.it

Abstract — Due to manufacturing and assembly variations, there are tolerances associated with the nominal dimensions of complex electromagnetic devices. A possible approach to take into account such tolerances in the early design phases is the “worst case tolerance analysis”, whose goal is to determine the effect of the smallest and largest assembly dimensions on the product performance. On the other hand, when many tolerances must be considered, locating the worst case with combinatorial effects could get very time consuming, since performance assessment of such devices may require numerical field analysis. In the paper, a fast approach based on the performance sensitivity with respect to design parameters is presented, and applied to the tolerance analysis of nuclear magnetic resonance magnets.

I. INTRODUCTION

The main requirement in the design of superconducting (SC) magnets for Nuclear Magnetic Resonance (NMR) is the high uniformity of the magnetic field that must be guaranteed within a very tight limit inside a suitable Volume Of Interest (VOI). The uniformity is usually evaluated as the maximum discrepancy of the magnetic field amplitude with respect to the nominal value on the boundary of the VOI. In order to guarantee the right resolution, such uniformity must be within few parts per million (ppm). Unfortunately, in practical realisations, due to construction and assembling tolerances, the actual magnets differ from the nominal ones [1, 2]. Then, suitable sets of shimming coils are included able to counteract the error field. However, before starting construction, especially for such expensive devices, an assessment of the impact of tolerances is required, to verify if design performance are guaranteed also for real magnets, and, in addition, to evaluate the actual requirements of shimming systems.

On the other hand, the treatment of the tolerances in the design phase implies a relevant impact on the computational cost, since the relationship among design parameters and device performance indexes is usually a complex non-linear function, possibly involving numerical magnetic field computations. In the paper, a fast approach to tolerance analysis, based on the worst case approach and on the use of performance index sensitivity, will be presented, and applied to the performance assessment of NMR magnets.

II. TOLERANCE ANALYSIS

Tolerancing plays a key role in design and manufacturing of industrial products. In the following, according to [3], *tolerances* are defined as the maximum deviations from a nominal specification within which the part is acceptable for

its intended purpose. Tolerances are usually expressed as lower and upper deviations from the nominal value.

Basically, tolerancing implies two different aspects:

- Tolerance *analysis*, involving identification of related tolerances in a design, and calculation of the stackup of these related tolerances. If design requirements are not met, tolerance values are adjusted and the stackup recalculated.
- Tolerance *synthesis*, the process of distributing tolerance values among dimensions in order to guarantee functionality or assemblability.

In general, tolerance analysis involves building linear or nonlinear models of the problem at hand, depending upon the design complexity.

A tolerancing problem can be solved either using a worst-case approach or a statistical approach. In the first case, the extreme values of tolerances are considered, while in the second case, tolerance calculation are performed based on the fact that actual dimensions are randomly distributed around their nominal values.

Statistical tolerancing, as it allows to reduce the average cost by accepting to include in the overall production also a (possibly small) number of unacceptable elements, is well-suited for mass production. Some of the popular methods for statistical tolerance analysis are search-space smoothing using Monte Carlo yield estimation, statistical model-based methods, and six-sigma tolerance analysis tools [3, 4].

The worst-case approach is better suited for single piece or small-lot productions for critical applications; of course the design of high field magnets falls in the second class. The typical approach uses nominal values for all variables except for one, which is once simulated with the upper and once with the lower boundary. Then, the next variable is chosen. It is missing the effect of the combination of several tolerances that might together cross the performance acceptance threshold. In principle also the cross effects of the tolerances could be considered. However this implies to calculate each possible combination of tolerance term boundaries, leading to a strong growth of computing time which is exponential in the number of tolerance sources. The interval arithmetic approach also suffers from the curse of dimensionality described above.

The topic of tolerance analysis has received a great deal of attention from researchers in the field of mechanics [3-6], and also relevant contributions are available in the field of electronic circuits design (a few, non exhaustive examples are [7], [8]). On the other hand, the complexity of electromagnetic devices performance assessment limited the

investigation in the field until sufficient computational power was made available.

Aim of the paper is to propose an approach to reduce the computational cost for worst case localization, based on the availability of the sensitivity of device performance index with respect to the design and constructive parameters. As a matter of fact, the array of sensitivities can be related to the gradient of the performance index in the parameters space, and the worst case is likely to be identified by following the gradient direction.

On the other hand, constraints are usually present among different parameters, limiting the actual values that each parameter can take inside the tolerance range. In addition, in some cases the gradient could become very small, and higher order derivatives must be considered in the search for the worst case.

In the full paper, an approach able to systematically take into account the above cited issues will be proposed. For exemplification purposes, in the following section the tolerance assessment of field homogeneity for a MRI magnet will tackled, either using worst case analysis taking advantage of sensitivities, and using Monte Carlo method, to compare drawbacks and advantages of both approaches.

III. ASSESSMENT OF MRI DESIGN

The possibility of locating worst case using performance index sensitivity in the design of demanding electromagnetic devices has been evaluated with reference to a SC magnet for NMR spectroscopy, described in Fig. 1 and Table I.

TABLE I
PARAMETERS OF NMR MAGNET

Parameter	Value
Number of Coils	6 NbTi coils
Central Field	2.5 T
Field Uniformity	3.2 ppm on 5 cm sphere
Minimum inner radius	210 mm
Overall length	640 mm
Tolerances	+/- 1 μ m for all dimensions, except radial and longitudinal coord. of barycentre for Coil 1, for which a tolerance of +/- 1 mm is assumed

Fig. 1 – Sketch of the magnet for NMR spectroscopy considered in the paper.

In order to get meaningful results from stochastic analysis within a reasonable computation time, the tolerances on all geometrical dimensions have been assumed very small (1 μ m) except for radial and longitudinal coordinates of coil 1 baricentre, for which tolerances of +/-1 mm have been

assumed. No constrains among design variables are considered. In this way convergence of statistical analysis was achieved after 20000 cases for Monte Carlo method, and provided a worst case uniformity of 316 ppm. Worst case analysis using sensitivities (in this case, simply multiplying the sensitivity with respect to each parameter times the related tolerance, and summing absolute values for all dimensions) provided a worst case uniformity of 319 ppm. Cumulative distribution function (CFD) of performance, average performance and worst case are reported in Fig. 2.

Fig. 2 – CDF, average and worst performance for NMR magnet.

IV. OUTLOOK

A possible fast approach for worst case tolerance analysis, based on the use of sensitivity information, has been introduced and its effectiveness has been checked in the case of tolerancing of NMR magnets. The comparison with usual statistical analysis showed that worst case performance is practically the same, yet requiring in the latter case a much higher computational effort. In the full paper, a complete description of the method will be presented, including the treatment of constraints and of possible vanishing gradient components.

homogenization in electromagnetism: a thermodynamic insight

Vincent G. Mazauric

Schneider Electric, Innovation Department, 38050, Grenoble Cedex 9, France

vincent.mazauric@schneider-electric.com

Abstract—Homogenization procedure is investigated from spatial averaging techniques and variational principles. The mean-field approximation requested by the procedure is clearly given and dispersive behavior laws are derived at the macroscopic scale. The technique is used to discuss the problem of dynamic hysteresis and extra-losses in soft magnetic materials. A validation is proposed by assessing losses on a 2D-Pry and Bean iron sheet. Discussion also includes a confrontation with Bertotti's experiments.

Index Terms—homogenization, multi-scale approach, magnetic materials, eddy currents, transient formulations, anomalous losses.

I. INTRODUCTION

Homogenization techniques consist in replacing an original problem described from deep within material by an equivalent one where the rapidly space-varying lengths at the design scale are discarded. From that viewpoint, macroscopic electromagnetism is already an homogenized theory, but further homogenizations could be carried out to take advantage of the spatial regularity occurring in various media. The benefits of homogenization are obvious: While taking into account the fine structure would be a huge or impossible task, the equivalent problem may be solved more cheaply, with a reasonable mesh size and a better conditioning. However a challenging task of any homogenization procedure consists in deriving unconventional behavior laws from a basic resolution at a “unit cell” scale in order to restore properly the dissipative phenomena occurring therein.

Some previous works paid attention to the conservation of local averages involved in the Maxwell equation set, *e.g.* [1]. Conversely, we adopt here a thermodynamic viewpoint where the conservation of global energy quantities, such as Gibbs' free energy or electrical power, comes first; whereas the structure of Maxwell equations is automatically kept as far as the variational principles are enforced. Hence, the mean field approximation requested to successfully achieve the homogenization is rigorously highlighted thanks to a spectral analysis.

A validation of the procedure is proposed by assessing anomalous losses on a 2D-Pry and Bean iron sheet [2]. Whereas numerical results are successfully faced with experiments, the domain of validity of the prior models is also emphasized.

II. VARIATIONAL PRINCIPLES IN ELECTROMAGNETISM

The magnetodynamic behavior of any electrical system may be derived from the variational principle [3]:

$$P_{\text{mech}}(\Omega) - \frac{dG}{dt}(\Omega) + P_{\text{elec}}(\Omega) = \min_{\mathbf{h}, \mathbf{e}} \left(\int_C \sigma^{-1} (\mathbf{curl} \mathbf{h})^2 d^3x + \frac{d}{dt} \int_{\Omega} (\mathbf{b}(\mathbf{h}) \cdot \mathbf{h} + \mathbf{d}(\mathbf{e}) \cdot \mathbf{e}) d^3x \right) \quad (1)$$

where the functional in the RHS exhibits:

- the magnetic field \mathbf{h} related to free and displacement currents according to the Maxwell-Ampere equation. The quasi-static approximation enforces $\mathbf{d} \equiv 0$ in conductors;
- the Joule losses P_{Joule} monitored in conductors $C \subset \Omega$. This term is even to respect invariance of losses with inversion of current $\mathbf{j} = \mathbf{curl} \mathbf{h}$ (σ^{-1} is the resistivity);

Fig. 1. Spectral decomposition of the current density: While the low-frequency peak involves scales given by the classical skin effect, the medium-frequency peak (resp. high-frequency) is associated to “unit cell” periodicity (resp. eddy currents pattern occurring in one unit cell). The splitting of this results from diluted enough unit cells to allow a mean field approximation.

- the variation with time of the electromagnetic energy coupling the field with the generator I and the mass V_0 ;
- the magnetic $\mathbf{b}(\mathbf{h})$ and electrostatic $\mathbf{d}(\mathbf{e})$ behavior laws derived from thermostatic equilibrium of the contribution of Ω to the Gibbs' potential:

$$G(T, I, V_0, \Omega) = \int_{\Omega} \left(\int_0^{\mathbf{h}} (-\mathbf{b}(\mathbf{h})) \cdot \delta \mathbf{h} + \int_0^{\mathbf{e}} (-\mathbf{d}(\mathbf{e})) \cdot \delta \mathbf{e} \right) d^3x \quad (2)$$

Extending the electric field in the conductor according to Ohm's law $\mathbf{e} = \sigma^{-1} \mathbf{j} - \mathbf{v} \times \mathbf{b}$, Faraday's law $\mathbf{curl} \mathbf{e} = -\partial_t \mathbf{b}$ may be viewed as acting *locally* to check *globally* a tendency towards reversibility. This striking property provides a thermodynamic-oriented insight of the variational theory of electromagnetism [4]. Hence, the minimum in (1) matches the LHS including the variations with time of the co-energy $-G(\Omega)$, the mechanical power $P_{\text{mech}}(\Omega)$ acting on Ω , and the electrical power $P_{\text{elec}}(\Omega) = -\oint_{\partial\Omega} (\mathbf{e} \times \mathbf{h}) \cdot d^2x$ supplied to Ω .

Taking advantage of their quadratic properties, thermodynamic functionals (1) and (2) support spatial filtering operations to provide a fully multi-scale framework: It is the key to derive robust homogenized models.

III. MACROSCOPIC FORMULATION

As matter of fact, the basis of the free current density \mathbf{j} in regular conducting structures involves a superposition of compact distributions of microscopic currents \mathbf{j}_w located within each “unit cell” Ω_w at position \mathbf{x}_w , with a density $n_w(\mathbf{x})$; and a possible macroscopic free current density \mathbf{J} . This description leads to the spectral decomposition given at the figure 1 where the splitting in several peaks means diluted unit cells and allows a *mean-field* hypothesis [5] which consists in performing independant minimizations for $k \geq k_{lp}$. Whereas the low-pass filtering process ($k < k_{lp}$) is equivalent to a smoothing procedure on the various fields [6], the high frequencies restore the

deepest magnetodynamic mechanisms. Hence, the restriction to C of the minimization in the RHS of (1) becomes:

$$\min_{\langle \mathbf{h} \rangle(t)} \int_C (\sigma^{-1} (\mathbf{curl} \langle \mathbf{h} \rangle)^2 + \partial_t (\langle \mathbf{b} \rangle \cdot \langle \mathbf{h} \rangle)) d^3x \quad (3a)$$

$$+ \sum_{w \in C} \min_{\mathbf{h}_\mu(t)} \int_{\Omega_w} (\sigma^{-1} (\mathbf{curl} \mathbf{h}_\mu)^2 + \partial_t (\mathbf{b}_\mu \cdot \mathbf{h}_\mu)) d^3x \quad (3b)$$

where $\langle \mathbf{h} \rangle$ (resp. $\langle \mathbf{b} \rangle$) denotes the averaged magnetic field (resp. averaged flux density) and is obtained through a convolution by the low-pass filter $\rho_{lp} \langle \mathbf{h} \rangle(\mathbf{x}) = \int \mathbf{h}(\mathbf{x}') \rho_{lp}(\mathbf{x} - \mathbf{x}') d^3x'$. Similarly, \mathbf{h}_μ (resp. \mathbf{b}_μ) stands for the rapidly space-varying part of the magnetic field (resp. flux density) and is obtained thanks to a convolution by a high-pass filter. Hence, the consistency between low- and high-spatial frequencies is enforced by:

- the conservation of the magnetic flux density after the smoothing procedure, *i.e.* $\mathbf{B} = \langle \mathbf{b} \rangle$;
- the modification of the Maxwell-Ampere equation according to the dynamic behavior of independent unit cells given by the minimization (3b). After the smoothing procedure on the microscopic eddy currents at the first order, the averaged magnetic field $\langle \mathbf{h} \rangle$ is shifted by the microscopic dynamic eddy currents to check a modified Maxwell-Ampere equation:

$$\mathbf{curl} (\langle \mathbf{h} \rangle + \sigma \Lambda^2 \partial_t \mathbf{B}) = \mathbf{J} \quad (4)$$

where Λ denotes a length parameter lumping *locally* all the complexity due to spatial dependence of \mathbf{j}_w [7].

Some additional assumptions on the magnetization mechanisms occurring in the media are necessary to resume the homogenization.

1) *Local media*: The knowledge of the local field \mathbf{h} in \mathbf{x} prescribes entirely the local flux density \mathbf{b} herein. Each unit cell may be viewed as large enough to achieve a thermodynamic equilibrium described by the Gibbs' free energy density. Its hessian provides locally the differential permeability as a positive tensor and the macroscopic behavior law is nothing but the average of the local behavior law. Introducing the macroscopic magnetic field $\mathbf{H} = \langle \mathbf{h} \rangle + \sigma \Lambda^2 \partial_t \mathbf{B}$ according to (4), the homogenization results in the delayed diffusion model [8]:

$$\delta \mathbf{B} = \mu_{\text{diff}}(\mathbf{H}) \cdot \delta (\mathbf{H} - \sigma \Lambda^2 \partial_t \mathbf{B}) \quad (5)$$

and Ohm's law is possibly kept at the macroscopic scale.

2) *Non-local media*: The thermodynamic equilibrium depends on a large neighborhood of \mathbf{x} . It is obviously the case for ferromagnetic materials because the domain pattern depends of the shape of the material. However, quasi-static approximation assumes that each time step checks a magnetostatic equilibrium described by the Gibbs' free energy G . Its density, at the *macroscopic scale*, is a function of the macroscopic magnetic field $\mathbf{H} = \langle \mathbf{h} \rangle + \sigma \Lambda^2 \partial_t \mathbf{B}$ and its hessian provides the differential permeability μ_{diff} as a positive tensor. Thus, small variations of the flux density follow the magnetic law:

$$\delta \mathbf{B} = \mu_{\text{diff}}(\mathbf{H}) \cdot \delta \mathbf{H} \quad (6)$$

Hence, stationary variations of (3a) with respect of $\langle \mathbf{h} \rangle$, yields, at the first order time-derivative, the macroscopic Maxwell-Faraday equation $\mathbf{curl} (\sigma^{-1} \mathbf{curl} \langle \mathbf{h} \rangle) = -\partial_t \mathbf{B}$ so that the macroscopic electric field \mathbf{E} appears, in the rest frame of the conductor, through a *deviated* Ohm's law:

$$\mathbf{E} = \sigma^{-1} \mathbf{J} - \mathbf{curl} (\Lambda^2 \partial_t \mathbf{B}) \quad (7)$$

In the following, the delayed diffusion model (5) and the deviated Ohm's law model (6)-(7) are adapted to the Pry and Bean geometry of domains occurring in an iron sheet [2].

Fig. 2. Loss assessment provided for an iron sheet (thickness $d = 0.21$ mm; $\mu_{\text{diff}} = 10,000\mu_0$; $\Lambda = 125 \mu\text{m}$). While solid line denotes the Bertotti's model derived from experimental data, the dashed lines (resp. dotted) are provided from the deviated Ohm's law (resp. delayed diffusion) model.

IV. RESULTS AND CONCLUSION

Both models provide domain wall motion-induced extra losses. But the latter follows Bertotti's experimental results [9] whereas the former does not restore the frequency dependence of excess losses on a large enough band, and actually underestimate them (Fig.2). These preliminary results argue for a diluted pattern of domain walls, the equilibrium of which being obtained at the macroscopic scale. Conversely, the delayed diffusion model seems more suitable to homogenize a stack of laminations from the behavior of one sheet.

In our knowledge, it is the first report of calculations able to reproduce the loss sketch observed in an iron lamination sheet by exhibiting the experimental dependence of anomalous losses on the frequency. Hence, implementing homogenized behavior laws suitable for Finite Element Analysis is very critical to achieve energy efficiency or reliability of power electrical devices [10]. Such developments are currently under progress in order to take into account transient regime, non-linear media involving several magnetic states, and massive magnetic cores.

Abstract—This paper presents a full finite element analysis for plasma discharge in etching process of semiconductor circuit. The charge transport equations of hydrodynamic diffusion-drift models and the electric field equation are numerically solved in a fully coupled system by using a standard finite element procedure for transient analysis. The proposed method is applied to a real plasma reactor in order to characterize the plasma sheath that is closely related to the yield of the etching process. The base electrode of the reactor is modified to improve the edge effect for the uniformity. The experiment and numerical results are examined along with SEM data of etching quality. The feasibility and usefulness of the proposed method is shown by both numerical and experimental results.

I. INTRODUCTION

Plasma etching and deposition is currently in widespread use in the manufacturing process of semiconductor circuit. However, despite of the importance of plasma processing, gas glow discharge is not well understood. This comes from the non-equilibrium nature of the plasma, and the complex interaction among potential field, transport phenomena, plasma chemistry, and surface reaction kinetics. So design of plasma reactor is still based largely on empirical approaches. Main requirements of plasma etching include high etching rate, uniformity, anisotropy, and selectivity. However, it is very difficult to satisfy all of the above requirements simultaneously. In addition, as the wafer size continues to increase, it becomes more difficult to satisfy uniformity and anisotropy.

Recently, there has been increasing interest in developing mathematical models and numerical analysis of the plasma process in an effort to better understand the process and to improve the design of plasma reactors. The most frequently used algorithms are method of characteristics, flux-corrected-transport(FCT) method and particle-in-cell(PIC) method. The above algorithms are so complex for numerical implementation that extra delicate techniques are required. In addition, they cost long computation time and sometimes cause numerical instability [1]-[4].

In this paper, we propose a full finite element approach where the charge transport equations of hydrodynamic diffusion-drift models and the electric field equation are numerically solved in a fully coupled system by using a standard finite element procedure for transient analysis. The proposed method is applied to a real plasma reactor in order to characterize the plasma sheath just above a targeted silicon wafer. The plasma sheath is closely related to the yield of the

etching process since it accelerates the bombing ions, whose motional properties determine the etching quality such as uniformity and anisotropy. Also, in this work the base electrode of the initial reactor is modified to improve the edge effect deteriorating the uniformity, and its experiment results of etching quality are compared with ones of the initial one by examining data of SEM(scanning electron microscope). That is, the feasibility and usefulness of the proposed method is shown by both numerical and experimental results.

II. ANALYSIS MODEL OF DRY ETCHING CHAMBER

Fig. 1 shows a cross-sectional diagram of the chamber for dry etching process. A wafer is placed between two electrodes. The upper electrode is connected to a voltage source and the lower one is set as ground. The electrodes supply external energy into the chamber for generating and sustaining the plasma. The electric field between the electrodes is downward and drives charge carries. The plasma sheath is formed just above the wafer and it accelerates heavy ions that bomb the wafer surface for etching. But the electric field above the wafer is not uniform in intensity and direction because of the fringing effect on the edge side. In this work, the uniformity of electric field is improved by substituting an existing quartz ring, which is located below the wafer, with an aluminum ring.

Fig. 1. Axis-symmetric geometry of dry etching chamber and design variables.

III. HYDRODYNAMIC DIFFUSION-DRIFT MODELS OF DISCHARGE

To analyze the phenomena of plasma discharge, hydrodynamic diffusion-drift models are employed. Three governing equations coupled with Poisson's equation are solved simultaneously for the concentration of the electron(N_e), positive(N_p) and neutral (N_n) with respect to time [5], [6]. The equations are as follow,

$$\begin{aligned} \frac{\partial N_e}{\partial t} + \nabla(N_e V_e) &= S + N_n \alpha |V_e| - N_e N_p \beta_{ep} \\ \frac{\partial N_p}{\partial t} + \nabla(N_p V_p) &= S + N_n \alpha |V_e| - N_e N_p \beta_{ep} \quad (1) \\ \frac{\partial N_n}{\partial t} + \nabla(N_n V_n) &= S - N_n \alpha |V_e| + \gamma \end{aligned}$$

where, V_e , V_p and V_n denotes the electron, positive and neutral ion drift velocities and α and β denotes the ionization and recombination coefficients, γ denotes the concentration of new supplied gas. S denotes the source term.

The electric field is calculated using Poisson's equation with the net charge of electron and ion.

$$\nabla(-\epsilon \nabla V) = e(N_p - N_e) \quad (2)$$

where, ϵ is electric permittivity, e is the quantity of electric charge and V is the electric scalar potential.

IV. NUMERICAL AND EXPERIMENTAL RESULTS

The discharge phenomena in chamber are modeled with the three transport equations coupled with Poisson's equation and they are calculated using the axisymmetric 3D finite element analysis. In Fig. 2(a) the electric potential along a z-direction is almost constant in the middle of two electrodes, meaning that plasma is neutral. A sheath region above the wafer is shown in Fig. 2(b).

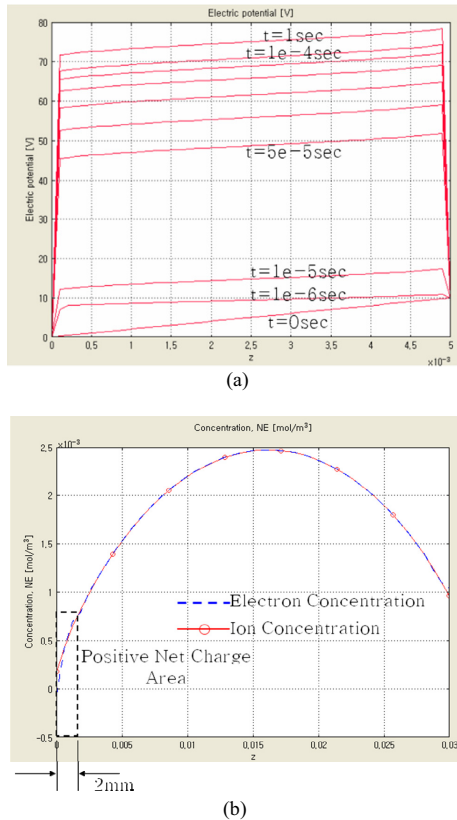

Fig. 2. Variation of (a) electric potential and (b) electron/ion density along the z-direction

From the field analysis of plasma chamber, the uniformity of electric field near wafer edge is improved as shown Fig. 3(b). It means that an incidence angle of ion to the wafer etching target is more perpendicular compared with Fig. 3(a).

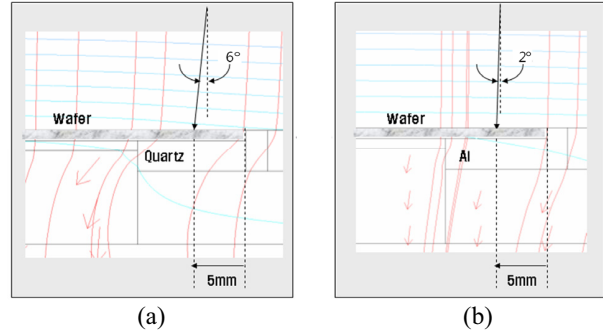

Fig. 3. Comparison of electric field distributions when the Q1 block is (a) quartz and (b) aluminum ring

Fig. 4(a) shows the SEM image of the cross section near the wafer edge after dry etching is performed. The trench near the edge is not perpendicular to wafer surface because of the fringing effect of electric field near the wafer edge. By substituting the quartz block with a aluminum one, the tilt angle of trench is improved as shown in Fig. 4(b).

Fig. 4. SEM images of wafer trench in (a) the existing quartz block and (b) the improved aluminum block.

Abstract — The steady-state and transient performance of a surface-inset permanent-magnet synchronous generator (PMSG) feeding an isolated load is studied using a couple-circuit, time-stepping, two-dimensional finite-element analysis. Nonlinearities in the field and electric circuit are taken into consideration and both passive ac load bridge rectifier dc load are analyzed. The computed results have been verified by experiments on a 2.5 kVA generator.

I. INTRODUCTION

Permanent magnet synchronous generators (PMSGs) are increasingly used for distributed generation and many stand-alone applications. For these applications the PMSG may supply a passive R-L load or a dc load via a diode bridge rectifier connected across the armature terminals [1]. The nonlinear electric and field systems pose considerable difficulties in analysis. In this paper, a time-stepping, coupled field-circuit finite element method [2], [3] is used for performance analysis of a surface-inset PMSG feeding an isolated load. Besides the field characteristics, the coupled field-circuit solution also yields other useful generator information, taking in consideration the armature current effect, magnetic saturation, and circuit nonlinearities. The analysis result helps in improving the generator design aspects. The computed results have been verified by experiments on a 2.5 kVA generator.

II. ANALYSIS

The electric circuit of a star-connected PMSG that supplies a three-wire R-L load comprises has six circuit variables, namely the resultant generated phase EMFs e_A , e_B , and e_C and the phase currents i_A , i_B and i_C . The external circuit comprises the armature resistance R , armature end-winding leakage inductance L_e , and the load impedance. In the case of a bridge rectifier load, additional circuit components include the six diodes D_1 to D_6 , the load resistance R_L , and the load inductance L_L . In the present FEA study the field circuit coupling is accomplished via the phase EMFs e_A , e_B , and e_C .

Maxwell's equations, applied to PMSG domains, will give rise to the diffusion equations

$$\begin{aligned} \nabla \times (\nu \nabla \times A) &= 0, & \text{in iron and air gap} \\ \nabla \times (\nu \nabla \times A) &= \frac{i_s}{s}, & \text{in armature windings (1)} \\ \nabla \times (\nu_{PM} \nabla \times A) &= \nabla \times (\nu_{PM} B_r), & \text{in permanent magnets} \end{aligned}$$

where A , ν , i_s , S , B_r and ν_{PM} are magnetic vector potential, reluctivity, armature phase current, total cross-sectional area

of one turn, remanent flux density of the PM and equivalent reluctivity, respectively.

The time-stepping, coupled field-circuit, 2-D FEA was performed in order to study the steady-state and transient performance the experimental PMSG with surface-inset rotor [3]. Constant speed operation is assumed and the PMSG supplies an isolated load. Fig. 1 shows the cross-section of the machine and the field plot obtained.

Fig. 1 Cross-section of PMSG with surface-inset rotor and the flux plot obtained from FEA.

III. GENERATOR PERFORMANCE

A. PMSG Supplying Isolated Load

Fig. 2 shows the computed and experimental waveforms of the PMSG on no load and Fig. 3 shows the computed and experimental waveforms of phase voltage and phase current when the PMSG is supplying a load resistance of 9.1Ω per phase. The increased harmonic distortion in phase voltage is due to increase in the triplen harmonics. Since a three-wire load is being supplied, the current waveform is practically sinusoidal since triplen harmonics are suppressed across the lines.

Fig. 2 Smith connection for single-phase operation of a three-phase induction motor.

B. Load Switching Transients

The time-stepping coupled field-circuit method was next used to study the transient performance of the PMSG. The PMSG was operating on no-load at rated speed when a balanced resistive load of 12.45 Ω per phase was connected across the generator terminals. As shown in Fig. 3, a brief transient period follows the application of load at time $t = 1.018$ s, and a notch is produced in the voltage waveform. Agreement between the computed and experimental waveforms is good in general, but the deviation in frequency becomes more pronounced due to the speed drop in the experimental machine set, a fact which was not accounted for in the FEA.

Fig. 3 Waveforms of phase voltage and phase current when a load resistance of 12.45 Ω per phase is switched across the generator terminals.

C. Short-Circuit Transients

The time-stepping coupled field-circuit method was also used for studying the short-circuit performance of the PMSG and the computed results are shown in Fig. 4. The PMSG is assumed to be running on open circuit when a three-phase short circuit occurs at the terminals. Since triplen harmonic currents cannot flow, the triplen harmonic voltage components remain in each phase during the short circuit (Fig. 4a). The steady-state short-circuit current, however, is quite sinusoidal as observed from Fig. 4b. The peak short-circuit current reaches 131 A, while the steady-state short-circuit current is 107 A (peak), or 76 A (rms), which is almost six times the rated current.

Fig. 5 shows the distribution of the normal flux density at the mean air gap of the PMSG computed at the instant when maximum short-circuit current (131 A) is flowing. Due to the inset rotor construction, the flux density is large in the interpolar regions (I) where the soft iron rotor pole pieces are located. Over the surfaces of magnets (II), however, the flux density is smaller due to the demagnetizing effect of the armature currents. There are also places with flux reversal, implying that partial demagnetization in the adjacent magnet regions is likely to occur in the event of a terminal short circuit.

Fig. 4 Three-phase short-circuit transients of PMSG: (a) Phase voltage waveforms; (b) phase current waveforms.

Fig. 5 Computed air gap flux density distribution of PMSG when Phase A is carrying maximum instantaneous short-circuit current (I: interpolar regions; II: surfaces of magnets).

D. Rectifier Load

Figs. 6a and 6b show the computed and experimental waveforms of the PMSG-rectifier-load system when $R_{dc} = 9.2$ Ω. Compared with the waveforms for passive loads (Fig. 2), the harmonic distortion the phase voltages and phase currents is more severe due to the nonlinear load. During commutation overlap, the phase voltage is approximately constant at 50 V while the phase current increases (or decreases) approximately linearly, giving rise to quasi-trapezoidal current pulses in the positive and negative half cycles (Fig. 6-a+b).

Fig. 6. Computed and experimental waveforms of phase current when the PMSG is supplying a rectifier load ($R_{dc} = 9.2$ Ω).

IV. ACKNOWLEDGMENT

The work described in this paper was fully supported by a grant from the Research Grants Council of the Hong Kong Special Administrative Region, China (Project No. PolyU 5121/06E).

Abstract — This paper introduces design and analysis of two different flux reversal linear synchronous motor(FRLSM) by 2D finite element method(FEM). The analysis models are optimized by response surface methodology(RSM) for a realistic comparison. Analysis results show that the proposed FRLSM with multiple auxiliary salient poles effectively increases thrust. A prototype of the proposed configuration is made and experimental results validate the design and analysis.

I. INTRODUCTION

Conventional flux reversal machine (FRM) consists of a passive rotor and multiple pole PMs of alternating polarity on each stator salient tooth. FRM can exhibit servo quality characteristics when driven by 3-phase sinusoidal vector control [1]. Most of previous research works related to FRM concentrated mainly on rotary machine except flux reversal linear oscillomachine for short stroke application [2]. Recent research works on FRLSM showed feasibility for long stroke linear motion systems [3], [4].

The proposed model in this paper introduces auxiliary salient poles between adjacent PMs. This unique magnetic circuit reduces flux leakage and also increases reluctance force, and thus thrust. This paper also analyzes a pole-PM type FRLSM which is linearized based on the conventional FRM for force comparison. For a realistic comparison between the analysis models, this paper performs optimization to maximize average thrust at rated MMF(magneto-motive force) using RSM which has been considered as an effective approach for electric machine optimization [6]. However, RSM optimization requires a large number of computations. Therefore, to reduce the number of computations, this paper adopts co-energy variation method to evaluate the average thrust by one phase since resultant thrust is a sum of thrust generated by each phase. Maxwell stress method is also applied for the performance comparison of the optimized models. The analysis reveals that the proposed configuration generates higher thrust than the conventional one. The proposed configuration is finally made based on the optimization results to validate the design and analysis.

II. ANALYSIS MODELS

Fig. 1 shows half model of each configuration and both models have the same external dimensions. Fig. 1(a) is a 5-PM FRLSM, which is linearized and modified based on a pole-PM FRM with odd number of PMs on a stator tooth [1], [3]. Fig. 1 (b) is the proposed FRLSM with multiple auxiliary salient poles. Major specifications of the models are listed in Table I.

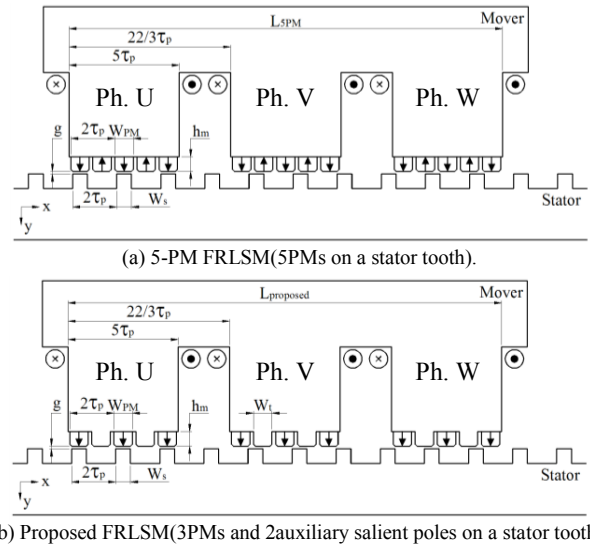

Fig. 1. Configurations of analysis models.

III. COMPUTATION METHODS

For magneto-static analysis, 2D FEM is performed using the commercial software ANSYS/Emag. To calculate average thrust, this paper adopts two different methods, maxwell stress method(MST) and co-energy variation method(CEV). It is computationally more efficient to apply CEV(2) than MST(1) since CEV needs only two computations(at 0 and τ_p) for the average thrust. Therefore, CEV is used for the optimization and MST is also used for steady-state comparison of the optimized models since MST provides thrust, normal force, and force ripple characteristics altogether.

TABLE I
SPECIFICATIONS OF ANALYSIS MODELS

Symbol	Item	Value	Unit
τ_p	Pole-pitch	6.0	mm
W_{PM}	PM width	To be optimized	mm
h_m	PM thickness	To be optimized	mm
g	Mechanical airgap	0.7	mm
h_s	Stack length	100.0	mm
W_s	Tooth width	To be optimized	mm
W_t	Salient pole width	$=W_{PM}$	mm
N	Number of turns/coil	50	-
L_{SPM}	Mover effective length	118	mm
$L_{proposed}$	Mover effective length	118	mm
MMF_{rated}	Rated MMF	400	AT
PM	$B_r = 1.3T, \mu_r = 1.05$	-	-
-	Mover/stator core material	S23	-

$$F_x = \frac{1}{\mu_0} \oint B_x B_y dl, \quad F_y = \frac{1}{2\mu_0} \oint (B_y^2 - B_x^2) dl \quad (1)$$

$$F_{x_avg.} = \frac{\Delta W_c}{\Delta x} \quad (2)$$

where F_x , F_y , μ_0 , B_x , B_y , $F_{x_avg.}$, W_c and J denote thrust, normal force, air permeability, x and y component of airgap flux density, average thrust, co-energy, and current density, respectively.

IV. OPTIMIZATION BY RSM

This paper adopts central composite design(CCD) for appropriate response models [5], [6]. Three important design parameters, W_{PM} , h_m and W_s , which are closely related to average thrust, are chosen in optimization. After statistical evaluations, the polynomial models of the responses are given as (3) and (4). The results obtained by each response model at optimal values and rated MMF are compared with those by MST and CEV in Table II. The average thrust values obtained by the three different methods show good agreement with each other with about 3% difference.

For steady-state operation of the optimized models, three-phase sinusoidal current is assumed to be applied in phase with each no load phase back-EMF. More detailed comparison by MST is numerically summarized in Table III. On average, the proposed FRLSM generates 22% higher thrust density than the 5-PM FRLSM. For the comparison of thrust ripples, this paper applies a multi-slices 2D model to consider skewing effects on the thrust ripples [7]. It can be seen in Table III that all models show extremely low force ripples after $2/3\tau_p$ skewing [3],[4].

$$F_{x_5PM} = -22.4 + 15.41W_{PM} - 11h_m + 5.27W_s - 1.24W_{PM}^2 - 0.68h_m^2 - 1.02W_s^2 \quad (3)$$

$$F_{x_proposed} = -87.16 + 38.67W_{PM} + 13.28h_m + 16.61W_s - 3.21W_{PM}^2 - 1.83h_m^2 - 2.4W_s^2 \quad (4)$$

V. PROTOTYPE EXPERIMENTS

A prototype of the proposed configuration is made after slight modifications from the optimized model. Fig. 2 and 3 show the prototype FRSLM unit and the mover core with PMs, respectively.

To validate the analysis, static thrust is measured by a force sensor at different positions and MMFs under DC current excitation between Ph. U and Ph. V since the motor is WYE connected and neutral point is not connectable. Fig. 3 compares analyses and experiments and shows quite good agreement.

TABLE II
RESULTS COMPARISON AT OPTIMAL VALUES AND RATED MMF

Design Parameters [mm]	5-PM FRLSM			Proposed FRLMS				
	Optimal value	MST [N]	CEV [N]	RSM [N]	Optimal value	MST [N]	CEV [N]	RSM [N]
W_{PM}	6.0				6.0			
h_m	2.0	55.4	56.0	57.6	3.6	79.6	80.6	82.1
W_s	3.0				3.5			

TABLE III
DETAILED COMPARISON BETWEEN 5-PM FRLSM AND PROPOSED FRLSM

MMF	Thrust density [kN/m ²]			Thrust Ripple [%]	
	5-PM	Proposed	Proposed/5-PM	5-PM	Proposed
200	7.9	10.3	131%	1.0	1.1
400	15.8	20.0	127%	0.6	0.7
600	23.7	28.3	120%	0.5	0.6

Fig. 4 Analyses and experiments.

VI. CONCLUSION

This paper proposes and analyzes FRLSM with multiple auxiliary salient poles. The comparison results of the optimized models by RSM verify that the proposed configuration effectively increases thrust. The experiments also confirms validity of the design and analysis. Dynamic characteristics will be extensively investigated in the future.

Reduction of Cogging Torque for Axial Flux Generator Applied to Small Wind Turbine

Min-Fu Hsieh¹, Yu-Han Yeh¹, D. G. Dorrell², and Samsul Ekram¹

¹Department of Systems and Naval Mechatronic Engineering, National Cheng Kung University, Tainan, Taiwan

²Faculty of Engineering, University of Technology, Sydney, Australia

Abstract—This paper presents a cogging torque reduction technique in axial-flux PM generators for small wind turbines. The compactness, large diameter and high power density make them suitable for wind turbines. The inherent cogging torque can cause problems during turbine cut-in. Here, a turbine is characterized via wind tunnel measurements to determine generator design specification. A “hybrid skew” method is proposed for cogging torque reduction. 3-D FEA is applied to evaluate the method and an 88 % reduction of peak cogging torque is obtained. This significantly improves the turbine performance by achieving low start-up speed. This method avoids confusion in N/S pole placement for manufacturing cost reduction.

I. INTRODUCTION

Axial-flux slotted PM machines have high power/torque density and simple construction; hence, they are suitable for wind turbine applications (particularly the two-sided configuration which balances the axial forces) [1]. Studies have been carried out to reduce cogging torque in axial flux machines (AFM) [2-4]. Some of these techniques require complex magnet shapes that increase manufacture cost or reduce magnet area that may reduce flux linkage and overall torque. There has been research on AFMs applied to wind turbines [5-6]; very few discuss reduction of cogging torque, which may cause potential start-up problems, noise and vibration. Past studies often used coreless designs [5-6] to avoid cogging torque; this may result in low power density [1].

In this paper, a double-rotor slotted AFM is investigated (for high flux linkage, low copper loss) for use in a direct-coupled wind turbine, with a solution put forward for cogging torque reduction. The proposed “hybrid skew” technique combines stator slot displacement to reduce cogging torque. In this technique, which is different from common methods, the North Poles have different shapes from the South Poles (Fig. 1(a)), where a complex shape is not required. The advantages are: (a) simple magnet shape to reduce manufacturing cost, (b) clarity of N/S pole orientation and placement, (c) little loss in magnet volume to maintain performance. For verification, 3-D FEA is applied. A performance comparison is made between the proposed hybrid skew approach and a machine which has no skew and exhibits cogging torque.

Fig. 1. (a) Hybrid skew in magnet, (b) symmetric arrangement and (c) asymmetric arrangement for the investigated axial flux machine

II. TURBINE CHARACTERIZATION AND GENERATOR DESIGN

The generator specifications can be determined by characterizing the turbine. This is critical since the turbine and generator should match each other on speed, torque and power for high efficiency energy conversion. The turbine (1.36 m in diameter) was installed in a wind tunnel with a dynamometer to measure the output torque and speed. The turbine output power measured under various wind speeds (V_a) is normalized to determine the power conversion coefficient (C_p) curve (Fig. 2(a)), where the peak conversion rate was found to be 32 % at a tip speed ratio (TSR) of 4.6. The TSR and C_p can be defined:

$$TSR = R_t \omega / V_a \quad (1)$$

$$C_p = T \omega / 0.5 \rho A V_a^3 \quad (2)$$

where R_t is the turbine radius, ω the turbine angular speed in rad/s, ρ the air density, A the turbine area facing the wind, and T the turbine shaft torque. In actual application, the rated wind speed is set at 11 m/s, where the turbine shaft output to the generator is 400 W (Fig. 2(b), which is expanded from Fig. 2(a)). At the rated point, the turbine speed and torque are 660 rpm and 5.79 N-m, which are used to determine the specifications of the generator, as shown in Table I.

TABLE I
GENERATOR SPECIFICATIONS

Rated voltage (V)	48	Rated speed (RPM)	660
Rated power (W)	580	Rated torque (N-m)	5.79
Number of pole	12	Number of slots	18
Magnet (NdFeB)	Br=1.24 T, H _{cb} =943kA/m kOe, H _{cj} =1585 kA/m		

The designed generator has a rated output voltage of 48 V at 11 m/s wind; this matches the input of a battery charger. The machine has double outer rotors with NdFeB magnets and a center inner stator (Fig. 3(a), with major dimensions). The detailed design process is not shown but it follows the procedure described in [7]. The air-gap is 0.67 mm and the magnet length is 3 mm. It should be noted that the 12-pole 18-slot configuration has a very high cogging torque and is used to emphasize the effectiveness of the proposed technique.

III. COGGING TORQUE ANALYSIS

The cogging torque can be expressed as [3]:

$$T_{cog} = -\frac{1}{2} \phi^2 \frac{dR}{d\theta} \quad (3)$$

where ϕ is the air-gap flux, R is the air-gap reluctance and θ is the angular position in electrical degrees.

For the dual-rotor generator, two parameters are defined for cogging torque analysis: one is the known stator slot displacement factor (K_d - stator slot displacement divided by slot pitch) [3] and the other is the “hybrid skew” angle θ (Fig.

1) proposed here. The proposed hybrid skew method when combined with an appropriate selection of K_d will give a significant reduction in cogging torque. This will be investigated using FEA.

Fig. 2. Turbine characteristics: (a) measured C_p , (b) power-speed curves

Fig. 3. (a) The designed generator with main dimensions, (b) FE model

Two rotor arrangements are considered: symmetry and asymmetry, as shown in Figs. 1(b) and (c). For asymmetry, the skew in the magnet of one rotor is opposite to that in the other while it is the same for the symmetrical case. From a manufacturing point of view, the symmetrical case is preferable since all N Pole magnets have a different shape from all S Pole magnets. Although magnet skew is a popular method [3-4], it may result in torque ripple or overall torque reduction. The proposed method aims to avoid this problem.

IV. SIMULATION RESULTS

The 3-D FE model is shown in Fig. 3(b). The individual action of slot displacement [3] and hybrid skew is first investigated, and the results are shown in Figs. 4(a) and (b). At $K_d = 0.1875$, the generator has the least cogging torque. The peak cogging torque for varying skew angles at $K_d = 0$ is the smallest at $\theta = 2.5$ deg. for the asymmetric case, as shown in Fig. 4(b) and Fig. 5. It is found that the proposed hybrid skew on its own reduces the cogging torque by 57 %.

The simulation results for the proposed technique combined with slot displacement [3] are presented in Fig. 6(a) (symmetric case). The best reduction in peak cogging torque is 88 % compared to the non-skewed magnet case, which verifies the effectiveness of the developed method. Another comparison is shown in Fig. 6(b), where the average air-gap flux density for the hybrid-skew machine is similar to the original arrangement without skew. The torque comparison and complete results will be shown in the final paper. This confirms that the proposed method does not affect the machine performance. The comparisons with other pole-slot combinations will also be provided in the final manuscript.

The target turbine has a start-up speed of 3.16 m/s with an output torque of 0.6 N-m. The peak cogging torque obtained using the proposed technique is very small and should not affect turbine power output and overall performance. In contrast, a non-skewed machine will have difficulty in starting when matched with the turbine.

V. CONCLUSION

A “hybrid skew” technique has been developed to reduce cogging torque in an axial-flux PM generator for a small wind turbine. A challenging 12-pole 18-slot axial flux machine with high cogging torque has been investigated. 3-D finite element analysis was used to carry out the simulation. It was found that the proposed method can achieve an excellent 88 % reduction in peak cogging torque when combined with the slot displacement method. Consequently, start-up problem of the wind turbine will be solved and the overall performance will not be affected. There will also be a reduction in manufacturing complexity and cost.

Abstract— This paper presents a comparison of magnetic characteristics according to stator core composition in transverse flux rotary machine (TFRM) in order to have high power density and reduce core losses. For one rotor, three types of stators are constructed depending on composition of soft magnetic composite core and silicon steel lamination core. The flux linkage, electromotive force, torque, and core losses of the three analysis models for the three stators, are calculated by 3- dimensional finite element analysis.

I. INTRODUCTION

Soft magnetic composite (SMC) has recently been developed as an alternative magnetic material, which can be utilized to reduce the iron losses in electric machine. Moreover SMC give a lot of degree of freedom for design of electric machines where the magnetic flux has to flow in the 3- dimension in the magnetic parts. However, SMC has less attractive magnetic properties than silicon steels. Because SMC is made from a mixture of ferromagnetic material and electrically insulating material, they have low saturation flux densities and permeability due to fact that there are air gaps between the iron particles. Moreover the shaping process for SMC's induces strain and stress in the particles. These can only be partially removed by a stress annealing process, since the electrically insulating material cannot withstand the temperatures needed for complete annealing. That limitation increase hysteresis losses considerably [1]-[2].

With silicon steel, magnetic circuits are established by stacking magnetic sheet. In these magnetic circuits, the magnetic flux has to flow in directions parallel to sheet steel's surface. This kind of material has very good magnetic properties but the anisotropy of laminated electrical steel and constraints due to their manufacturing impose limits on the geometries of the magnetic circuits possible [2].

This paper attempts to find a good composition with these two representative materials, SMC and silicon steel, in order to have high power density and reduce core losses in the design process of transverse flux rotary machine (TFRM) with 3- dimensional magnetic flux paths. Three analysis models are considered depending on the composition. In the analysis models, rotor is identical and stator has three types which are made by only SMC, by only silicon steel, and by both SMC and silicon steel. The conditions of the three analysis models are the same except of stator core materials, and the electromagnetic parameters for each model are computed by 3-dimensional finite element analysis (FEA).

Flux linkage, electromotive force (EMF), and torque are obtained by computation results of the time-domain magnetic fields in 3-dimension. And the core losses are calculated with both the magnetic computation results and core loss sample data instead of experimental equations [3]. In the case of the silicon steel, if the material class is fixed core thickness is the only variable of core samples' configuration. In the case of SMC core, however, the three dimensions, which are width (thickness), height, and area of the cross section, can be the variables of core samples' configuration. Therefore core losses of lots of samples are measured, which are made depending on variation of dimensions of cross section area.

The theoretical results are compared with experiments on a prototype machine with SMC stator core. This comparison gives reliance of analysis results and a comparison of magnetic characteristics in the three analysis models.

II. ANALYSIS MODELS

Fig. 1 shows a conceptual configuration of one phase in prototype permanent magnet (PM) excited TFRM and the magnetic flux path by current excitation. A brief specification of the prototype including magnetic material information is listed in Table 1.

Fig.1. Conceptual drawing of one phase in a TFRM; (a) configuration of a TFRM, and (b) flux path on the cross section of A

Table 1. Specifications of a prototype TFRM

Stator	Material	Somaloy 550 (SMC core)
	No. of Phase	2 phases
	No. of turns	135 turn /phase
	Rated current	4.6 Arms/phase
Rotor	Material	Somaloy 550 + Ferrite PM (Br=0.4T)
	No. of pole	PM=64, SMC core=64 (per phase)

The rotor consists of PMs and SMC cores, which are arranged in circumferential direction and the PMs are magnetized as shown in Fig. 1 (a) to concentrate the magnetic flux to the rotor core. The one phase stator consists of a coil and three pieces of cores which are a pair of outer core and one inner core - the inner and outer sections are a yoke and teeth, respectively. The outer teeth core is divided into upper and lower parts, and the lower teeth are shifted by a half pole-pitch with respect to upper teeth to reduce torque ripple and make high power density.

According to make the inner and outer cores with what kind of materials, the number of analysis models become three as shown in Fig. 2. The models are named as SM and LM as shown in Fig. 2 (a) and (b) if the materials of stator cores are SMC and silicon steel, respectively. If the material of inner and outer cores are SMC and silicon steel respectively, the model are named as SLM as shown in Fig. 2 (c).

For construction, model SM does not need to consider the 3-dimensional flux path as shown in Fig. 1 (b); however the model LM and SLM should be considered the stacking direction. In the analysis model, the lamination direction is considered.

III. MAGNETIC CHARACTERISTICS

3-dimensional magnetic field FEA is conducted to calculate the electromagnetic parameters and core losses of the three models.

The b-h curves of core materials and core loss sample data are shown in Fig. 3. Fig. 3 (b) is SMC core losses according to variation of frequency and peak magnetic flux density by the Epstein test method, and these data are an example among measured data of 13 kinds of samples depending on cross section area dimensions.

Flux linkage, EMF, torque, and core losses of the three analysis models are obtained by computation results of the time-domain magnetic fields at rated current. The experiments are performed for prototype, SM model. Analytical and experimental EMF and torque are compared as shown in Fig. 4 to show reliability of analysis results and a comparison of magnetic characteristics in the three analysis models.

The analysis results and comparisons of magnetic characteristics between three models will be presented in extended paper.

Abstract— This paper presents the optimal design method of cage-bars in a single-phase line-start permanent magnet synchronous motor (LSPMSM) considering the starting torque and magnetic saturation. This method consists of two procedures. First, the basic design of cage-bars is made by analytic method of an induction motor. In this case, the equivalent magnetic circuit method is used but this method cannot consider nonlinear characteristic as magnetic saturation and leakage flux. Second, for considering the nonlinear characteristics, the optimal design of cage-bars is performed by the FEM and the response surface method (RSM). To validate the proposed method, the prototype motor is manufactured and the simulation results are verified by experiment.

I. INTRODUCTION

The line-start permanent-magnet synchronous motor (LSPMSM) is a hybrid PM/re reluctance motor that has high-efficiency alternative to the induction motor [1].

In general, the stator with winding and air-gap volume (D^2L) in LSPMSM is the same as conventional single-phase induction motor for a wide use. Therefore, the design parameters of the LSPMSM are restricted to the rotor such as magnets, barriers and cage-bars. Among the design parameters, the shape of cage-bars is very important parameter because it related to the torque in stator state and the magnetic flux path in steady state. But conventional researches of LSPMSM deal with only design of magnets and barriers in rotor.

In this paper, the optimal design method of cage-bars is proposed in the LSPMSM. This method consists of the two procedures. First, the basic design of cage-bars is made by analytic method of an induction motor [2]. In this case, the equivalent magnetic circuit method is used but this method cannot consider nonlinear characteristic as magnetic saturation and leakage flux. Second, for considering the nonlinear characteristics, the optimal design of cage-bars is performed by the finite element method (FEM) and the response surface method (RSM). To validate the proposed method, the prototype motor is manufactured and the simulation results are compared with the experimental results.

II. PROCEDURE FOR OPTIMAL DESIGN OF LSPMSM

The rotor design process of LSPMSM is shown in Fig. 1. First, using the widely accepted D^2L of single-phase induction motor, the outside diameter of rotor can be determined. Next, the basic cage-bars design to maximize the starting torque is performed. It gives a full explanation in chapter III. After the basic cage-bars design is determined, the shape and position of permanent magnet are determined. The position of

permanent magnet is determined as close as possible to the cage-bar to maximize magnetic flux density of air-gap. The size of permanent magnet is determined by considering the demagnetization and the magnetic flux density of air-gap at rated torque. And the barrier is designed to minimize leakage of magnetic flux. The previous design process is very rough, but the design of cage-bars doesn't have big problems. Because the optimal designed cage-bars can be performed by controlling flux of permanent magnet at steady state, the basis design can be compensated by blocking the leakage flux. Finally, the cage-bar optimal design is explained in chapter IV in detail.

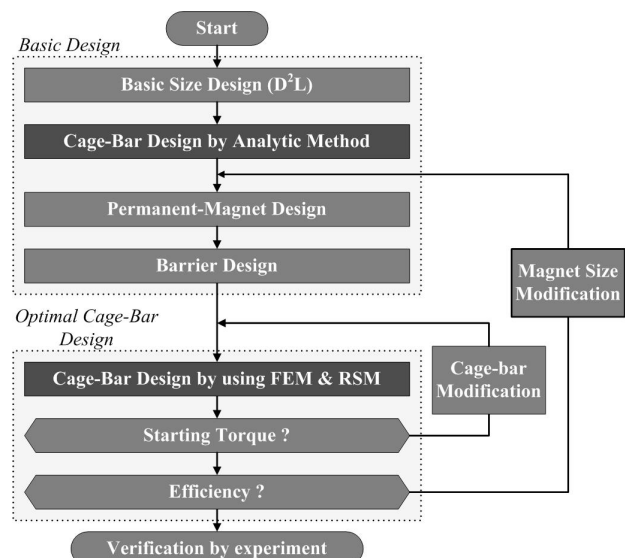

Fig. 1. Flowchart of proposed design procedure of LSPMSM

III. BASIC DESIGN OF CAGE-BARS BY ANALYTIC METHOD

Based on past experience, slot combination between the stator and rotor numbers of slots is chose to reduce parasitic torque, additional losses, radial forces, noise, and vibration.

Single phase LSPMSM has same starting performance of single phase induction motor due to using rotor cage at starting. So, through improving starting torque of single phase induction motor, we try to improve starting torque of LSPMSM. The starting torque of single phase induction motor can be calculated as follows:

$$T_s = \frac{2p_1}{\omega_1} I_s R_{rm} \quad (1)$$

$$Z_s = \sqrt{(R_{sm} + R_{rm})^2 + (X_{sm} + X_{rm})^2} \quad (2)$$

The method that starting current is increased is undesirable for high starting torque. Therefore, rotor cage resistance is very important factor for high starting torque.

Rotor cage resistance is to subdivide it into two part, rotor bar resistance and end ring resistance. We can write the following resistance equations.

The equation of equivalent cage resistance is:

$$R_{be} = R_b K_R + \frac{R_{ring}}{2 \sin^2(\pi p_1 / N_r)} \quad (3)$$

Where K_R is skin effect resistance coefficient for bar, N_r is number of rotor slot. The skin effects increase with the slot height for slip frequency.

Notice that equivalent cage resistance has to be reduced to the stator. Therefore rotor cage resistance can be calculated as follows:

$$R_{rm} = R_{be} \frac{12 K_{wm}^2 W_m^2}{N_r} \quad (4)$$

In this study, we design only rotor of LSPMSM using stator of single phase induction motor. Therefore we consider only equivalent cage resistance, we can write the following equivalent cage resistance equations again.

$$R_{be} = \left[\rho_{Al} \frac{l_b h_r}{\left(\frac{d_1 + d_2}{2}\right) h_r + \frac{\pi d_1^2}{4}} \sqrt{\omega_l \mu_0} + \frac{\rho_{Al} l_{ring}}{2 \sin\left(\frac{\pi p_1}{N_r}\right) A_{ring}} \right] \quad (5)$$

In this equation, assume the change of end ring is little, so the adjustable variables are slot upper width, slot lower width and slot height. These variables are adjusted for high starting torque motor.

IV. OPTIMAL DESIGN OF CAGE-BARS BY NUMERICAL METHOD AND RSM

The basic design of rotor is only considered to the starting torque at starting state. Because the magnetic flux path is adjusted by the barrier as well as the cage bar, we cannot consider the magnetic saturation and leakage flux using analytic method. So, the optimal design is necessary. Fig. 2 shows flux density by using FEM analysis. We choose the points which can be doubted the saturation region or the leakage flux region by using FEM analysis. And the parameter design of the cage-bars is tried not to exceed the limited value of flux density at this region. Finally, the optimal value is obtained by optimal design using FEM analysis and RSM.

Fig. 3 shows the starting characteristic of the conventional induction motor and the proposed LSPMSM. Although the LSPMSM has the breaking torque due to permanent magnet, the induction motor and the LSPMSM have similar starting time due to the designed cage-bars.

V. EXPERIMENT

The LSPMSM with the proposed design method is manufactured as shown in Fig. 4(a). In order to verify the validity of the optimal design method, the experiment results of the rating torque are compared with the results of the simulation as shown in Fig. 4(b). From the results, it is evident

that the FEM analysis gives good agreement with the experimental one.

VI. CONCLUSION

In this paper, the optimal design method of cage-bars considering starting torque and magnetic saturation by using FEM and RSM is proposed in LSPMSM. To verify the validation of proposed design method, the results of simulation are compared with characteristics of proto type.

Analysis of Very Fast Transient Overvoltages and Electric Field Stresses in Conventional Tesla Transformers Using FDTD Method

E. Agheb, E. Hashemi, K. Niayesh, A. Mousavi and M. Faridi
School of Electrical and Computer Engineering, University of Tehran
Azad University of Khodabandeh
e.agheb@gmail.com

Abstract — Very fast transient overvoltages (VFTOs) in the secondary winding of air-cored Tesla transformers have been surveyed using a comprehensive model based on Multi-conductor Transmission Lines (MTLs) theory. The governing equations have been solved by Finite Difference Time Domain (FDTD) method. Voltage distribution in two different structures of Tesla transformers, tapered single layer and multi-layer secondary windings has been investigated. The experimentally validated simulation results show considerable fluctuations and overvoltages in some sections of the transformer winding that should be considered in insulation coordination.

I. INTRODUCTION

In pulsed power generators, the amplitude of output pulse of a Tesla transformer is even higher than several hundred kilovolts. The induced traveling waves in the secondary windings of such transformers include high-order harmonics that can bring about internal resonance and cause exceedingly uneven turn to ground and inter-turn voltage distributions. Since this unevenness can cause inter-turn insulation failure or partial discharge, it is essential to investigate the voltage distribution in the secondary winding of Tesla transformers. Mainly there are three models to study the VFTOs in the windings of transformers: Lumped circuit model [1], Multi-conductor Transmission-Lines theory [2] and full-wave solution [3].

An appropriate simulation model is the most fundamental condition for the research of the voltage distribution in transformer windings. Since the frequency of VFTO is very high, the lumped parameter model could not satisfy the computation request and also the full-wave solution is hard to obtain due to the complexity of model and lots of degrees of freedom. Considering the fact that the MTL theory is very accurate in case of pulses with short rise/fall times and where the coils are long compared to the wavelength, in the current study, this model is utilized for very fast transient simulations.

To study the voltage distribution in transformer windings under VFTO, a model for transformer windings has been developed based on MTLs theory. A common way of determining the time-domain response of a MTL is the use of finite difference-time-domain method.

In this paper, based on FDTD method, distribution of voltage in the secondary winding of two conventional types of Tesla transformers, tapered single layer and multi-layer, is studied and turn to ground, inter-turn and inter-layer overvoltages are evaluated. Furthermore, numerical results are

compared with measurements. Simulation and measuring results obviously demonstrate the fluctuation and oscillation of the voltage in different turns which would result in insulation failure.

II. THE WINDING MODEL

To have a proper evaluation of time domain response, the electrical parameters should be assessed precisely. For this purpose, these parameters are evaluated via Finite Element Method (FEM). Moreover, the frequency dependency of the parameters is considered in this method. The recursion relations of voltage and current are as follows:

$$V_k^{n+1} = V_k^n - \frac{\Delta t}{\Delta z} C^{-1} (I_k^{n+\frac{1}{2}} - I_{k-1}^{n+\frac{1}{2}}). \quad (1)$$

$$\begin{aligned} I_k^{n+\frac{1}{2}} = & F^{-1} \left(I \frac{\Delta z}{\Delta t} - A \frac{\Delta z}{2} + B \frac{\Delta z}{\sqrt{\pi \Delta t}} Z_0(0) \right) I_k^{n+\frac{1}{2}} \\ & - F^{-1} B \frac{\Delta z}{\sqrt{\pi \Delta t}} \sum_{m=1}^n (I_k^{n+\frac{1}{2}-m} - I_{k-1}^{n+\frac{1}{2}-m}) Z_0(m) \\ & - F^{-1} \left[(V_{k+1}^{n+1} - V_k^{n+1}) + \frac{\Delta z}{2} (V_{Fk}^{n+\frac{1}{2}} - V_{Fk}^{n+\frac{1}{2}}) \right] \end{aligned} \quad (2)$$

Two different structures of Tesla transformers are being studied, tapered single layer and multi-layer which are illustrated in Fig. 1.

Fig. 1. Two conventional structures, single layer (left) and multi-layer (right)

III. RESULTS

Voltage at different turns of the high voltage winding is shown in fig. 2 for a transformer with single layer winding structure. As shown in this figure there is high magnitude transient over voltages across the terminal turns (see fig. 2f). Similar pattern has been achieved for two layer structure and is depicted in Fig. 3.

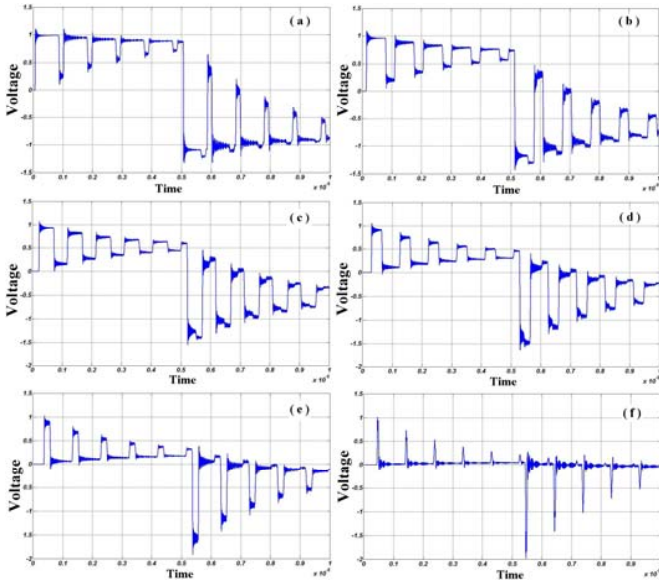

Fig. 2. Voltage at different conductors in a single layer winding if input is a 100 kHz pulse at conductors: a) 15th, b) 30th, c) 45th, d) 60th, e) 75th and f) 95th

Fig. 3. Voltage at different conductors in a two layer winding if input is a 100 kHz pulse at conductors: a) 15th, b) 30th, c) 45th, d) 60th, e) 75th and f) 95th

Maximum inter-turn overvoltage plays an important role in insulation design of transformer windings. As depicted in Fig. 4 maximum overvoltage happens in middle part of the winding where winding direction inverses (red circle in fig. 1). It must be noted that this voltage difference should be zero under steady state condition, but in transient condition the insulation material is subjected to very high stresses.

Fig. 4. Voltage difference between two layers

According to calculated overvoltages, electric field stresses have been analyzed by FEM method in discussed structures. These transient overvoltages have been investigated by using a test setup including windings similar to the simulation ones. Measurements are in good agreement with the simulation results. The measured values clearly show that the highest overvoltages occur at head end of winding in case of single layer and at the middle of the winding in the case of two layer winding structure, as predicted by simulations.

IV. CONCLUSION

The study of VFTO in an air-cored Tesla transformer’s winding is important for insulation co-ordination. It is especially important to determine the position of maximum inter-turn overvoltage, which depends on the configuration of the winding and wave style. In this paper, studying voltage distribution in the secondary windings of conventional Tesla transformers based on FDTD method, the maximum overvoltages in these windings have been simulated. Calculation of the electric field stresses demonstrates the risk of insulation failures in different parts of the high voltage winding depending on its structure.

Abstract—This paper discusses the calculation of fringing fields and forces which exist in slotted tubular permanent magnet actuators. The magnetic field distribution will be calculated in a semi-analytical manner and with two-dimensional finite element analysis in the cylindrical coordinate system. The semi-analytical model is based on Fourier analysis to describe various magnetization profiles and the resulting magnetic field distribution. A periodic model with a single semi-closed slot geometry will be considered for both models which reduces the computational time. These modeling techniques allow for accurate calculation of the fringing fields and the resulting cogging force.

Index Terms—Actuator, cylindrical, permanent magnet, slotting effect.

I. INTRODUCTION

When tubular permanent actuators with a high force density are required, a slotted armature is more preferred since the effective airgap is reduced. However, the introduction of the slots results in a distortion of the magnetic field due to the magnets, giving fringing fields at the tooth tips. This field distortion leads to a force ripple which is generally referred to as a cogging force. It is beneficial to predict the resulting force ripples for various slot-pole combination in a fast way in order to choose the optimal slot-pole combination regarding the application. The effect of slotting on the magnetic field distribution is extensively investigated in the literature, providing analytical and numerical tools for predicting the resulting cogging forces. Recently, Liu [1], presented an exact semi-analytical solution of the airgap flux density for slotted linear machines with an extension to rotary machines. Based upon his work, this paper provides the exact semi-analytical solution for the cylindrical coordinate system including the more complicated semi-closed slot geometry as shown in Fig. 2. The slotting effect will be described for a single slot traveling across one pole-pair. The cogging force due to a single slot can be calculated and the total solution can be obtained by synthesis of the single slot solution, [2]. From the semi-analytical field solution, the cogging force can be calculated by means of the Maxwell-Stress method. Next to that, a 2D finite element model will be considered for calculation of the slotting effect and the related cogging force. This force component will be calculated by means of the virtual work method. Comparisons between the two models will be made in terms of accuracy and computational time.

Fig. 1. A three phase slotted tubular permanent magnet actuator.

II. THE SEMI-ANALYTICAL MODEL

The tubular structure inhibits angular symmetry and hence a 2D-cylindrical coordinate system, (r, z) , can be considered. The iron is assumed infinitely permeable, hence saturation is not included. The magnets are modeled having a linear second quadrant characteristic. Although only a single slot is considered, it should be noted that it is possible to consider the total solution, including all slots in once, however the complexity increases drastically and numerical instability becomes dominant, these influences will be shown in the final paper. Furthermore, three different magnetization profiles (radial, quasi Halbach and axial) will be considered since the boundary value problem is different for each of them. For example, when axial magnetization is considered, five different regions, need to be distinguished, the shaft (I), the permanent magnet (II), the airgap (III), the slot opening (IV) and the slot (V) region, respectively, see Fig. 2. This boundary value problem is solved by considering the magneto static Maxwell equations, which can be reduced to a Poisson equation written in terms of the magnetic vector potential \vec{A} as $\vec{B} = \nabla \times \vec{A}$,

$$\nabla^2 \vec{A} = -\mu_0 \nabla \times \vec{M}, \quad (1)$$

where, $\vec{M} = 0$ for regions I, III, IV and V. Fourier analysis will be used to describe the magnetization vectors and consequently, the solution for the radial and axial flux density distribution will be written as a Fourier series which will be given in the final paper. Note that this semi-analytical model is an exact solution for the magneto static Maxwell equations with the limitation that only a finite number of harmonics can be included in the numerical implementation. This gives inaccuracies of the magnetic field solution at discontinuous

Fig. 2. The boundary value problem with division in regions for the axial magnetized topology.

points in the structure, for example at the boundary of the magnets or at the corner points of the slotted armature. However, for calculation of the cogging force, the Maxwell Stress method is used at the center of the airgap where a more accurate field solution can be obtained since the harmonic content is lower here.

III. THE FINITE ELEMENT MODEL

In order to be able to minimize the slotting effect by means of finite element analysis, a model is preferred which only considers the slotting effect without the effect due to the finite stator length (end effect). In [3], this is obtained by converting the tubular actuator to a rotary actuator which allows for periodic modeling in finite element packages. An alternative way is to consider only the cogging force due to a single slot and obtaining the total solution by means of synthesis of the single slot solution for the proper pole-slot combination, [2]. This allows one to focus on the single slot cogging force calculation which significantly reduces the model and allowing for implementation of the finite element model for only one period as done for the semi-analytical model. Periodic boundary conditions are applied to the axis symmetric model at 0 and $z = 2\tau_p$ and triangular mesh elements are used where the airgap consists of two layers of mesh elements in the airgap. In order to make a fair comparison with the semi-analytical model, the tangential component of the magnetic field strength is set to zero at the soft-magnetic boundary of the slotted stator.

IV. COMPARISON

The radial and axial component of the flux density in the center of the airgap are shown in Fig. 3 for the semi-analytical and finite element model. A close up of the slotting effect is shown next to the figure. It can be observed that excellent agreement is obtained which is as expected since the linear 2D FE model has the same assumptions as the semi-analytical model. For the finite element modeling, the virtual work method is applied to calculate the cogging force which is compared with the semi-analytical solution in Fig. 4 for radial, quasi Halbach and axial magnetization where excellent agreement is obtained. The final paper will give a more detailed discussion about numerical accuracy and stability of the analytical solution. The semi-analytical calculation is around 40 times faster than a finite element calculation.

Fig. 3. Magnetic field solution of the axial magnetized topology in the center of the airgap, $\Delta z = 20$ mm.

Fig. 4. Cogging force calculation with the semi-analytical and finite element model.

V. CONCLUSION

This paper compares computational methods for calculation of the fringing fields and resulting cogging forces due to the slotted armature in tubular permanent magnet actuators. The semi-analytical and the finite element method are compared in terms of accuracy and computational time. The solution is given for a single slot traveling across one pole-pair where besides quasi Halbach magnetization, radial and axial magnetization will be considered in the final paper. Excellent agreement between the semi-analytical and finite element model is obtained for the magnetic field distribution and cogging force calculation.

Abstract — The magnetic fields in 1-phase and 3-phase transformers with amorphous modular cores have been analyzed. Scalar magnetic potentials have been implemented for 3D Finite Element (FE) field calculation. Due to inability to simulate each thin amorphous layer, we introduced supplementary permeabilities of the core along the main directions of magnetization. Calculated fluxes in the cores were tested on the prototype.

I. INTRODUCTION

Usually to build the transformer core thin sheets cold rolled, grain-oriented silicon steel are used [8]. The amorphous ferromagnetic alloys were manufactured at the end of the fifties [5]. The right way to manufacture them limits the ribbon thickness from 30 to 50 μm [3]. Due to this, and the material structure, their core losses are several times lower than those in silicon steel [1], [4], and [6].

II. DESCRIPTION OF THE ANALYSED OBJECT

Fig. 1. Transformer with modular amorphous core

The outline of the 3-phase transformer with amorphous modular core is given in Fig. 1, where coordinate system and main dimensions are depicted. Each column consists of two hollow cylinders (toroids). In both prototypes the primary and secondary windings are cylindrical. The primary (internal) ones, which are close to the columns, are divided into two sections: with $N_{11}=116$ and $N_{12}=75$ turns. The turn number of the secondary windings is $N_2=116$. Rated power of the 3-phase transformer prototype is $S=10$ kVA. The nominal currents are $I_{1N}=15.2$ A and $I_{2N}=26$ A.

III. CALCULATION MODEL

The analysed object has XZ plane of symmetry (Fig. 1). After halving the field region, only one part has been chosen for the Finite Element (FE) analysis. For the 3D calculations

we used two scalar potentials: the first one, (called total potential) ψ , and the second one (called reduced potential) ϕ [2]. Total potential is obligatory in the current free regions and satisfies the Laplace's equation

$$\nabla \cdot (\mu \nabla \psi) = 0. \quad (1)$$

In the current carrying regions, the reduced potential ϕ satisfies the elliptic equation

$$\nabla \cdot (\mu \nabla \phi) - \nabla \cdot (\mu \vec{H}_S) = 0. \quad (2)$$

The field intensity \vec{H}_S , arisen from the excited coils, can be calculated independently before the FEM solver runs.

The magnetic flux is parallel to the rolling up direction of the yokes. In each column, it is perpendicular to the direction of the magnetic strip winding. As we were not able to discretize each thin amorphous layer, we introduced supplementary permeabilities of the core along the two directions of magnetization. Thus, in the mathematical model we introduced two different $\mu(H)$ curves for legs and yokes, respectively. For the lamination layers the core losses were neglected in the field modeling.

Using the FE method, after discretization of the equations above, we obtained the difference equations set, which can be written in matrix form

$$[K] [\Phi] = [S] \quad (3)$$

Due to the $\mu(H)$ curves, the equation (3) with the matrix $[K]$, is non-linear. The known right hand side, n-dimensional vector $[S]$, is calculated including the given current excitations and boundary conditions. The vector $[\Phi]$ of the unknown nodal potentials is calculated with Newton-Raphson method [2].

Including the previous solution $[\Phi]^{(k)}$, a the new one, $[\Phi]^{(k+1)}$ is found in the iteration process [1], [2] by solving the linearized system

$$[\Phi]^{(k+1)} = [\Phi]^{(k)} - \{[J]^{(k)}\}^{-1} [R]^{(k)} \quad (4)$$

The residual vector $[R]^{(k)}$ and the Jacobean matrix $[J]^{(k)}$ in the (k) iteration are expressed below

$$[R]^{(k)} = [K]^{(k)} [\Phi]^{(k)} - [S]^{(k)} \quad (5)$$

$$[J]^{(k)} = \frac{\partial}{\partial [\Phi]^{(k)}} ([K]^{(k)} [\Phi]^{(k)} - [S]^{(k)}) \quad (6)$$

IV. CALCULATION RESULTS

We studied two configurations of the modular core transformer system at no load state. The magnetic fields, for several values of the magnetizing current were analysed in the

1-phase configuration. In Fig 2 we presented the flux density B distributions at the plane shifted by $y=1$ cm from the plane XZ (Fig. 1). The B values were excited by the magnetizing current amplitude of $I=1.41$ A. The maximal values are around the yokes and columns connections. The B values at edge points of the core are much lower. Inside the yokes, they are slightly higher than those inside the columns.

Fig. 2. B_{mod} distribution for $I=1.41$ A

Distribution of flux density modulus and the vectors \vec{B} are also presented for the 3-phase transformer with amorphous modular core (Fig 3). It concerns the current arrangement, with rms values equal to $I_B=1,27A$ and $I_A= I_C=0,705A$. Depicted map is drawn for the surface $y=1$ cm (Fig. 1). Due to the currents, the B values are relatively high in whole region of the middle column. The flux density is lower in the yokes.

Fig. 3. B_{mod} distribution for $I_B=1.27$ A.

Fig. 4. B_z distribution for 3-phase transformer.

Fields in the described transformers were analyzed under short circuit state, as well. We assumed current values $I_{1N}= I_{2N}=15A$ in

the primary and secondary coils with $N=116$ turns. In Fig. 4 we presented the B_z component distribution at the XY plane.

V. MEASURED VERIFICATION OF THE CALCULATION

Magnetic flux values under the under short circuit state of the 3-phase transformer were compared with the measured ones. They were tested at the middle of each column toroids. The mean values from the three columns were compared in Fig. 5.

Fig. 5. The mean values of the flux in 3 transformer columns.

VI. CONCLUSIONS

The new constructions of the 1-phase and 3-phase modular transformers with amorphous cores have been studied with FEM. In 3D field calculations, magnetic anisotropy of the amorphous (Fe based) alloy was included. The different magnetization characteristics for the yokes and columns were assumed. The calculated fluxes values were confirmed experimentally. Thanks to modular technique, the described structure is convenient for assembling and repairing.

Abstract— A pending workbench shall be designed, that is able to perform linear and rotational movements in four axes with high accuracy, so that different operations can be run on the work piece. The design of this workbench is supported by numerical simulations. Since the workbench's movement is free in a certain range, simulations have to be run for the high number of possible positions. When optimizing the device's layout by varying different parameters, simulations are needed for all positions in which the device shows an extreme behavior. The numerousness of simulations leads to very high efforts concerning pre- and post-processing. To reduce these efforts, a CAD software and a mesh software have been automated.

I. INTRODUCTION

Linear induction motors and servo motors can be used for accurate positioning systems. A combination of both principles can realize several degrees of freedom of motion, if the moving part is pending or mounted in a way that allows these movements. The pending part is called flotor. A similar principle was realized for a haptic device in 1999 [1]. Six degrees of freedom of motion have been realized but only with strongly limited translational movements and rotational angles.

This paper deals with the development of a workbench for the machining of small pieces.

II. THE PENDING WORKBENCH

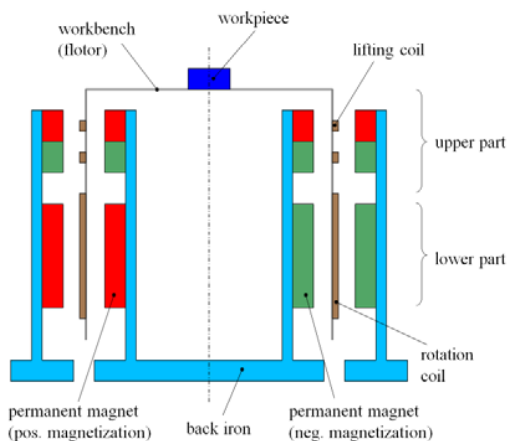

Fig. 1. Cross section through the yz-plane of the workbench device

A pending *flotor* shall carry a small workpiece and perform translational movements in three axes and rotational

movements around the z-axis. The translational movement is limited on the workpiece size. The rotation should cover a range of 360 degrees.

Fig. 1 shows a schematic view on the device. The upper part performs movements in horizontal direction and compensates torques around the x- and y-axis. The lower part performs translations in x- and y-direction and rotations around the z-axis.

Fig. 2. Isometric view on the flotor's coils and the stator's permanent magnets

Fig. 2 shows an isometric view on the device. A design approach to realize six degrees of freedom of motion is presented in [2]. It also contains a more detailed description of how the different types of motion are realized.

III. THE NUMERICAL SIMULATION

A multitude of simulations has to be run for every design approach. Forces and torques between stator and flotor are obtained by magnetostatic computations and the application of Maxwell's stress tensor. These simulations show, if it is possible to generate forces that can compensate the process forces and carry or accelerate the flotor.

The non-linearity of the magnetic material requires an iterative algorithm, the optimization process requires a large number of computations. These efforts are reduced by the application of a volume integral equation method (VIEM) in combination with the fast multipole method (FMM). Since the air-gaps between coils and permanent magnets are large, only a small number of degrees of freedom occurs compared to a similar FEM simulation.

11. Electric Machines and Drives

A bigger problem from an economical point of view is the manpower invested in preprocessing. This paper deals with how to automate the simulation steps in the design process of the pending workbench.

A. The Optimization Process

A first design approach is developed considering mechanical requirements by means of approximation formulas. The resulting values are chosen as first step parameters of the numerical optimization process.

B. The CAD Tool

The first step in a numerical simulation is to create the geometrical data. The commercial software Rhinoceros® has been chosen, because it is easy to handle and it can be controlled by a Visual Basic Script (VBS) [3].

Many parameters can be varied, as there are geometrical properties such as diameters, or heights, the number of coils and magnetic poles as well as the flotor's position to the stator. Due to the modular design of the implemented script, further parameters can be appended.

The script delivers a CAD-file in IGES-format that can be imported by the meshing tool and a text file with geometrical data that has to be pasted into the input file of the numerical software. Some variables are returned to control the meshing software. Fig. 2 has been created with this script.

C. The Meshing Tool

As a second step, the geometrical bodies have to be divided into finite elements of an appropriate size. The IGES-file is imported by the program Hypermesh®, which creates volume meshes of the coils, magnets, and back irons and puts out a text file with the volume elements' and their respective collectors' data. Hypermesh can be automated by Tool command language (TCL) [4]. Some global parameters like the maximum element lengths are defined in the control program.

D. The Numerical Software FAMU

Our numerical software FAMU is based on the VIEM, the system matrix is reduced by the FMM. The magnetostatic problem is solved by an iterative $\mathbf{M}(\mathbf{H})$ algorithm. The required input parameters are the text file with the mesh data and a text file with control parameters containing information about the coil's and magnet's positions and geometrical shapes and a lot of other control parameters that remain the same in the majority of cases. The changing parameters are set by the control program considering the output of the CAD-tool. The software delivers a text file which contains the needed results.

E. The Control Software

The control software starts the mentioned programs according to a user-set sequence. New design approaches are evaluated by running simulations in critical positions between stator and flotor. To describe the behavior of the chosen design approach, the control software shall be extended in a way that makes it possible to create matrices \mathbf{A} for every

displacement \mathbf{r} and rotation φ which describe the relation between impressed coil currents I and the resulting forces \mathbf{F} and torques \mathbf{M} :

$$\mathbf{A}(\mathbf{r}, \varphi) \begin{pmatrix} I_1 \\ \vdots \\ I_n \end{pmatrix} = \begin{pmatrix} \mathbf{F} \\ \mathbf{M} \end{pmatrix} \quad (1)$$

The x- and y-component of \mathbf{M} are used to compensate unsymmetric process forces and unwanted torques excited by stray fields. The predictions about the device's behavior received from the matrices are computed with a superposition principle which leads to a small error. To reduce computational costs, these errors are neglected, if it can be assured that they are limited to a certain barrier.

IV. NUMERICAL RESULTS

Some preliminary numerical results are presented here. Similar to the synchronous motor, the coils of the lower part have to excite a rotating field to realize rotations. To create the mentioned matrices, it is necessary to know the forces and torques generated by a single coil at every interesting position.

Fig. 3. Torque of a single rotation coil over the rotation angle

Fig. 3 shows the torque generated by applying a constant current to a single rotation coil. The translational deviations are zero and the number of magnetic poles is eight, therefore the rotation angle is varied from 0 to 90 degrees. Hence, the coil passes two different magnetic poles. In the middle of the air-gap the intersection between the magnetic fields of the two different poles is very long. Therefore, the device has to be realized with a small number of poles.

Abstract— So far, effects of load variation have not been investigated for eccentricity fault diagnosis in synchronous motors. In this paper, a synchronous motor under static and dynamic eccentricity with different loads is modeled using winding function method. Self inductances of the stator and rotor, mutual inductances between stator and rotor, stator current, torque and speed motor are evaluated and analyzed. Spectrum of the stator current is utilized for detection of eccentricity occurrence, recognition of its type and determination of its percentage. Variation of eccentricity degrees and loads on the selected index is scrutinized separately and simultaneously. The accuracy of obtained simulation results is verified using experimental results.

I. INTRODUCTION

Fault conditions disturb machines performance and declare their life spans. Also, persistent faults damage the machines and consequently outage time for repairing is extremely costly. Therefore, faults diagnosis and condition monitoring of the synchronous motors as efficient machines in different industries are necessary. In [1]-[2], a salient-pole synchronous generator under dynamic eccentricity has been modeled using winding function method (WFM). Revision of the assumptions and basic equations of the WFM show that the theory differs for non-uniform air gap [3]. In addition, the stator and rotor windings distribution and air-gap permeance have been taken into account in [3] while this has not been considered in [1]-[2]. Amplitude of harmonic components at frequencies 17th and 19th has been employed for dynamic eccentricity in [1]-[3]. So far, round rotor synchronous motors under static and mixed eccentricity have not been investigated. Meanwhile, effects of the load variation on the eccentricity fault diagnosis in synchronous motors have not been studied.

II. SYNCHRONOUS MOTORS MODELING USING WFM

Precise modeling of the faulty machines is the most important stage of any reliable fault diagnosis procedure. Modeling methods which are developed based on magnetic field components of the machines can be utilized to calculate required parameters and signals incisively. Albeit WFM ignores non-linear characteristics of the stator and rotor cores, considers many effective parameters of the machines [1]-[3]. The principal equation of this theory which presents the mutual inductance of two arbitrary windings x and y in respect to the winding distribution is as follows:

$$L_{yx} = 2\pi \langle n_x n_y \rangle - 2\pi \frac{\langle P n_x \rangle \langle P n_y \rangle}{\langle P \rangle} \quad (1)$$

where operator $\langle f \rangle$ is defined as the mean of function f over $[0, 2\pi]$ and P is the permeance distribution of the air-gap.

Since, it is an arbitrary angle in the stator reference frame, it follows that:

$$\langle f \rangle = \frac{1}{2\pi} \int_0^{2\pi} f(\alpha) d\alpha \quad (2)$$

Equations (1) and (2) have been developed by taking into account a more precise distribution of stator phases and rotor excitation windings and also a more precise computation of the air-gap permeance. Air-gap permeance is proportional to the inverse of the air-gap length. Therefore, the air-gap permeance distribution, between the rotor and stator, is as follows:

$$P(\alpha) = \mu_0 \frac{r_{av}(\alpha)}{g(\alpha)} \quad (3)$$

where $r_{av}(\alpha)$ and $g(\alpha)$ are the mean radius of air-gap and air-gap distribution, respectively. These two quantities are constant for all the points between the rotor and stator, in the symmetrical case.

III. PERFORMANCE ANALYSIS OF THE FAULTY MOTOR

A. Stator Inductances

Fig. 1 depicts the per phase self-inductance of the stator winding of a synchronous motor in healthy and 50% static eccentricity. Fig. 1 exposes that the static eccentricity increases the inductance and distorts distribution of the inductance. The reason is that in the static eccentricity case, the air gap permeance depends on the rotor angular position. Since this angle varies continuously the distribution of the inductance is asymmetrical.

B. Rotor Inductances

Fig. 2 illustrates the self-inductance of the excitation winding of a synchronous motor in healthy and 50% static eccentricity. Comparison of Fig. 1 and Fig. 2 shows that the variation rate of the mutual inductance in static eccentricity is higher than that of the self-inductance.

C. Stator current

Stator current of the healthy and faulty synchronous motor and their spectrum have been presented in Fig. 3 and Fig. 4. Referring to these figures presents the considerable increases of amplitude of 17th and 19th harmonic components due to static eccentricity which can be utilized as a proper index for eccentricity fault detection in synchronous motors. This is because of distortion of magnetic flux density which strains motor inductances. Therefore, stator currents are unbalanced and the amplitude of harmonic components is increased.

Fig. 1. Per phase self-inductance of the stator winding in (a) healthy and (b) 50%, static eccentricity

Fig. 2. Per phase self-inductance of the rotor winding in (a) healthy and (b) 50%, static eccentricity

IV. EFFECTS OF LOAD VARIATION

Fig. 4 shows the amplitude of the 17th harmonic component for different loads and different static eccentricity degrees (DED). The peak of harmonic amplitude is seen at the highest DED and the maximum load. On the other hand, the minimum harmonic amplitude is seen at the lowest DED and no-load. As shown in Fig. 4, an increase in the eccentricity degree and load, consequently increases the amplitude of the 17th harmonic component. According to Fig. 6, it is noticeable that the effects of increase of DED are much considerable on the amplitude of 17th harmonic component in which, effects of load variation can be ignored. Indeed, amplitude of the 17th harmonic component is fairly constant against load variation.

V. CONCLUSION

In this paper static and dynamic eccentricities were modeled and analyzed using WFEM. This modeling method provided us with exact calculation and analysis of air gap permeance and so the machine inductances were calculated precisely. It was shown that, static and static eccentricities increase the magnitude, distort the distribution and these both affect on machine inductances.

Abstract— This paper describes the dynamic analysis method for a spherical resonant actuator using the three-dimensional finite element method (3-D FEM). In this computation, the magnetic field equation is coupled with the electric circuit equation and the motion equation. And the mesh modification method using the Laplace equation is applied for the rotation of a spherical actuator. The dynamic characteristics of this actuator are quantitatively clarified using this method.

I. INTRODUCTION

Recently, it is desired to develop a magnetic actuator that can move in arbitrary direction without auxiliary mechanism. We have been developing some novel spherical resonant actuators [1]. This paper describes a dynamic analysis method for a spherical resonant actuator using the 3-D FEM [2]. It is difficult to modify the FEM meshes of a complicated spherical actuator in accordance with rotation of an armature. Therefore, the mesh modification method using the Laplace equation is employed. The dynamic characteristics of this actuator are clarified using this method.

II. ANALYSIS METHOD

A. Magnetic Field Analysis

The equations of the magnetic field and the electric circuit are coupled using the 3-D FEM, which are given by the magnetic vector potential \mathbf{A} and the exciting current I_0 as follows:

$$\text{rot}(\nu \text{rot } \mathbf{A}) = \mathbf{J}_0 + \nu_0 \text{rot } \mathbf{M} \quad (1)$$

$$E = V_0 - RI_0 - \frac{d\Psi}{dt} = 0 \quad (2)$$

$$\mathbf{J}_0 = \frac{n_c}{S_c} I_0 \mathbf{n}_s \quad (3)$$

where ν is the reluctivity, \mathbf{J}_0 is the exciting current density, ν_0 is the reluctivity of the vacuum, \mathbf{M} is the magnetization of permanent magnet, V_0 is the applied voltage, R is the effective resistance, Ψ is the interlinkage flux of exciting coil, n_c and S_c are the number of turns and the cross-sectional area of the coil respectively, and \mathbf{n}_s is the unit vector along with the direction of exciting current.

The motion of the armature is described as follows:

$$I \frac{d^2\theta}{dt^2} + D \frac{d\theta}{dt} + k\theta = T_m \quad (4)$$

where I is the moment of inertia, θ is the rotation angle, D is the viscous damping coefficient, k is the spring constant, and T_m is the torque acting on the armature.

B. Mesh Modification by solving the Laplace equation

The procedure of mesh modification for next time step is executed by solving the Laplace equation, which is given as follows [3]:

$$\frac{\partial^2\theta}{\partial x^2} + \frac{\partial^2\theta}{\partial y^2} + \frac{\partial^2\theta}{\partial z^2} = 0 \quad (5)$$

where θ is the potential, which can be regarded as the rotation angle of the armature.

(i) The potential θ_{rotation} , which is the rotation angle of the armature, is given to nodes in the armature region, and the potential zero is given to nodes in the stator region.

(ii) The distribution of potential θ of the armature region is calculated by solving (5).

(iii) The coordinates of nodes in the mesh are modified according to each potential θ .

The meshes of the gap between the armature and the stator are smoothly modified by using this mesh modification method. Fig. 1 shows the flowchart of the dynamic analysis method.

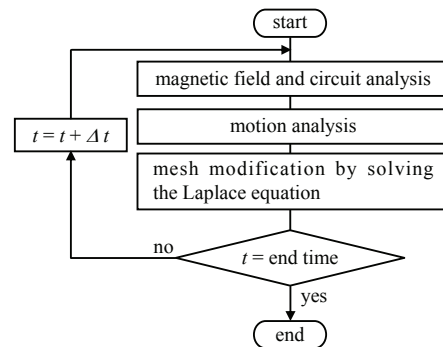

Fig. 1. Flowchart of dynamic analysis.

III. ANALYZED MODEL AND ANALYSIS CONDITIONS

Fig. 2 shows the analyzed model. The stator has four poles and a couple of coils in this study to consider the rotation only in y-axis. The armature is composed of the spherical-shaped core with the ring-shaped permanent magnet, which is connected to the resonance spring. The rotation angle θ is defined as shown in Fig. 3. θ is 0 in the initial position. The magnetic flux caused by the permanent magnet flows as shown in Fig. 4. The armature is stable at the center because of balanced magnetic flux in the gap between the armature and the stator. The torque is generated on the armature when the current is excited to the coil, and the armature rotates in y-axis. Table I shows the analysis conditions. In this computation, the rectangular voltage is applied to the coil. The discretization data and CPU time is shown in Table II.

IV. RESULTS AND DISCUSSION

Fig. 5 shows the waveforms of current and rotation angle of the armature in resonance. From this figure, the effective value of current and the maximum rotation angle are 0.94A and 7.5°, respectively. Fig. 6 shows the characteristics of rotation angle versus operating frequency. From this figure, it is found that this actuator has a resonance frequency of 127Hz. The effectiveness of the calculated results will be confirmed through the comparison with the measured ones in the full paper.

Finite Element Processing Methods to Peripheral Flux Leakage in Axial Field Flux-Switching PM Machines

Mingyao Lin, Lei Zhang, Xin Li and Haitao Yu

School of Electrical Engineering, Southeast University, Nanjing, 210096, P.R. China
mylin@seu.edu.cn

Abstract—In this paper, a finite element(FE) analysis of the peripheral flux leakage in a novel axial field flux-switching permanent magnet (AFFSPM) machine was presented by using energy method. The size of peripheral air cylinders in FE analysis model of AFFSPM machine was determined by the suggested method. Thus, it was possible to optimize between the computational precision and time. The calculation results are coincide with that by permanent magnet (PM) flux method. In addition, the presented method was also used in 2D FE simulation. The investigation shows that this method is useful in the application of machines with PM in stator.

Index Terms—peripheral flux leakage; air cylinder; energy method; AFFSPM machine.

I. INTRODUCTION

The peak-to-peak values of the PM flux and the induced electromotive force (EMF) computed by FE method are larger than their actual values due to the peripheral flux leakage in a AFSFPM machine with PM in the stator. In order to decrease the computation error, it is necessary to add peripheral air cylinders to the periphery of FE analysis model of machines. However, this increases the workload for meshing, computing and post-processing. Therefore, it's very practical to determine the sizes of air cylinders and to optimize the computation precision and time.

FE simulations of PM machines, including the design, the optimization of machines, the calculation of parameters, have been studied in the literatures. However, how to decide the sizes of peripheral air cylinders in the FE analysis model have rarely been investigated. In this paper, an energy method is suggested to determine the sizes of the air cylinders for a novel AFFSPM machine. The calculated results is compared with that gotten by the PM flux method.

The energy method is discussed in section II. In section III, PM flux method is introduced and the results are compared. In order to illuminate that the energy method is applicable to 2D FE simulation, a 2D FE example is presented in section IV.

II. THE ENERGY METHOD

A. The simulation model of AFFSPM machine

The magnetic energy is a sum of the magnetic co-energy in each element. For each one, the magnetic co-energy is calculated as follows:

$$W_c = \int_{-H_c}^H \{B\} \cdot \{dH\} \quad (1)$$

where W_c is the stored magnetic co-energy, H_c is the coercive force, B is the flux density vector, and H is the magnetic field

intensity vector. For the static magnetic field in the zero-current condition, the interrelated parameters are governed by the following three equations:

$$\begin{cases} \nabla \times H = 0 \\ \nabla \cdot B = 0 \\ B = \mu H \end{cases} \quad (2)$$

where μ is the magnetic permeability. To solve these equations, a magnetic scalar potential is introduced to describe H :

$$H = -\nabla \psi \quad (3)$$

where ψ is the magnetic scalar potential, which could deduce the requisite parameters.

Fig. 1 shows a typical AFFSPM machine of the type to be investigated in this paper. The machine consists of two outer stators and one inner rotor.

There are three peripheral air covers in the FE analysis models of the AFFSPM machine, that is, a radial outer peripheral air cylinder, a radial inner air cylinder and a terminal air cylinder. The three peripheral air cylinders are added in the FE analysis model in turn and their sizes should be determined. Fig.2 shows the 3D FE analysis model of a AFFSPM machine.

Fig.1. configuration of a AFFSPM machine

Fig. 2. 3D FE analysis model of AFFSPM machine

11. Electric Machines and Drives

B. Determination of radial peripheral air cylinder size

The outer diameter of the radial peripheral air cylinder was calculated. If k_{oair} is defined as a changeable coefficient for the undetermined parameter, and it is

$$k_{oair} = D_{oair} / D_o \quad (4)$$

Where D_{oair} is the outer diameter of the radial peripheral air cylinder, and D_o is the outer diameter of AFFSPM machine. Fig.3 shows the magnetic energy varied with k_{oair} at initial rotor position angle, and the change of magnetic energy in one cycle at different k_{oair} is shown in Fig.4.

The magnetic energy is constant when k_{oair} is larger than 1.5(Fig.3), which is also demonstrated by the results in Fig.4. Therefore, $1.5D_{oair}$ is determined as the outer diameter of the radial periphery air cylinder.

The sizes of radial inner air cylinder and terminal air cylinder are also determined according to the above analysis. $0.5D_i$ is selected as the inner diameter of radial inner air cylinder, and $1.1h_s$ is the axial depth of the terminal air cylinder, where D_i is the inner diameter of AFFSPM machine, and h_s is the axial length of the stator.

Fig.3. Magnetic energy at the initial position angle Fig.4. Magnetic energy in one cycle

III. THE PM FLUX METHOD

The PM flux is one of most important parameters in the design and optimization of PM machines. The relationship between the peak-to-peak value of the PM flux and the k_{oair} in one phase is shown in the Fig.5. The peak-to-peak value of the PM flux is constant when the k_{oair} value is larger than 1.5, and this is coincide with that obtained from the energy method.

The relations of PM flux peak-to-peak with the sizes of the radial inner air cylinder in one phase and the terminal cylinder are also obtained by the same method. The inner diameter of the radial inner air cylinder is determined as $0.5D_i$, and the axial length of the terminal air cylinder is $1.1h_s$. These are coincide with those obtained by the energy method.

IV. 2D FE ANALYSIS

In the 2D FE analysis model of a radial field flux-switching PM machine, a circle was added to the periphery of the stator to simulate the air condition. Fig.6 shows the FE analysis model of the machine. The outer diameter of the peripheral air circle is determined. The calculated results based on the energy method are shown in Fig.7 and Fig.8, where k_{airso} is the proportion of the outer diameter of the air circle to the outer diameter of the stator. According to the

Fig.5. PM flux peak- to-peak value

Fig.6. 2D FE analysis model of a radial field flux-switching PM machine

Fig.7. Magnetic energy at the initial rotor position.

Fig.8. Magnetic energy in one cycle

calculation of the magnetic energy, $1.5D_{so}$ is determined as the outer diameter of air circle, where D_{so} is the outer diameter of the stator. This result can also be obtained by using the PM flux method.

V. CONCLUSIONS

In this paper, an energy method is presented and used to determine the sizes of peripheral air cylinders in the FE analysis models of the flux-switching machines. The simulation results are confirmed by the PM flux method in the 3D and the 2D FE simulation. In additional, the peak-to-peak values of the PM flux and the induced EMF computed by the FE method are larger than their actual values, which is caused by the difference of the PM flux at different air cylinder sizes. The determination of the sizes of peripheral air cylinders on the FE analysis models of flux-switching machines is important to obtain the balance between the computation precision and the time. Therefore, it's useful to determine the air cylinder sizes by the energy method in the FE simulation of machines with PM in the stator.

Slotted and Torus PM Generators for Low Speed Direct Drive Applications using an Analytical/Static 2D FEA Design Technique

David G. Dorrell

School University of Technology Sydney, Broadway, Sydney, Australia
ddorrell@eng.uts.edu.au

Abstract — Direct-drive permanent-magnet generators for use in low speed applications are described and compared. A target specification is set and a design procedure is carried out for a radial-flux slotted machine and a Torus machine. The design for the fractional-slot high-pole number brushless permanent-magnet generator is developed using an analytical design package and verified using a finite element analysis. The design is compared with a preliminary Torus machine design.

I. INTRODUCTION

With the development of new generation systems which are both low-speed and variable power there is an increasing need for direct-drive generators. Unfortunately many PM generators suffer from low power factor [1] and will require controlled rectification. It is an advantage to have high p.f. so that a diode bridge load can be utilized for simple and robust operation [2].

The topology of these machines can vary considerably – they can be of conventional radial-flux [2] with slotted stator and surface/internal magnets, axial flux machines with air-gap windings [3], torus arrangements [4] or Vernier hybrid [5].

In the paper a comparison between direct-drive PM generators is made. The basic target specification is outlined and the design carried out and verified using finite element analysis. This paper represents an interesting electromagnetic design challenge and sets out a simple procedure for machine designers using modern design and analysis tools.

Fig. 1. (a) Winding arrangement and (b) stator cross section.

II. SPECIFICATION AND OUTLINING OF SLOTTED MACHINE

The application here is low speed. If the target speed is 15 rpm and 200 Nm, and allowing a frequency of 12.5 Hz at this speed, then a pole number of 100 is obtained; this was used for the slotted design. The frequency is low because the generator may be required to operate at higher speed (above 60 rpm) and also the pole number would be prohibitively high. This generator is aimed at being used in a Bristol Cylinder [6]. For the slotted design, surface magnets are used to prevent saliency

and minimize X_q . The slot number should be a multiple of 3. A convenient number for 100 poles is 90 slots with two coil-sides per slot. The machine uses rare earth magnets. Fig. 1 shows the machine and winding layout (for 3 phases). The periodicity of this arrangement is 9 slots (10 poles). The use of fractional slot stator topology is necessary to reduce cogging torque.

III. DETAILED SLOTTED MACHINE DESIGN AND ANALYSIS

A. Sizing

If the target speed is 15 rpm, and the frequency of 12.5 Hz at this speed, then the pole number is 100. [7] suggests that the torque per rotor volume (TRV) for a high-performance servo machine should be between 20 and 45 kNm/m³; the low end of the range is taken for a prototype. The total axial length for the machine is 270 mm so the core length of the machine is about half. Using this length gives a rotor diameter of

$$D = 2 \sqrt{\frac{T}{TRV \times \pi L_{stk}}} = 2 \sqrt{\frac{200}{20 \times 10^3} \times \frac{1}{\pi \times 0.135}} = 0.307 \text{ m} \quad (1)$$

Hence, the radius of the rotor is 150 mm and the axial length is 135 mm. The sizing is calculated to fill the generator voids in the cylinder. Fig. 1(a) shows the coil arrangement. The slots and stator are scaled to give appropriate slot area (211 mm²), tooth width (4 mm) and yoke depth (30 mm). This is shown in Fig. 1(b). The outer radius is 420 mm which is much less than the maximum allowed. The slot opening was set to 3 mm and the coils consist of 60 series turns. The gross slot fill is 0.5.

B. Phasor Diagram

The phase winding back-EMF has a good sinusoidal waveform with 3rd harmonic (which does not affect the operation). The torque has little ripple (a mean of 228 Nm). The machine is current fed and the current phasor is on the $-q$ axis. The phasor diagram is also shown in Fig. 2(a). When the machine is attached to a diode bridge rectifier the performance will be degraded, this is because the current will not be in phase with the back-EMF and not sinusoidal. Low $I_q X_q$ will help the diode bridge performance.

C. Finite Element Analysis and I-Psi Diagram

The model was fed through to an FEA package. The model spanned 10 poles. The derived current/flux-linkage loop is shown in Fig. 2(b). This is similar to the loops used in switched-reluctance machines. The current and rotor rotation are cycled round together and the flux linkage measured at each step. The area enclosed is the work done and therefore torque can be calculated in a straightforward manner. If the

11. Electric Machines and Drives

loop is long and thin then the machine is operating poorly however this example shows good conversion. These loops are calculated both analytically (solid line – torque = 222 Nm) and in FEA (dotted line – torque = 254 Nm).

Fig. 2. (a) Phasor diagram and (b) I-Psi loop for one phase

D. Cogging Torque

Cogging torque requires fine detail of the machine magnetic circuit to calculate an accurate model. Cogging torque is very susceptible to numerical error. The air-gap had four regular layers and the distance between the nodes round the central air-gap boundary is equal to the step angle between steps. The cogging torque was found to be about 2.8 Nm peak-to-peak.

IV. TORUS DESIGN

In this section a short comparison is done with an alternative design – the Torus machine. There is little in the literature that gives direct comparison between the two machines.

A. Torus design

The Torus arrangement has the advantage of low armature reactance and can be either radial flux or axial flux [11]. This machine has air-gap windings and the disadvantage to this arrangement is that the coupling with the winding is reduced and available winding area is limited. In addition there can be additional eddy current losses in the air-gap copper so that many parallel strands of thin wire may be required. Therefore to design this machine then maximum diameter should be used in the initial design. Here it was decided to use a 760 mm diameter for the outer diameter of the machine and the same magnet material. The pole number was increased to 120 poles and since there is no cogging torque then an integral number of coils per pole can be utilized (120 coils per phase).

The rotor diameter is 735 mm so that the machine is more of a ring in structure which requires careful mounting within a frame and bearing mountings. The thickness of the winding layer was limited to 1.4 mm with a low 0.7 mm air-gap. This is to attempt to maintain good flux linkage with the rotor. Because the Torus arrangement has limited end-winding (since the coils are wound around the toroidal laminated stator core) it is possible to increase the axial length (up to 170 mm here). This is necessary because of the limited number of turns that can be used so every effort should be made to improve the flux linkage per turn. Since it is easier to wind this machine then the slot fill was increased to 0.7 – this will be difficult to achieve and rectangular conductors would probably have to be used. Fig. 8 shows the finite element analysis of this machine

while Table 1 shows a comparison of the designs.

Fig. 3. Radial-flux Torus design showing one pole pair (stator at top showing three coils per pole around stator core).

TABLE I COMPARISON OF MACHINE DESIGNS (AT LOAD AND 15 RPM)

Parameter	Slotted	Torus	Parameter	Slotted	Torus
Outer Diameter [mm]	420	760	Core length [mm]	135	170
Copper [Kg]	12.4	6.5	Magnet [Kg]	2.3	7.6
Load current (set) [A]	1.77	1.77	Torque [Nm]	228	231
Back-EMF [V]	68.3	68.9	Power Factor	0.87	1
Copper losses [W]	99	162.9	Efficiency [%]	69.9	55.5

B. Comparison with slotted machine

Table I shows that the issue with the limited area for the winding leads to the requirement for more magnet material while there is additional copper losses in the winding because it runs with a higher current density in the copper. Even with the increase in poles it is still difficult to get sufficient flux linkage and hence back-EMF. With further design it would probably be possible to obtain better performance by optimizing the magnet thickness and winding window to obtain the optimum back-EMF and copper losses which gives best efficiency. However this does illustrate that the slotted machine is much easier to design for a given specification because of the flexibility of the winding area available.

V. CONCLUSIONS

In this paper a comparison has been made between a slotted machine and a Torus machine using standard design techniques and 2D FEA validation of design calculations. It was found that Torus machine required a larger diameter to meet the specification. A direct comparison highlighted the advantages and disadvantages of both. Neither is of high efficiency; further refinement is needed to improve this.

A General Cuboidal Element for Three-Dimensional Thermal Modeling

R. Wrobel and P. H. Mellor

Department of Electrical and Electronic Engineering,
University of Bristol, Merchant Venturers Building,
Woodland Road, Bristol, BS8 1UB, UK
R.Wrobel@bristol.ac.uk

Abstract — This paper presents a lumped parameter thermal modeling approach for three-dimensional (3D) thermal modeling based upon the use of general 3D elements which are formulated to accurately cater for internal heat generation. Commonly used thermal networks do not account for an internal heat generation that is essential for accurate temperature predictions. In contrast, the general element proposed in this paper includes the internal heat generation as well as a material thermal anisotropy. To validate the technique, a thermal model of an inductor using the equivalent circuit method with the cuboidal element and 3D finite element method (FEM) was constructed and analysed. The calculated results from the cuboidal element method show good agreement with the FEM predictions.

I. INTRODUCTION

One of the main factors limiting the design of an electrical device such as motor or transformer is its thermal performance. Accurate prediction of the temperature within a device is therefore very desirable. There are a number of methods allowing for theoretical predictions of temperature. These include analytical, lumped-parameter thermal network and numerical, finite element method (FEM) and computational fluid dynamics [1]. As the numerical techniques suffer from long model setup and computation times, the analytical lumped-parameter network is still a valuable method.

The resistive element commonly used in the thermal equivalent network can be derived from one-dimensional steady-state heat diffusion equation for zero internal heat generation [2]. This solution however, does not include internal heat generation essential for accurate temperature predictions. To include the internal heat generation a combination of solutions for two heat diffusion equations with zero internal heat generation and zero surface temperatures is required [3]. This approach has proven its usefulness resulting in development of a general cylindrical element that was used in thermal analysis of electrical machines [4]. This paper extends the application of the technique from a cylindrical to a Cartesian coordinate system using a general cuboidal element. The cuboidal element allows for three-dimensional thermal analysis using the equivalent circuit method. This includes internal heat generation as well as a material thermal anisotropy. Initial information about the thermal flux circulation is not required to construct the thermal network when using the cuboidal element. To validate this new approach, a thermal model of an inductor using the equivalent circuit method with the cuboidal element and 3D finite element method (FEM) was constructed and analysed.

II. MATHEMATICAL DESCRIPTION

To define the general cuboidal element an assumption of independent heat transfer within axes of the Cartesian coordinate system has been made. That simplifies the cuboidal element derivation to one-dimensional problem as the all axes of the coordinate system can be analysed individually.

Fig. 1. Outline of a general cuboidal element

Fig. 1 shows a geometrical representation of the general cuboidal element, where T_1 and T_2 are the surface temperatures, k_x is the thermal conductivity in x -axis, q_x is the conduction heat rate in x -axis, A_x is the surface area normal to q_x and l_x is dimension of the cuboid in the x -axis.

Fig. 2. Equivalent thermal network for a general cuboidal element

The equivalent thermal network in the x -axis for the cuboid is shown in Fig. 2. The mean temperature and the total heat generation within the cuboid are given by \bar{T} and q_x respectively, where

$$q_x = \dot{q}V = \dot{q}A_x l_x \quad (1)$$

To determine the thermal resistances ($R_{1,x}$, $R_{2,x}$ and $R_{3,x}$), the two cases of the one-dimensional, steady-state heat diffusion

equation need to be analysed, *A.* zero internal heat generation and *B.* zero surface temperatures and then applying superposition.

A. Zero internal heat generation

The heat equation for one-dimensional steady-state example with zero internal heat generation and constant thermal conductivity k_x is given in the following form

$$\frac{d}{dx}\left(k_x \frac{dT}{dx}\right) = 0 \quad (2)$$

By solving (2), both of the thermal resistances R_{1x} and R_{2x} can be found

$$R_{1x} = R_{2x} = \frac{l_x}{2k_x A_x} \quad (3)$$

B. Zero surface temperatures

The heat equation for one-dimensional steady-state example with internal heat generation is given in the following form

$$\frac{d^2 T}{dx^2} + \frac{\dot{q}}{k_x} = 0 \quad (4)$$

An average temperature \bar{T} within the cuboid is derived by solving (4) and then the thermal resistance R_{3x} can be found

$$R_{3x} = -\frac{l_x}{6k_x A_x} \quad (5)$$

A complete 3D description of the cuboid has been derived by replicating (2) and (5) for the remaining axes of the Cartesian coordinate system. The equivalent circuits for all the axes are then linked together in the node of the average temperature. A power source and the thermal capacitance of the cuboidal element is also connected to this node.

III. MODEL VALIDATION

To validate the cuboidal element a thermal analysis of an inductor has been carried out. The inductor includes a laminated core pack and Litz wire wound coil. Fig. 3 presents an outline of the inductor together with region labels assumed in the equivalent network model. Due to symmetry only a quarter of the inductor is modeled. The equivalent network model includes only 13 cuboidal elements in contrast to 70,629 elements for the FEA. It has been assumed that the inductor is mounted on a cold-plate at 60°C. Surfaces that are not in contact with the cold-plate are adiabatically insulated. The Litz wire wound coil is represented as a lumped region with anisotropic properties that were obtained experimentally. Calculations were carried out for a constant power loss of 40W within the inductor's winding. Table I includes temperature predictions from both FEM and equivalent network method with cuboidal element showing good agreement.

Fig 3. Outline of the inductor's model with region labels.

TABLE I TEMPERATURE PREDICTIONS

Region number	FEM [°C]	Equivalent network method [°C]
1 (core)	67.2	68.7
2 (core)	68.1	69.4
3 (core)	67.9	69.6
4 (core)	64.9	65.2
5 (coil)	70.3	69.5
6 (core)	65.9	68.6
7 (coil)	71.6	69.2
8 (coil)	71.1	69.4
9 (coil)	72.2	69.3
10 (core)	61.0	61.0
11 (core)	60.8	60.7
12 (core)	61.3	61.6

IV. CONCLUSION

The cuboidal element technique presented allows for fast three-dimensional temperature prediction using the equivalent circuit method. This is essential when a transient thermal analysis is required. The element includes the internal heat generation as well as a material thermal anisotropy, in contrast to the commonly used resistive element. Model construction using the cuboidal element does not require initial information about heat flux and only geometrical and material data is used. This new technique has been validated with a 3D FEM model showing good agreement.

Time-Stepping Finite Element Analysis of a Salient-pole and Round-Rotor Synchronous Generators under Dynamic Eccentricity Fault

Jawad Faiz, Mojtaba Babaie, Bashir Mahdi Ebrahimi and Jalal Nazarzadeh

University of Tehran, Tehran, Iran

Abstract— This paper compares the effects of dynamic eccentricity (DE) on the performance of a salient-pole and round-rotor synchronous generators. Time stepping finite element (TSFE) method has been used for calculating the self and mutual inductances of the stator phases and rotor windings. It also used to determine the influence of the eccentricities on the flux distribution and no-load voltage characteristics in aforementioned generators. Then, new index is introduced for dynamic eccentricity fault detection in the two types of synchronous generators. This index which is extracted from the spectrum analysis of the stator current can be utilized to determine the dynamic eccentricity degree accurately.

I. INTRODUCTION

Operation of generators under faults condition can disturb their performances and declare their life spans. Also, persistent faults can damage the generators and consequence outage time for repairing is extremely costly. Therefore, faults detection and condition monitoring of the generators allow more flexibility in operation by knowing the performance and extend generator life by adjusting the operation to avoid known operating regimes or ranges and cost effectiveness.

Mechanical faults such as eccentricity are one of the major faults in electrical machines caused by mechanical parts such as bearing, shaft and coupling [1]-[2]. In the case of dynamic eccentricity, the center of rotation and the center of stator are the same. Therefore, the air gap length is both time and space dependent [3].

Many researches have been devoted to the eccentricity fault in induction machine [4], but it is considerably poor in the field of the synchronous generator. Hence, study of the generator performance under this fault seems to be necessary.

In this paper, from the basic geometry, nonlinear properties of the magnetic materials and winding layout of the two generators, the FE approach is implemented using Flux2D 10.2 software package. All signal and the characteristics of the two generators have been calculated by TSFE method with a very high accuracy. The standard Galerkin formulation is applied to the field and current equations, moving-band technique is taken into account the movement and Newton-Raphson method has been used to consider the nonlinearity of the magnetic materials.

II. IMPACTS OF THE ECCENTRICITY FAULT UPON THE FLUX DISTRIBUTION IN THE SYNCHRONOUS GENERATORS

The synchronous generators field winding is subject to the dc saturated current equal to 12A at no load condition. The magnetic field equations solved in the given structure via the FE approach. The eccentricity degree, δ , is definite as follows:

$$\delta = \frac{e}{l_g} \times 100 \quad (1)$$

Where e is the displacement of the rotor in the horizontal direction in respect to the stator symmetry center and l_g is the air gap length in healthy condition [3]. In the case of 40% eccentricity degree to the right at no load, it is observed in Fig. 1 that the eccentricity clearly affects the flux distribution in generators and the magnetic flux distributions are not identical on both sides of the generators.

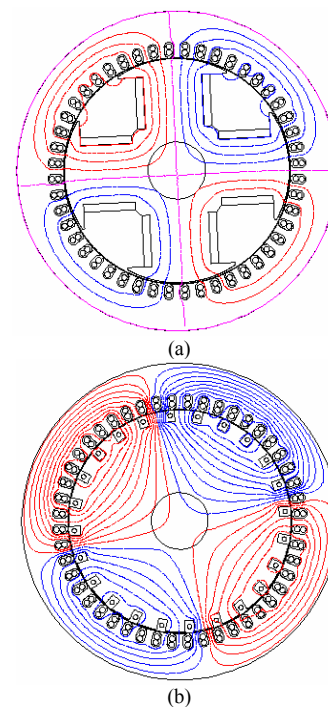

Fig. 2. Flux distribution in the generator at no load in case of the 40% eccentric air gap, (a) salient-pole, (b) round-rotor.

III. SPECTRUM ANALYSIS OF THE STATOR CURRENT FOR DE FAULT DIAGNOSIS IN THE SYNCHRONOUS GENERATORS

In the presence of eccentricity faults, some harmonics related to the faults appear in the air gap field of the synchronous generator. These harmonics will increase as eccentricity degree rises. They should induce corresponding current harmonics in the stationary stator windings. Consequently, the stator current signatures of synchronous generator can be utilized for diagnosis eccentricity fault.

The synchronous generators under dynamic eccentricity (DE) faults are simulated very accurately in full-load condition using TSFE method and current signal are extracted for the analysis and extracting efficient index related to the faults. Fig. 2 shows the frequency spectrum of the stator current of the round-rotor synchronous generator for the healthy and 40% DE faults. It is observe that the 19th harmonic increase from the -88.38 dB to -83.95 dB with increase in 40% DE. Also, amplitudes (in dB) variation of harmonics for healthy, 10%, 20%, 30%, and 40% DE are shown in Fig. 3. It is clear that the 19th harmonic of stator current of the synchronous generator can be utilized for diagnosis the DE fault. Fig. 4 presents the corresponding curve for the salient-pole synchronous generator under above mentioned degrees of DE fault. It indicates that the 29th harmonic is a suitable index which can be used for DE fault diagnosis in salient-pole synchronous generator. Because of the approximately linear rise of 29th harmonic amplitude due to increasing DE fault, it can be used for identify the degree of the DE fault.

IV. CONCLUSIONS

In this paper, comparison between the performance of the round-rotor and salient-pole synchronous generator under DE fault was carried out using 2-D TSFE method. For this, the flux distribution within the generator, self- and mutual-inductances of rotor and stator windings and stator current signature analysis were studied. Stator current signal spectrum analysis was employed for DE fault diagnosis in the synchronous generators. It was shown that the harmonic frequency components of 19th and 29th are suitable indices which can be used for diagnosis of the DE fault and determination of its degree in round-rotor and salient-pole generator, respectively. The completed results for DE fault will be presented in the full paper.

 E-mail Address : psshin@hongik.ac.kr

Abstract— This paper proposes a method to calculate vibration modes and forces of a large scale BLDC motor by using a magneto-mechanically coupling formulation. The mechanical vibrations are the results of the magnetic forces acting on the surfaces of the stator. The procedure of the vibration force calculation is three steps: FEM calculation of the magnetic field, local force density calculation, and calculation of the dynamic displacement and vibration modes of the stator. To verify the algorithm 3 MW BLDC motor is simulated, and the vibration modes, forces and displacement are calculated.

I. INTRODUCTION

A Vibration analysis of the large scale BLDC motor is very important for design of the mechanical structure of the motor as well as for diagnostics of the motor system. For the magnetically forced vibration analysis of the BLDC motor, the calculated magnetic forces from FE analysis are put into the equations of the mechanical motion of the stator.

Additionally, magnetoelastic phenomena is to be taken into account in the magnetic force calculation of the motor. So, it is considered not only electromagnetic exciting force but also magnetostrictive forces which effect on electrical sheets of the large stator core. The permeability and the saturated magnetization of electrical sheets are distorted by the magnetostrictive force.

To verify the proposed algorithm 3 MW BLDC motor is simulated, and the vibration modes, forces and displacement are calculated. As the results of the simulation, the displacement and the 6 major modes are found, and the results are also compared with those of the existence of the magnetostrictive force.

The magnetic field distribution and the mechanical vibrations are calculated by the finite element method. The one pole pitch model(1/32 model) is used for the magnetic field and the surface force density calculation. The whole model of the stator with frame is used for the calculation of the mechanical vibrations.

The calculation of the magnetically forced vibration is divided into three steps: to calculate the transient behavior of the magnet field vectors, to evaluate the force density on the stator surface and to transform it into the mechanical equations, and to calculate the displacement by using the components of force as forward signals.

II. MAGNETIC FIELD, FORCE AND DISPLACEMENT CALCULATION

The electromagnetic force generated by the interaction of load current with the magnet flux is calculated by the Maxwell stress method based on the finite element analysis of the equation:

$$\nabla \times (1/\mu)\nabla \times A = J - j\omega_e\sigma A + \omega_e^2 A, \quad (1)$$

where A is magnetic vector potential, σ electrical conductivity, ω_e power frequency, μ permeability, respectively. The magnetic flux density, B , and the magnetic field intensity, H , are estimated by using A .

The simulation model of the 3 MW BLDC motor has 32 poles, 192 slots with 12-phase winding in the stator. Fig.1 shows the FE model of the motor. To analyze the field in one pole-pitch(1/32 model), a magnetic field computation at 30 stator-rotor positions is carried out.

Fig.1. 1/32 Model of 5 MW BLDC motor and airgap flux density in the normal direction

For a linear approximation of the ferromagnetic material, an expression of the local surface force density, κ , is given by the Maxwell's stress tensor:

$$\kappa = \frac{1}{2}n_{12}[B_n(H_{1n} - H_{2n}) - H_t(B_{1t} - B_{2t})] \quad (2)$$

The values B and H represent the magnetic flux density and magnetic field intensity, and the subscript n , 1, and 2 describe the normal direction, region 1 and region 2 respectively(see Fig.2). Equation (2) has some assumptions of the definition of the stress tensor and the electrodynamic field-conditions on the boundary(Div $B=0$ and Rot $H=0$). Because the force is a periodic function in one pole, the surface force density function has to be approximated by a number of models, each with another rotor position. The magnetic force, F , acting on the stator surface, can be calculated by integrating κ over a closed surface.

Fig.2 Boundary condition of the surface force density

The FE calculation of the dynamic displacements is based upon the principle of Hamilton, which prescribes to find the minimum of the difference from the kinetic energy and the elastic potential of the whole structure[1]. Using this principle the following system of equations is obtained.

$$M \cdot D'' + K \cdot D = F \text{ or } (K - \omega_{mech}^2 \cdot M) \cdot D = F \quad (3)$$

D'' is the global vector of node displacements, M is the global mass matrix including the information of inertia and K is the global stiffness matrix, describing the elastic features of the structure[2]. The vector F includes the amplitudes of the exciting force densities which is calculated by Eq.(2). For a transient characteristics, a dynamic response analysis is performed at a point by using mode superposition method[3].

The simulation model is shown in Fig. 3(a) for mechanic calculation. The model has about 280 thousands nodes and about 185 thousands tetrahedral meshes. Fig.3(b) shows the surface force density on the stator boundary. Fig.4 shows vibration modes of 3 MW BLDC motor stator with frame: the first mode is 60.55hz, the third mode 127.63Hz, the fifth mode 199.2 hz. Fig.5 shows a time response of displacement on a point of the stator to the radial direction. Fig. 6 shows an effect of the magnetostrictive force on the displacements in the axis direction: type A is the conventional, type B is considered the magnetostrictive force.

III. SUMMARY

This paper proposes a method to calculate the vibration modes and forces of a large scale BLDC motor by using an electromechanically coupled formulation. The mechanical vibrations are the results of the magnetic forces acting on the surfaces of the stator. The procedure of the vibration force calculation is three steps: FEM calculation of the magnetic field, local force density calculation, and calculation of the dynamic displacement of the stator. To verify the algorithm 3 MW BLDC motor is simulated, and the vibration modes, forces and displacement are calculated.

Abstract— A permanent magnet spherical motor is novel concept an electric machine which has two performance features as rotation mode and position one [1]. In this paper the authors propose the modified coil position on the stator of the permanent magnet spherical motor for improving characteristic of position mode. A characteristic of the holding torque depends on the position between stator coils and rotor magnets, because the rotation of the stator and rotor has to be considered on 3-dimensional. A characteristic of the holding torque is important factor to decide the stable tilt angle of the rotor. Therefore the authors researched into the feature of the holding torque as using the finite element method and another numerical one. As following results from the comparison two methods, the improved performance of the spherical motor is verified by experimental results.

I. INTRODUCTION

The manipulator, 3D-measuring instruments, and robot system have a characteristic of multi-degree of freedom performance. These machines have several motors which can rotate as multi-degree of freedom operation.

Fig. 1. Permanent-magnet spherical motor

The permanent-magnet spherical motor can perform the multi-degree of freedom as only one motor like Fig. 1. The remarkable feature of the permanent magnet spherical motor is that the shaft can be tilted while the rotor is rotating continuously [2]-[3]. However the characteristic of tilt operation depends on mechanical structure of the machine and position between coils and magnets of the motor. Especially, the coils position has to be optimized for improving the motor

performance first. Besides the coil position relates with torque stabilization and operating range of the rotor tilt degree. Therefore the authors researched into the characteristic of the holding torque by using numerical methods as a function of coil position.

II. TORQUE CHARACTERISTIC

A. Proposed Model

The permanent-magnet spherical motor consists of 4 Nd-permanent magnets on the rotor and 12 coils on the stator. The summed holding torque, which is generated between coils and magnets, decides a rotor position. The structure is shown in fig. 2.

Fig. 2. Structure of permanent magnet spherical motor

B. System Modeling

The components position of rotor and stator is identified as using spherical coordinates system : r , θ , and φ as well as their torque like (1) [4]-[5].

$$\vec{T}_{jk} = f(\varphi_{jk}) \frac{\vec{S}_j \times \vec{R}_k}{|\vec{S}_j \times \vec{R}_k|} n_c i_j \quad (1)$$

n_c : the number of turns per coil
 i_j : the current value of i_{jk}
 S_j : the position vector of j_{th} coil
 R_k : the position vector of k_{th} magnet
 φ_{jk} : the angle between S_j and R_k

The holding torque is summed vector calculated from position as coils and magnets. Therefore the torque is computed by using the torque profile function as $f(\varphi_{jk})$ and unit direction vector of each component as coils and magnets. The torque profile function is calculated by using Finite Element Method. Even though the Finite Element Method is useful computation method for electromagnetic field calculation, the long computation time is a serious

disadvantage. Therefore it has many advantages that the holding torque is computed by the torque profile function.

III. IMPROVEMENT TORQUE CHARACTERISTIC

The torque is generated between coils on the stator and magnets on the rotor. Fig. 3 shows the torque characteristic as function of the position between coil and magnet.

Fig. 3. The torque profile function as using FEM and Regression Method

Fig. 4 shows simulation models for studying the torque characteristic. Each simulation model shows different stability characteristic of the holding torque. In this paper, optimized structure of stator improving coil position is researched.

Fig. 4. Simulation model for optimization of the holding torque

Fig. 5 shows simulation results of holding torque profile. The holding torque shows different stability depending on situation of magnet position with coils. Therefore, in this paper, factor of instability holding torque is analyzed and the coil position on the stator is optimized by using numerical method for computation electromagnetic field. Finally the results are verified by experiment.

IV. CONCLUSION

The permanent magnet spherical wheel motor is able to tilt and rotate at 3 axes as the Yaw, Pitch, and Roll. Because the holding torque depends on structure of coils and magnets, however, the torque which is generated from them has to be

simulated by numerical method as 3D FEM. Even though the FEM method is used to analysis for the electromagnetic field, it is a problem to have a long computation time. For improving the disadvantage of calculation time, the authors use novel numerical method as using the torque profile function for calculating electromagnetic field. When the magnet is controlled by 4 coils, the holding torque shows instability phenomenon. Based on this torque feature, the model of 60 degrees coil position which is prototype motor is modified to 36 degrees coil position. Finally the torque is generated for holding the rotor stably.

Abstract — In this work the inductances of an induction motor, which rotor may be misaligned, are evaluated. This motor is intended to be used as a self bearing motor with split windings. Two types of analysis are performed: Analytical method (AM) and Finite Element Method (FEM). Results suggest the best reliability of FEM as with AM it is not possible to take into account effects like leakage flux.

I. INTRODUCTION

Induction motors with split windings operating as self bearing motors are being studied since 1989 [1]-[2]. With this configuration it is possible to generate torque and radial positioning forces. With this approach some works were reported in the literature focusing on starting and constant speed operation [3], [4]. Strategies of speed control with good responses were also reported in [5] and [6]. Nevertheless, the effects of possible misalignment between rotor and stator were not considered.

With this in mind, the interaction between magnetic fluxes from induction motor when submitted to misalignment is being studied [7]-[8]. One interesting analytical method (AM) is presented in [9]. This is characterized by considering cylindrical the surfaces of stator and rotor. In this work, this method is compared with simulations using the Finite Elements Method (FEM) which has been consolidated as an useful tool in the study of non-linear phenomena and of great complexity.

The aim of this work is to study the behavior of self and mutual inductances of an induction motor when submitted to radial misalignment. These results will allow for the prediction of possible interferences between the magnetic effects inside the motor: torque and radial forces. These concerns are present in the so called self bearing motor with split windings.

II. ANALYTICAL DETERMINATION OF MOTOR INDUCTANCES WITH NON UNIFORM AIRGAP

The machine analyzed in this work is a four poles, two phase induction motor. Each phase is composed of four windings that are connected in series in normal operation. When operating as a self bearing motor, each of the windings of one phase is supplied separately in order to get radial positioning. The other windings are connected in series and supplied simultaneously allowing starting torque.

A. Analytical Method

Assuming that the eccentricity of the rotor is limited to the airgap, it is possible to approximate the inverse to airgap as the following function [7]:

$$P(\kappa) = \frac{1}{g(\kappa)} = \frac{1}{g_0} \sum_{i=0}^{\infty} P_i \cos(i\kappa - i\alpha). \quad (1)$$

Where κ is the reference angle of stator windings, α is the mechanical angle of displacement of the rotor, g_0 is the uniform airgap, and:

$$P_0 = \frac{1}{\sqrt{1-\varepsilon^2}}$$

$$P_i = 2P_0 \left(\frac{1-\sqrt{1-\varepsilon^2}}{\varepsilon} \right)^i. \quad (2)$$

Where ε is the eccentricity between of the centers of rotor and stator, as shown in Fig. 1.

Fig. 1. Eccentricity of airgap.

Due to the variation of magnetic field caused by the eccentricities of airgap along any portion of winding v , it is possible to find:

$$\int_{air-gap} \vec{H}_v(\kappa) \cdot d\vec{l} = n_v(\kappa) i_v. \quad (3)$$

Where H_v is the magnetic field intensity, n_v , the turn function (number of coils), which depends of κ and i_v is the winding current.

Manipulating (3) and (1), using the Gauss law for magnetic fields in closed surfaces, assuming that the magnetic permeability of the core is infinite, that magnetic field is homogenous along the axial direction, that the dispersion of the magnetic field on both extremities of the rotor is neglected and considering that the airgap is very short when compared with the rotor radius, self and mutual inductances can be evaluated as in (4) and (5) respectively.

$$L_{vv} = \frac{\lambda_{vv}}{i_v} = \mu_o r l \int_0^{2\pi} n_v(\kappa) N_v(\kappa) P(\kappa) d\kappa \quad (4)$$

$$L_{vw} = \frac{\lambda_{vw}}{i_w} = \mu_o r l \int_0^{2\pi} n_v(\kappa) N_w(\kappa) P(\kappa) d\kappa \quad (5)$$

Where N_v and N_w are the winding functions.

B. Finite Elements Method (FEM)

The complexity of the machine demands great care in its modeling through FEM. A three dimensional simulation would be more appropriate but it demands a high computational effort. For this reason it was chosen a two dimensional simulation using an appropriated refinement on the mesh.

From electromagnetism the inductance can be expressed as:

$$L = \frac{N}{I} \Psi. \quad (6)$$

Where L is the inductance, I is the current, N is the number of coils and Ψ is the magnetic flux which can be obtained from (7).

$$\Psi = \int (\nabla \times \mathbf{A}) \cdot d\mathbf{s}. \quad (7)$$

According to *Stoke* theorem and calculating the vector potential from its nodal values, it is possible to determine one relationship to calculate the inductance in a general form:

$$L = \frac{N}{I} \frac{l}{S} \sum_{i=1}^m \left(\frac{S_i}{n} \sum_{j=1}^n A_{ij} \right). \quad (8)$$

Where l is the length, A_{ij} the nodal potential vector, S is the total area in study, S_i the element area, m is the number of element and n is the number of nodes by element (first-order triangle elements).

III. COMPARATIVE RESULTS

As an example, the self inductances of horizontal windings of phase-A were evaluated using the two methods. In Fig. 2 were considered horizontal disalignments. As observed, the average error between analytical results and FEM results was around 7% which can be explained by the strong approximations used with the analytical method.

Additionally, with FEM it was possible to evaluate inductance variations when angular changes of the rotor were simulated. The analytical simulation would be extremely complex. As one example, the behavior of self inductance of the second winding of phase-A, when submitted to radial and angular displacements, is shown in Fig. 3.

Fig. 2. Self inductances of horizontal windings of phase A submitted to horizontal displacements.

Fig. 3. Behavior of the self inductance of the winding 2 from phase A submitted to linear and angular displacements.

A. Conclusion

The results suggest the reliability on finite elements method in order to calculate inductance variations when there are linear and angular displacements inside an induction motor. The importance of these results is related to the use of them to evaluate the performance of a self bearing motor, where there are simultaneous torque and radial force effects.

Abstract— This paper presents the development of a flexible phase variable model for the performance prediction of two phase hybrid stepping motor (HSM) by employing advanced design and analysis techniques. In the parameter calculation of the motor, a virtual magnetic gateway based 2-D magnetic field finite element analysis with multi-levels are conducted to calculate the air gap flux, back electromotive force (*emf*), and self and mutual inductances of the stator windings. To predict the dynamic performance, a Simulink-based phase variable model is built, taking into account the real waveforms of applied phase voltage, back *emf* and current. To increase the flexibility and accuracy of the model, both the mixed digital-analog based technique for different digital-analog mixed systems and the controllable voltage source based technique for the nonlinearity of HSM are introduced. The model has been implemented in the development of a HSM drive system for driving embroidery machine. The predictions are in good agreement with experimental results.

I. INTRODUCTION

Hybrid stepping motors (HSMs) have been popular in low speed applications thanks to their many advantages such as high torque density and high resolution [1]. Considering the wide use of the HSM drives which are often highly nonlinear, it is desired to develop a numerical model with high practical merit for predicting the drive performance. To achieve the practical merit, including the accuracy, efficiency, flexibility and easiness, the following issues should be resolved first: calculation of the parameters in the equivalent electric circuit of HSM, flexible structure of numerical model, and appropriate expression of electrical parts in the circuit [2]-[4].

HSM drives belong to the field-circuit coupled system with high nonlinearity. The HSM features 3-D flux pattern and very tiny air gap which causes high magnetic saturation in the teeth, so 3-D numerical magnetic field analysis is a very challenging task and little satisfactory work has been completed so far. In this paper, a virtual magnetic gateway based 2-D finite element analyses (FEA) with multi-levels are applied to calculate the air gap flux. Based on the field solutions, all the parameters in the equivalent electric circuit of HSM such as back electromotive force (*emf*) and self and mutual winding inductances can be obtained efficiently.

A modern HSM drive system is often composed of both digital subsystem and analogue subsystem. A digital system can be modified by designing the corresponding program in a

block. However, as an analog system has fixed characteristic and a model cannot satisfy the requirement of different systems, it is required that the function of analog system in the simulation tool can be easily modified. In this paper, Simulink is used to build the simulation model, which can provide the functions of digital system and analog system simultaneously.

The self and mutual inductances and back *emf* in the HSM model are generally processed as the function of applied magneto-motive force (*mmf*) and rotor position, but there no such direct corresponding parts in the power electronics block of Simulink. In this paper, the technique of controllable voltage source obtained by combining power electronics block and general simulation block in Simulink is proposed.

II. PHYSICAL PHASE VARIABLE MODEL

The phase variable model of two-phase HSM is given as

$$\begin{bmatrix} U_a \\ U_b \end{bmatrix} = r \begin{bmatrix} i_a \\ i_b \end{bmatrix} + \frac{d}{dt} \begin{bmatrix} \psi_{sa} \\ \psi_{sb} \end{bmatrix} + \begin{bmatrix} e_a \\ e_b \end{bmatrix} \quad (1)$$

$$\begin{bmatrix} \psi_{sa} \\ \psi_{sb} \end{bmatrix} = \begin{bmatrix} L_{aa} & L_{ab} \\ L_{ba} & L_{bb} \end{bmatrix} \begin{bmatrix} i_a \\ i_b \end{bmatrix} \quad (2)$$

$$\begin{bmatrix} \frac{d\psi_a}{dt} \\ \frac{d\psi_b}{dt} \end{bmatrix} = \begin{bmatrix} \frac{\partial \psi_a}{\partial i_a} & \frac{\partial \psi_a}{\partial i_b} \\ \frac{\partial \psi_b}{\partial i_a} & \frac{\partial \psi_b}{\partial i_b} \end{bmatrix} \begin{bmatrix} \frac{di_a}{dt} \\ \frac{di_b}{dt} \end{bmatrix} + \begin{bmatrix} \frac{\partial \psi_a}{\partial \theta} \\ \frac{\partial \psi_b}{\partial \theta} \end{bmatrix} \frac{d\theta}{dt} \\ = \begin{bmatrix} L'_{aa} & L'_{ab} \\ L'_{ba} & L'_{bb} \end{bmatrix} \begin{bmatrix} \frac{di_a}{dt} \\ \frac{di_b}{dt} \end{bmatrix} + \begin{bmatrix} \frac{dL_{aa}}{d\theta} & \frac{dL_{ab}}{d\theta} \\ \frac{dL_{ba}}{d\theta} & \frac{dL_{bb}}{d\theta} \end{bmatrix} \begin{bmatrix} i_a \\ i_b \end{bmatrix} \Omega \quad (3)$$

$$T_e = \frac{e_a i_a + e_b i_b}{\Omega} + T_{cog} \quad (4)$$

$$J \frac{d\Omega}{dt} = T_e - B\Omega - T_L \quad (5)$$

$$d\theta_m / dt = \Omega, \theta = Z_r \theta_m \quad (6)$$

where e_a and e_b are the back *emfs*, the ψ_{sa} and ψ_{sb} are the flux linkages contributed by the stator currents, θ is the electrical

angle, θ_m is the mechanical angle, Z_r is the number of gears on the rotor, L is the apparent inductance and L' is the incremental inductance. The rest variables are used as their conventional meaning.

III. ANALYSIS AND RESULTS

According to (1)-(6), the physical phase variable model of HSM is illustrated in Fig. 1, which consists of two parts: the power electronics circuit block and the digital control system; both of them correspond to the practical HSM drive system.

As an example, the circuit diagram of the phase “a” winding of the HSM is shown in Fig. 2, in which the controlled voltage source (CVS) or the controlled current source (CCS) is used, and all the parameters such as apparent inductance, increment inductance and back *emf* are calculated in advance by FEA and stored in look-up tables.

For parameters calculation, a virtual magnetic gateway based 2-D magnetic FEA with multi-levels are applied to calculate the air gap flux. It is known that the distribution of magnetic flux density in the air gap varies sharply [1]-[2], but the distribution of magnetic flux density varies smoothly in the teeth. According to the FEA results, the magnetic force lines in the tooth root are approximately parallel, showing that the magnetic potential level of each point on the circle with the same radius is similar, then the radial permeance between the stator tooth root and the rotor tooth root can be processed as a function of applied *mmf* and rotor position. Fig. 3 shows the FEA result using the virtual magnet gateway. Based on field solutions, all the parameters in the equivalent electric circuit of HSM such as back *emf*, self and mutual inductances of the stator windings are obtained efficiently. Detailed field analysis will be presented in full paper.

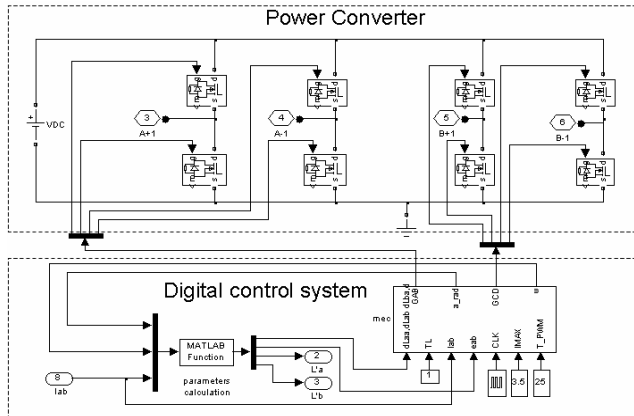

Fig. 1. Developed physical phase variable model

Fig. 2. Circuit diagram of the HSM stator phase winding

Fig. 3. FEA of a two-phase HSM using virtual magnetic gateway

Running the Simulink based model with the calculated parameters, various drive performance can be obtained and some results are shown in Fig. 4. Experiments have been conducted on the two phase HSM, validating the simulations.

More theoretical analysis and experimental results will be presented in the full paper.

Novel Modeling of Flux-barriers in Interior-type PM Synchronous Motor For Pulsation Torque Reduction: Part I. Various Flux-barrier Design

Liang Fang, Jeong-Jong Lee, Jung-Pyo Hong
 Department of Automotive Engineering, Hanyang University
 Haengdang-dong, Seongdong-gu, Seoul 133-791, Korea
 fangliang@hanyang.ac.kr, hongjp@hanyang.ac.kr

Abstract—This paper examines the flexibility of flux-barrier design for pulsation torque reduction in an interior permanent magnet synchronous motor(IPMSM). As well known, the torque characteristics are significantly related to the magnet pole-arc variation, which can be flexibly determined by the unique flux-barrier design in the IPM rotor. In this study, a prototype conventional single-layer IPMSM model, a popular double-layer IPMSM model and a proposed novel double-barrier IPMSM model are built and optimized for reducing the pulsation torque, consisting torque ripple and cogging torque. The novel IPMSM model has beneficial attributes of economic single-layer IPM for manufacture and flexible double pair of flux-barriers for IPM rotor design. The geometries of buried flux-barriers in analysis models are optimized by using the response surface methodology (RSM). Finite element analysis(FEA) and test results confirmed the validity of presented pulsation torque computation. In final, the proposed novel double-barrier IPMSM model is well proved to be quite effective for pulsation torque reduction.

I. INTRODUCTION

The interior permanent magnet synchronous motors (IPMSM) have wide applications in household goods, industrial use, and electric and hybrid vehicle propulsion[1]. The IPMSMs offer some superior advantages, such as high efficiency, high torque density and wide speed range[1].

However, from the torque characteristic point of view, the significant pulsation torque is an inherent drawback of IPMSM. For most practical applications, the reduction of torque ripple and cogging torque is always an essential requirement, for avoiding mechanical resonance, vibration, acoustic noise and damage to drive component, realizing motor runs smoothly[1]. There are many papers focused on torque ripple or cogging torque reduction in IPMSM, and proposed some effective approaches, such as the magnet pole-arc design method.

As known, the conventional single-layer IPMSM has only one pair of flux-barriers with each single PM piece buried in rotor iron, that propitious to manufacture. And the popular double-layer IPMSMs are attractive since their double pair of flux-barriers can be utilized for reducing torque pulsation[2]. In addition, this paper proposes a novel IPMSM model features double flux-barrier created with each single-layer IPM.

By using response surface methodology(RSM), the shape of flux-barriers in analysis models are optimized. Then, finite element analysis(FEA) and test results confirm the validity of the proposed design is effective for reducing torque pulsation.

Fig. 1. Configuration of conventional single-layer IPMSM model.

II. ANALYSIS MODELS

As Fig.1 shows, a prototype 6-pole/9-slot IPMSM model is given as a driving compressor of a hybrid electric vehicle. The stator has 3-phase concentrated windings, and the rotor adopts conventional single-layer IPM design, in which the PM pole-arc is described by flux-barrier with pole-arc_#1 and #2.

III. FLUX-BARRIERS DESIGNS IN IPMSM

The effect of various flux-barrier designs on the reduction of pulsation torque in IPMSM is analyzed in this study. Base on the prototype single-layer IPMSM model, a double-layer IPMSM model is built by splitting the same amount of PM into thin pieces. It correspondingly creates two pairs of separated flux-barrier to be utilized for effectively distributing the magnetic flux crossing into air-gap field, as Fig. 2(a) gives. It should be noticed that double-layer IPM design will unavoidably increase the manufacture cost, and may cause PM irreversible demagnetization since thin PMs are employed.

A novel double-barrier IPM rotor model is proposed, as Fig. 2(b) illustrates. The single-layer buried PM has two pairs of connected flux-barrier, which is similar to the effectivity of double-layer IPM design for redistributing magnetic flux.

IV. IPM ROTOR DESIGN OPTIMIZATION

The multiple flux-barriers design is very complex owing to many design factors. Therefore, RSM, as a validated economic optimization technique[3], is applied to flux-barriers optimal design. The torque ripple and cogging torque are chosen as the design objectives in RSM, which are calculated by using the equivalent circuit method coupled with FEA.

In each flux-barrier optimal design, the magnet pole-arcs determined by the flux-barriers variation are used as the only design variables for simple consideration. TABLE 1 lists the experiment ranges of each design variables in RSM.

TABLE 1
RANGES OF DESIGN VARIABLES FOR OPTIMIZATION IN RSM

Analysis IPMSM Model	Pole-arc #0 [Outer layer]	Pole-arc #1 [Inner layer]	Pole-arc #2 [Inner layer]
Single-layer design		41° ~ 48°	54.2° ~ 59.2°
Double-layer design	35.4° ~ 41°	46° ~ 52°	54.2° ~ 59.2°
Double-barrier design	35.4° ~ 41°	46° ~ 52°	54.2° ~ 59.2°

* Outer layer: the upper PM layer closing to rotor surface.
* Pole-arc #0 is defined for the pole-arc of "Outer-layer" PM with red lines.

V. RESULTS AND DISCUSS

The optimal flux-barriers designs of each IPMSM models are determined with desired design objective results in RSM, as Fig. 3 illustrates. And their torque ripple and cogging torque characteristics are confirmed by FEA. Compare with single-layer IPM design, the double-layer IPM design and proposed novel double-barrier IPM design are both effective for reducing the pulsation torque, by which the torque ripple reduced from 16.5% to 10.0% and 7.0% separately, and cogging torque relatively decreased 46.7% and 66.7%, as Fig.4 results show. In addition, the optimized double-layer IPMSM is fabricated and tested as Fig. 5 shows. The tested cogging torque has a good agreement with FEA result, as Fig. 6 gives, and the measured torque ripple [7.8%] is smaller than the FEA result [10.0%]. The error is thought caused by the influence of reduction gear inertial.

VI. CONCLUSION

Torque ripple and cogging torque reduction in IPMSMs by flexibly designing the buried flux-barriers is presented in this paper. The proposed novel double-barrier IPMSM design has unique features as each single-layer IPM coupled with double pairs of connected flux-barriers, which shows similar attribute of the popular double-layer IPMSM design, but realizing the simplicity and low-costing for manufacture. The novel double-barrier design is proved to be an effective approach for reducing pulsation torque in IPMSM by comparing with the other two design models. The FEA and test results well confirmed the validity of presented pulsation torque analysis. Generally, the proposed novel IPM design has cost advantage to the double-layer IPM design for effectively reducing pulsation torque.

Parametric Finite Element Analyses of a Permanent Magnet Synchronous Machine with an External Rotor

Erich Schmidt, Marko Sušić

Institute of Electrical Drives and Machines, Vienna University of Technology, Vienna, Austria
erich.schmidt@ieam.tuwien.ac.at, marko.susic@ieam.tuwien.ac.at

Abstract – Permanent magnet synchronous machines with an external rotor nowadays gain in significance for high performance electrical drive systems such as with hybrid electric vehicles. With these applications, the machine will operate in a wide speed range and on the other hand with very fast changing loads in both motor and generator operational modes. In order to achieve a robust machine design, a position-sensorless control scheme using the dependence of the stator inductances on the rotor position is of great interest. With this intent, the paper discusses finite element analyses for the optimization of such permanent magnet machines with external rotors. Regarding the geometry parameters, a magnetic saliency necessary for the sensorless control scheme has to be preserved in the whole range of the operational modes.

I. FINITE ELEMENT MODELLING

Fig. 1 depicts the basic geometry with 24 poles of the investigated permanent magnet synchronous machine with an external rotor. In order to study the torque ripples, both unskewed and skewed stator slots as well as integer and fractional slot windings with concentrated coils are concerned with the analyses.

Fig. 1: Cross section of the permanent magnet synchronous machine with an external rotor, angular rotor position 0°

One set of calculation uses current driven analyses to obtain the related parameters such as torque and inductances in dependence on the stator currents and the angular rotor position. As proposed in [1], transient voltage driven analysis with high frequency voltage pulses are additionally used for an evaluation of the position dependent inductances of the permanent magnet synchronous machine.

All analyses utilize separated 2D models of rotor and stator which are coupled by floating boundary

conditions in dependence on the angular rotor position along the sliding surface interface within the air-gap [2], [3]. In case of the skewed stator slots, a multi-slice approach with a Gauss distribution of the slices will be used [4], [5].

II. SPACE VECTOR CALCULUS

In the dq rotor fixed reference frame [6], the normalized stator current and stator flux space vectors are given by

$$\underline{i}_{S,dq} = i_S e^{j\beta} = i_{S,d} + j i_{S,q} , \quad (1)$$

$$\underline{\psi}_{S,dq} = \psi_S e^{j\vartheta} = \psi_{S,d} + j \psi_{S,q} , \quad (2)$$

where β, ϑ are the stator current angle and the stator flux angle, respectively. The components of the stator flux linkage are defined by

$$\psi_{S,d} = l_d i_{S,d} + \psi_M , \quad (3a)$$

$$\psi_{S,q} = l_q i_{S,q} , \quad (3b)$$

where l_d, l_q are the direct and quadrature axis inductances and ψ_M denotes the flux linkage of the permanent magnets.

In order to inject the stator currents in the finite element model, the stator current and stator flux space vectors are transformed as given by

$$\underline{i}_{S,\alpha\beta} = \underline{i}_{S,dq} e^{j\gamma} , \quad (4)$$

$$\underline{\psi}_{S,\alpha\beta} = \underline{\psi}_{S,dq} e^{j\gamma} , \quad (5)$$

where γ denotes the angular rotor position. As the stator winding is Y-connected, any zero sequence stator currents are impossible.

III. SAMPLE ANALYSIS RESULTS

The sample results presented herein are focussed on the magnetic saliency obtained from stator currents only in direct and quadrature axes. Since the machine is highly nonlinear, there are several methods to evaluate a stator inductance in dependence of the stator currents [7]. As the high frequency voltage pulses slightly shift the actual operating point, differential inductances as evaluated underneath will describe the transient behaviour of the machine in an appropriate way.

With the linear dependency $i = i_0 + \Delta i$, the magnetic energy

$$W_m = \int_{\Omega} \mathbf{H} \cdot \mathbf{B} d\Omega \quad (6)$$

allows for an approximation of the normalized magnetic energy

$$w_m(i_0, \Delta i) = w_{m0}(i_0) + w_{m1}(i_0) \Delta i + w_{m2}(i_0) \Delta i^2 \quad (7)$$

yielding the nonlinear inductance as

$$l_{w_m}(i_0) = w_{m2}(i_0) = \frac{w_m(i_0, +\Delta i) - 2w_m(i_0, 0) + w_m(i_0, -\Delta i)}{2\Delta i^2} \quad (8)$$

On the other hand, the flux linkage

$$\Psi = \frac{\int_{\Omega} \mathbf{A} \cdot \mathbf{J} d\Omega}{\int_{\Gamma} \mathbf{J} \cdot \mathbf{n} d\Gamma} \quad (9)$$

allows for an approximation of the normalized flux linkage

$$\psi(i_0, \Delta i) = \psi_0(i_0) + \psi_1(i_0) \Delta i \quad (10)$$

yielding the nonlinear inductance as

$$l_{\psi}(i_0) = \psi_1(i_0) = \frac{\psi(i_0, +\Delta i) - \psi(i_0, -\Delta i)}{2\Delta i} \quad (11)$$

Finally, the fundamental distribution of the radial component of the magnetic flux density along the air-gap obtained from a Fourier series expansion defines the normalized fundamental component of the flux linkage ψ_1 within the air-gap which yields the nonlinear inductance

$$l_{\psi_1}(i_0) = \frac{\psi_1(i_0, +\Delta i) - \psi_1(i_0, -\Delta i)}{2\Delta i} \quad (12)$$

Fig. 2 and Fig. 3 depict the ratio $l_d(i_d)/l_q(i_q)$ of the three inductances (8),(11),(12) for an assumption of linear materials and for the actual nonlinear behaviour of the permanent magnet synchronous machine. Obviously, all three ratios are equal with linear materials and there is no significant magnetic saliency of the machine. On the other hand with nonlinear materials, only the flux linkage inductances (11) and the fundamental inductances (12) are further useable while the inductance values obtained from the magnetic energy (8) are not applicable.

IV. CONCLUDING REMARKS

The full paper will discuss in detail the design variations to obtain the desired magnetic saliency in the whole range of the operational modes. As these position dependent inductances of the permanent magnet synchronous machine are the most important criterion for an application with a high performance drive system and a position-sensorless control scheme, an optimization of the machine design can be carried out in the design stage without any prototype of the machine.

2D Exact Analytical Solution of Open Circuit Magnetic Field in Slotted Surface Mounted PM Radial Flux Synchronous Machines

Y. Amara, J. Raharijaona and G. Barakat

Groupe de Recherche en Electrotechnique et Automatique du Havre - EA 3220, Department of Electronic and Electrical Engineering, University of Le Havre
25 rue Philippe Lebon - B.P. 1123 - 76063 Le Havre cedex, France

Abstract — This paper presents an analytical technique for prediction of open circuit magnetic field distribution in slotted surface mounted permanent magnet radial flux synchronous machines. This technique can either be used in the case of internal or external rotor radial-field machines topologies. It involves solution of Maxwell's equations in slots, airgap and the PM's region. The obtained analytical model is used to estimate the cogging torque and induced back electromotive force. Results from this analytical model are compared to corresponding finite element analyses.
